Foreword

VOLUME 62 of the Transactions of The American Society of Mechanical Engineers contains the individual papers published during 1940 under the sponsorship of the Society's professional divisions and technical committees, including the contributions of the Applied Mechanics Division issued originally in a quarterly known as *Journal of Applied Mechanics*, and the 1940 Society Records and Index. The technical papers and reports that make up this volume represent the Society's annual contribution to the permanent record of mechanical-engineering achievement. Most of these papers and reports were presented at meetings of the Society and of its professional divisions and local sections and were published in monthly issues, eight being distributed as the Transactions of The American Society of Mechanical Engineers and four as the *Journal of Applied Mechanics*. Indexes to other A.S.M.E. papers and publications will be found on page RI-75 at the end of this volume. In view of the fact that material of which this volume is composed was originally issued periodically as Transactions, *Journal of Applied Mechanics*, and Society Records, three sets of page numbers will be found. Numbers without letter symbols are those of the eight issues of the Transactions, those with letter symbol A preceding the number refer to the pages of the *Journal of Applied Mechanics*, which follow, and those with letter symbol RI to the Society Records section, which concludes the volume.

All sections of the Transactions are bound together at the end of the year for the convenience of libraries and of engineers who wish all of the papers in permanent form. Copies of the bound Transactions will be found in depositories located in selected engineering, university, and public libraries throughout the world. A complete list of these depositories will be found on pages RI-71 to RI-74 of the Society Records and Index. Copies of the Transactions have also been set aside for sale.

The Society Records of the A.S.M.E. for 1940, which form a part of these Transactions, are the permanent records of the Society's activities for the year, including lists of committees and memorial biographies. The Index provides a means of locating special A.S.M.E. publications and articles in *Mechanical Engineering* as well as those in the Transactions.

THE COMMITTEE ON PUBLICATIONS

Toward Economic Air-Line Equipment

By A. F. BONNALIE,[1] CHICAGO, ILL.

The paper is a discussion of some of the apparent factors determining the worth of the transport airplane. The author treats size, speed, range, and utilization as being among the major considerations for economic operation. Items of interest both in cost of operation and in sales of service are included.

The author finds no immediate limit to the size of airplanes, but does raise the question of crowding when larger numbers of passengers are involved. He also points out that, due to continual improvement, equipment in the future will be more economic.

WHILE the transport airplane has a reasonably long history, it is only recently that some of the economic relationships have become evident. The technical problems of air transportation, in common with similar problems of all other forms of transportation, can be considered under four headings, namely, location, finance, management, and equipment. In the solution of problems of the first two categories, the experience of older transportation can be drawn upon with but little change; management involves much that is familiar, except changed operating technique, but the equipment problem is very different and is of major importance.

To be truly economic, air-line equipment must be not only financially and mechanically efficient but it must have sufficient sales merit to attract a substantial volume of traffic in spite of adverse factors of considerable magnitude. As pointed out by the author previously,[2] the major factors in the development of passenger traffic are speed, comfort, cost, and fear. Other factors of convenience and utility are definitely limiting and reduce the applicability of air transportation to a limited field, auxiliary to surface transportation. Passenger traffic is herein given major consideration for four reasons:

1 It is at present the major source of income for the air lines.

2 It is most demanding and is determinative of much of the design specification for equipment.

3 It offers the largest field for the development of real business volume.

4 Revenue return from other sources of traffic cannot be affected by equipment change to any considerable extent because their rates are determined outside of the control of equipment or management.[3]

The vehicle, with older forms of transportation, affects costs to a limited degree and sales to a maximum degree. The success of the so-called streamline train has proved this. Something of the same relationship exists with air transportation, except that equipment affects costs to a much higher degree. Where the expenses of the railroads are mostly bonded indebtedness, cost of fixed property and its maintenance, none of these appear in the air-line expense column to any marked extent. Instead, equipment depreciation and upkeep, pay of flying personnel, and fuel become the major cost burdens.

Much of this discussion of air-line equipment must be academic in character and while the author believes it to be sound, the problem is so complex that exceptions are bound to exist. It must also be appreciated that the viewpoint is biased and represents the opinions of one student and not necessarily those of any one else. No claim to originality is made and much of the material is well understood throughout the industry, but the author believes that no comprehensive presentation of such data has been made.

Of the many economic factors involved, size, speed, and degree of equipment utilization are receiving a great deal of attention. These three will be considered first.

The Size of Airplanes

Any study of air-transportation equipment must attempt to answer the problem of economic size. That inadequate answers are the usual result is merely indicative of the difficulty of the problem. That this answer will be no more adequate than others is a foregone conclusion, for the final answer can never be written as long as changing economic conditions exist and clever engineers are able to develop new materials, methods, processes, and mechanism.

For the moment it will be accepted that traffic will be sufficient to allow the economic operation of large equipment. The questions then become what is large and how large is economic? How large can airplanes be built? Not all of these questions can be answered in other than general terms. Specific applications as to range and other requirements, together with the need of suitable operation off restricted flying-field areas, nature of the terrain, and weather must be considered.

Fig. 1 shows the effect of increased size—on the costs per airplane-mile and per capacity-ton-mile of pay load. The costs are computed on a basis of average costs for the domestic air lines of the United States and necessarily certain specific design proportions had to be set for the family of airplanes under consideration. This chart was computed some three years ago and it is interesting that the operating costs of equipment built since that time have come well within acceptable estimating margins.

As many of the costs of air-line operation do not vary directly with the increased size of equipment, it is to be expected that the ton-mile costs of transportation will improve as the size of the airplane increases. A radical change in design proportions would change the shape of these curves of costs per ton-mile and costs per airplane-mile, but most of the present-day airplanes are within a reasonable margin of these figures. Some small operations, with less-than-average overhead, have lower costs than those shown, but others will be somewhat higher.

The entire answer to the question of size cannot be covered by cost alone. Fig. 1 is based on the assumption that the proportioning is constant to the installed power. This is not strictly correct. As the size of the power units increases, there is definite decrease in their specific and installed weight. The per-horsepower weight of instrument and other equipment also decreases. Variations in structural weight of the airplane are much more complex, governed somewhat by the law of similitude.

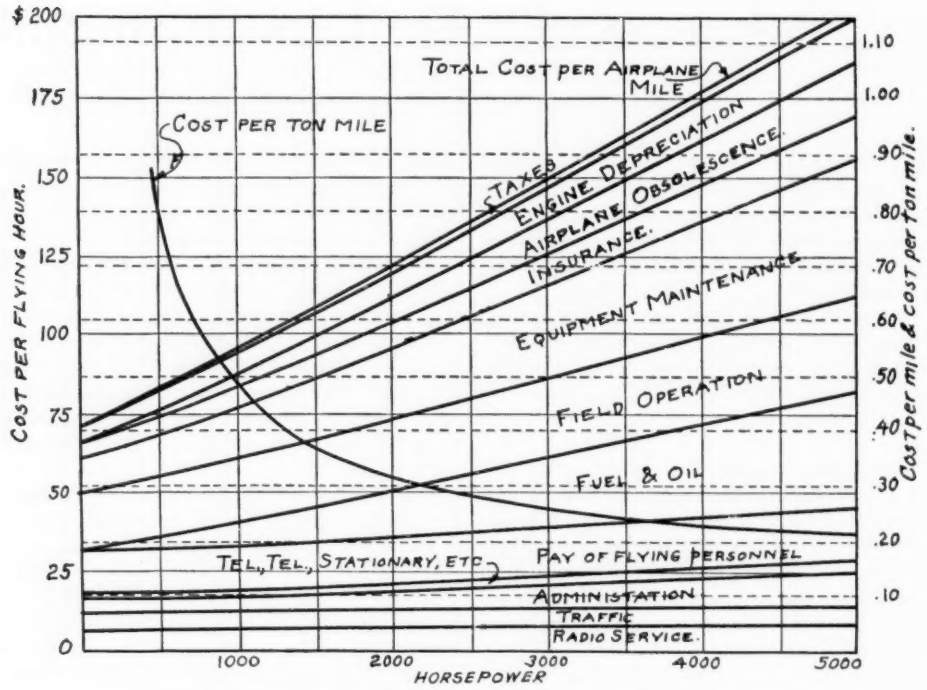

FIG. 1 EFFECT OF AIRPLANE SIZE ON COSTS OF SERVICE
(Based on 200 hr per month, 175 mph, 2¼ lb pay load per hp.)

LAW OF SIMILITUDE

This law, simply stated, is that with a geometric increase in size the weight will vary as the cube of the dimension, and the lifting surface as the square. Accordingly, increasing the dimensions of an airplane would (where d is the ratio between the larger and smaller significant dimension):

(*a*) Multiply gross weight by d^3
(*b*) Multiply wing area by d^2
(*c*) Multiply wing loading by d
(*d*) Multiply power by d^3
(*e*) Multiply power loading by $d^3/d^3 = 1$
(*f*) Multiply load factors by $1/d$.

Increasing the wing loading and reducing the strength would not be practicable except for small changes in dimension. The performance would be affected as follows:

(*a*) Landing speed would be increased approximately as the ratio of $d^{1/2}$.

(*b*) Maximum speed would be improved somewhat better than the ratio of $d^{1/3}$.

(*c*) The take-off run would be lengthened; the relationship is rather involved.

Fortunately, the situation is not as severe as the foregoing would indicate. Many parts of the large airplane would not need to be proportional because smaller airplanes have many members determined by the minimum sizes that can be used, which are accordingly overstrength and overweight. It is also possible to reduce load factors somewhat (or their equivalent) as the size of the airplane is increased. The reducing of load factors cannot be carried too far, however. Better materials are also beneficial. It is to be noted that in the hypothetical case under consideration the useful-load ratio would remain unchanged. It has been argued many times that the law of similitude wrote a definite limit to the size of airplanes. This has always been said whenever the state of the existing art exhausted the available materials, methods, design, and mechanism. Advance has so far invariably pushed the frontier farther, allowing more progress. Unquestionably, some limit exists, but the art has not progressed far enough for it to be apparent at the moment.

Increasing size is accompanied by other problems. It is of course possible that the airplanes now considered huge will, as time passes, be quite as ordinary in the future as the large airplanes of a few years ago seem now. One of the possible limits is the physiological one. This does not seem to be acute however, for the author has seen a test pilot leave a forty-ton transport and, overnight, test-fly a ton-and-a-half airplane, handling it to perfection. In other words, the competent pilot seems to be sufficiently adaptable to the physical size of the aircraft to be capable of making the necessary allowances for the size, thereby insuring equally satisfactory control over a wide range of size.

ABILITY OF CREWS TO HANDLE THE LARGER AIRCRAFT

The heaviest airplane that has been built, the *Dornier DOX* (129,000 lb), or the two versions built for Italy, seemed to be within the capabilities of their crews. Likewise, the *Maxim Gorky*, with the largest span (207 ft 0 in.) that has been flown was controllable and flyable. The use of servo controls makes it practicable to put the control of almost any reasonably sized airplane to within the comfortable strength of one man.

L. C. McCarty, Jr., project engineer of the Glenn L. Martin Company, analyzes the problem of landing large flying boats[4] as follows:

> What is the safe limit for landing speeds? This is a question of .... basic importance to future safety, speed, and efficiency....
>
> With no limiting obstacles the safety in landing and taking off is dependent largely on the impact loads imposed on the structure in the event of bad landings, a bounce, or contact with an advancing wave.
>
> From dimensional analysis, the following important conclusions are indicated:

[4] "Ocean Air Transportation," by L. C. McCarty, Jr., *S.A.E. Journal*, vol. 40, no. 5, May, 1937.

1 The height of free drop increases directly as the linear-scale ratio or as weight to the $^1/_3$ power for the same acceleration.

2 Also for the same acceleration, the landing speed increases as the $^1/_2$ power of the linear scale or as the weight to the $^1/_6$ power.

3 With increasing speeds, for a bounce of the same acceleration, the time interval to the subsequent contact with the water is increasing as the linear scale to the $^1/_2$ power, thus allowing greater time for piloting decision and action.

4 Since the height of free drop varies with the linear scale, the vertical velocity at contact (for the same acceleration) increases as the linear scale to the $^1/_3$ power. Extending this reasoning, greater seaworthiness is indicated with the same design accelerations and with the landing speeds increasing as the $^1/_2$ power of the linear scale.

5 The physiological limitations of the average pilot in judging absolute distance above the water as affected by increased landing speeds, sinking speeds, and his height over the water at the instant of landing are under investigation. Preliminary indications are that, other things being equal, the physiological limitations in this respect have not been approached.

Summarizing it appears that, as the size increases and without "instrument" landings or the use of power in landing, the average pilot will be able to make landings with lower loads on the structure, less discomfort to the occupants, and with greater seaworthiness at increasing landing speeds.

As an example, applying these principles, a landing speed of 75 mph for a 50,000-lb flying boat (Martin 130) would indicate landing speeds of 98 mph for 250,000 lb gross weight and 39 mph for 1000-lb gross weight.

Space Limitations for Passengers

One thing that seems to have definite limits, at least for any long-range aircraft, is the rapidly increasing crowding effect with increased numbers of passengers. Compartmentalization of habitable spaces will help, but even this has limits. The required volume of space per passenger is a variable that needs much consideration. The problem becomes most acute when any more than a relatively small number of passengers are involved for more than a relatively short space of time. Assuming adequate ventilation and heating, apparently the factors to be considered include: number of persons, number of personal contacts, length of trip, whether night or day, the relative diversion of interest, and the gregariousness of those involved.

For instance, a small group of people, well known to each other and making a daylight trip of a few hours in a private automobile, represent the smallest practicable cubature per person. A small car capable of carrying a maximum of six persons will have a total cubature of 114 cu ft, or 19 cu ft per person. It is probable that these six people are either closely related or at least quite well known and friendly to each other. The horizon from the car is limited, the scenery and events are in close proximity, the change of scenery is rapid, and the constant stream of opposing traffic, each unit of which opens a potential hazard of collision, all combine to offer the rider diversion of a high order. Analysis of this situation gives the following:

Number of persons	6
Number of personal contacts, $n\,(n-1)/2$	15
Time of journey	short
Gregarious factor	high
Diversion factor	high

It is probable that this space represents the lower limit per person that could be used. On long journeys the small car becomes rather cramped for capacity loads. The inclusion of strangers lowers the gregarious factor rapidly and any reduction of the diversion factor tends to aggravate conditions. Total strangers with no desire for contact with their fellows and no diversions of any kind would feel comfortable only if the space were proportional to the number of contacts (combinations of two) that are possible. This would be the extreme limit of space demand. Fig. 2 shows the two limiting curves. The lower curve is the straight-line relationship of 19 cu ft per person, the lower limit. The steeper curve is an assumed upper limit of 19 cu ft per possible personal contact or 19 $n\,(n-1)/2$.

This problem of space and diversion is a real one. As the number of passengers increases, the difficulty of providing for the human pay load increases faster than the numbers involved. Even the development of airplanes large enough to have habitable wings may not be more than a minor relief. It is also going to be necessary to take these factors into consideration in the construction of terminal facilities, waiting rooms, and so on.

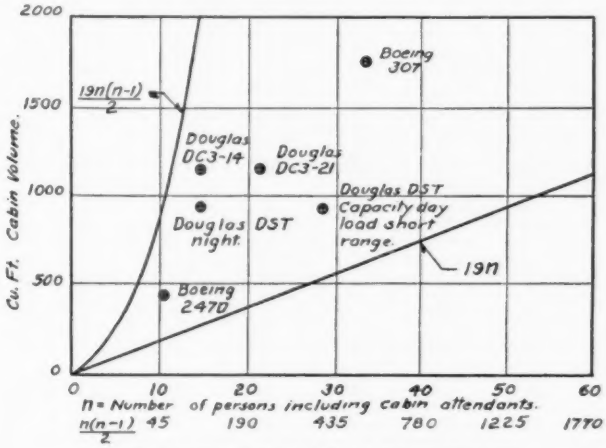

Fig. 2 Limits in Cabin-Space Requirements

The suitability of any design from the standpoint of space for passengers may be expressed as

$$Q = 2\,H_v/[n(n-1)b] \quad \ldots\ldots\ldots\ldots\ldots [1]$$

Where Q = the relative space factor
n = the number of persons in the cabin, including the attendants
H_v = habitable volume of the airplane, cu ft
b = the number of compartments or divisions of space

Q will really be the smallest practicable space per occupant in a rather low-capacity vehicle. Q should vary with the time of uninterrupted occupancy and the available diversions.

The Effects of Speed

Fig. 3 shows the effect of speed on operating costs, assuming that speed is gained by aerodynamic improvement and mechanical development, not by merely increasing power. The reduction in costs per airplane-mile that accompanies increased speed, while not spectacular, is important.

Fig. 4 shows the per-mile costs plotted against speed where change of speed is made by change of power. Much of the increased cost at the higher speeds is due to the decrease in reliability of power plants at the higher outputs. Some assumptions of cost due to power-plant failure were made in this computation, but the decrease in reliability is based on fact. Improvement in power-plant reliability and durability would allow increased speed with accompanying reduced cost. Overpowered equipment is another question, however, that cannot be covered here.

Speed is extremely important to air transportation for it is one of the major reasons for the method. Wright, in his paper[5] expresses the speed-merit relation as

$$F_T = F_0 V_c = V_c^2\,U/(22.7\,W_g + 1000\,P_e + 100\,U) \ldots [2]$$

[5] "The Economics of Speed," by T. P. Wright, read before a meeting of the Institute of the Aeronautical Sciences at Cleveland, Ohio, on Sept. 4, 1937, reported in *Western Flying*, October, 1937.

Where W_g = gross weight, lb
P_c = cruising brake horsepower (usually 60 per cent normal rated power)
U = useful load, lb
F_0 = airplane-operating efficiency factor
F_T = air-transport efficiency factor
V_c = cruising speed, mph.

Wright credits Kendall Perkins with the development of this relation and further says that it is based on the findings that 22

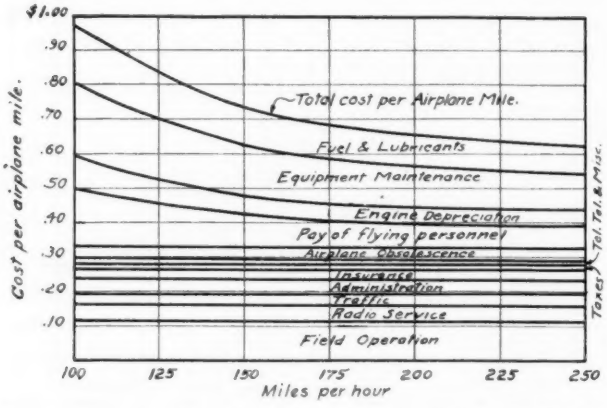

FIG. 3 EFFECT ON PER-MILE COSTS OF INCREASED SPEED DUE TO AERODYNAMIC AND MECHANICAL IMPROVEMENTS
(Typical air-carrier airplane in average U. S. A. domestic operation.)

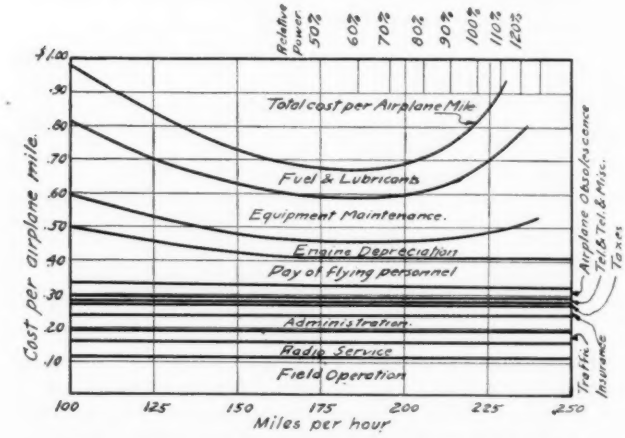

FIG. 4 EFFECT OF INCREASED POWER ON PER-MILE COSTS
(Typical air-carrier airplane in average U. S. A. domestic operation. Speed increased by higher power without improved durability and reliability of power plants.)

per cent of average operating costs can be assigned to gross weight (airplane depreciation and maintenance), 46 per cent can be assigned to power (fuel, oil, engine depreciation, and maintenance), 32 per cent can be assigned to useful load (all types of insurance and crew pay).

According to this analysis, the most important economic factor is speed, followed by useful load, power, and gross weight in that order. Range does not appear in the formula except by the inference that it depends in part on useful load and cruising power.

This rating formula, while it attempts to include the sales value of speed, overlooks other sales factors of relatively great value, particularly comfort. It is a repetition of the old ideal of trying to put into one simple relationship the full merit of the vehicle. Such a hope is obviously a vain one, for no one formula can possibly include the necessary considerations of, say, an operation on the Belgian Congo, across the American continent, and a service into Tibet at one and the same time—to say nothing of including transoceanic services or possibly nonstop over-the-pole operations. Each of these operations and innumerable others would call for widely different characteristics for an ideal piece of equipment. An almost unlimited number of equipment specifications can be drawn and as many or more aircraft built to meet them. Accordingly, only this one figure of merit is considered here, although many have been proposed.

SPEED

The von Kármán formula for speed, somewhat modified by Lesley, expressed in mph, hp units

$$V_{max} = 7.22 \left(\frac{\eta C_{L\max} V_L^2}{C_D P_L \delta} \right)^{1/3} \quad \ldots\ldots [3]$$

Where η = propeller efficiency
C_L = lift coefficient (absolute)
V_L = landing speed, mph
C_D = absolute drag coefficient, whole airplane
P_L = power loading, lb per hp
δ = ratio atmospheric density.

Indirectly this formula takes into account wing loading W/S and wing power hp/S and is directly concerned with the over-all efficiency of the design. From this, it can be seen that the important items for the development of high speed are:

1 Wing load, as high as is practicable considering landing, take-off, and maneuverability.

2 Lowest possible drag for the airplane with the highest possible propeller efficiency.

3 Lowest possible weight per horsepower. In other words, highest possible wing power.

4 Lowest atmospheric-density ratio with maximum thrust (highest propeller efficiency and horsepower output at high altitude).

Putting the above formula into another form, expressed in ft-lb-per-second units

$$V = \left(\frac{C_{L\max} \eta V_L^2}{C_D (W/P) \delta} \right)^{1/3} \quad \ldots\ldots [4]$$

W = weight
P = power = $hp \times 550$
However, $V_L^2 = 2W/C_{L\max} S\rho$
ρ = mass density of the air
S = wing area, sq ft

Substituting $V = (2\eta P/C_D \rho S)^{1/3} \quad \ldots\ldots [5]$

If it is assumed that η (propeller efficiency) is constant, that at any one altitude ρ (mass density of the air) is constant, also that C_D (coefficient of drag) is constant, speed can be seen to vary as the cube root of the wing power. For all practical purposes this relationship has been found to be true. Some authorities, notably Warner and McGinty, have used $(2\eta/C_D\rho)^{1/3}$ as a constant for any one airplane. When English units and constants are used, this figure sometimes called "specific speed," is the speed of the airplane in miles per hour were its engine developing one horsepower for each square foot of wing area. It is a good measure of the relative cleanliness of any design.

DEGREE OF EQUIPMENT UTILIZATION

This factor is of two parts:

(*a*) The actual utilization of pay load in a given vehicle on a given operation called load factor.

(*b*) The amount of hours of flying that can be accomplished by the average airplane on the average operation.

Load Factor (Ratio of Revenue Load to Capacity Pay Load). It is, of course, important that the highest possible load factor be maintained in order that the greatest possible percentage of capacity revenue be developed. Fig. 5 shows a plot of idealized loads showing variations in load factor. This plot is not taken from fact, but shows variations between limits, with even variations being assumed. For instance, when the load is 100 per cent and 0 per cent on two successive trips, the load factor is 50 per cent. When the variation is uniform between 100 and 60 per cent, the load factor is 80 per cent. Actually, in order to develop high load factors it is necessary that full loads be carried oftener than light loads. Whenever the revenue load actually developed approaches the capacity pay load, it is probable that some business has been turned away because of lack of capacity. Furthermore, a great deal of airplane business is emergency in character.

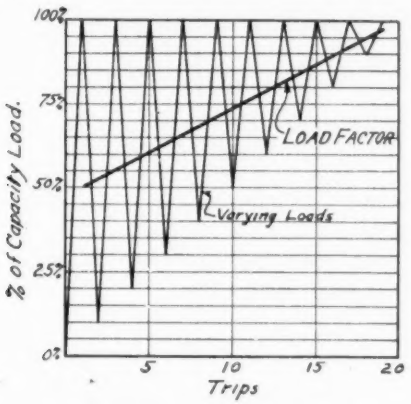

FIG. 5 VARIATION IN LOAD FACTOR

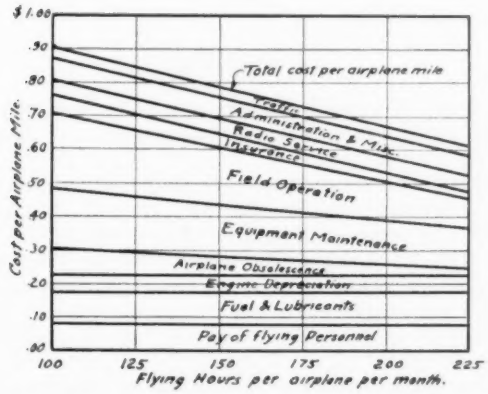

FIG. 6 PER-MILE COSTS VERSUS FLYING HOURS PER MONTH
(Typical air-carrier airplane.)

When the carrier is unable to accommodate an emergency due to lack of capacity, it is failing in its service in the public convenience and necessity.

From Fig. 5 it can be seen that the development of load factors much higher than about 60 per cent allows little reserve capacity for possible demands. It is accordingly essential that the air carrier be able to perform its service with a load factor not much in excess of 60 per cent in order that it may be able to discharge the obligation assumed as a common carrier. Airplanes that can operate on this load factor at a profit on passenger rates are still a matter for future development.

Flight Utilization. Fig. 6 shows the effect of varying the hours of flying per month on the operating costs of the typical air-line airplane previously considered. As it is regular practice to service air-carrier airplanes after not exceeding 20 hr of flight with engine changes at intervals of from 450 to 600 hr of flight, it is difficult to operate at more than about 180 hr per month in regular schedule.

RANGE

The next factor of importance economically is range. Any airplane having a theoretical range of about 10,000 miles will be capable of flying from any habitable portion of the earth to practically any other habitable location. This is still beyond the best that has been done, even with all of the carrying capacity devoted to fuel with the minimum of crew.

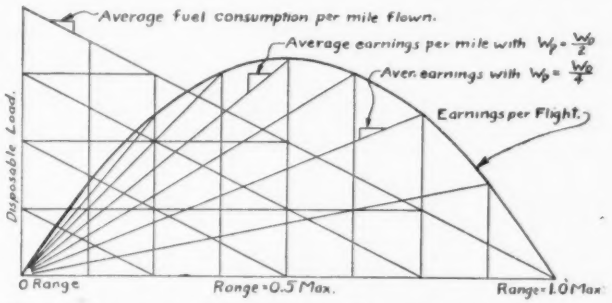

FIG. 7 GRAPHICAL DEVELOPMENT, EARNINGS PER FLIGHT AT VARIOUS RANGES

W_U = useful load = gross weight less empty weight
W_D = disposable load = useful load less crew and supplies
W_P = pay load = disposable load less consumable load (fuel)
Earnings for any one flight are a maximum when
$W_P = W_D/2$ (Consumable load = pay load = ½ disposable load)

Disregarding fuel reserve, other operational and geographical limitations, and assuming that pay load produces revenue on a direct pound-mile basis, a strictly theoretical concept shows the revenue situation in Fig. 7. Fuel is zero when the disposable load is all pay load, so earnings are also zero. Likewise, when the disposable load is all fuel, earnings are again zero for no pay load is carried. Earnings are a maximum when fuel load equals pay load on any one flight. As a transport operation is mostly one flight added to another and so on, the graph shows that earnings will be a maximum for a completed trip when fuel is held to a minimum and frequent stops are made. These relationships have become familiar from many repetitions, and, while academic in character, study will help a true concept to develop.

It is obviously impracticable to use too many operating stops as the operation will be slower and sale of traffic more difficult. The longer nonstop operations assess a penalty in reduction of pay load by the heavier fuel needs, but selling is enhanced and under certain conditions such operations are accordingly justified. The longer the distance between stops the lower is the cost of operation per mile. Additional landings not only slow down the flight speed, but actually increase operating expenses.

If the theory of range be simplified by assuming fixed power output and accordingly fixed fuel consumption per hour, then

$$R = EV_c \quad \ldots\ldots [6]$$

where R = range, miles; E = endurance, hr; and V_c = cruising speed, mph.

But

$$E = (W_0 - W_1)/hp_cC \quad \ldots\ldots [7]$$

where W_0 = initial gross weight, W_1 = final gross weight, C = specific fuel consumption (average), hp_c = average cruising horsepower, and

$$V_c = 7.22\left(\frac{\eta C_{L\,max}\, V_L^2}{C_D\,(W/hp_c)}\right)^{1/3} \quad \ldots\ldots [8]$$

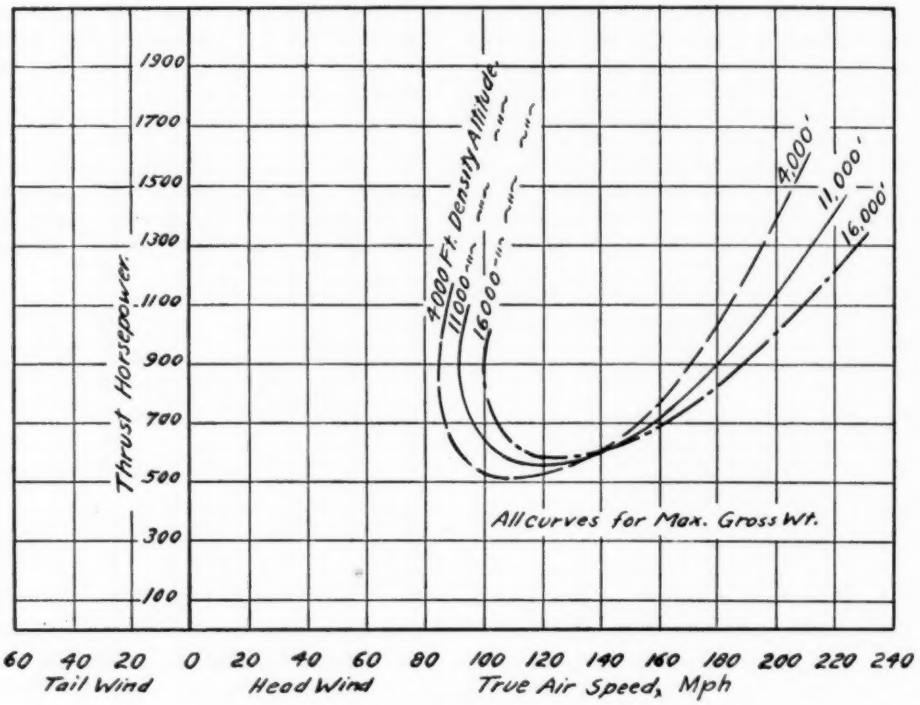

FIG. 8 POWER REQUIREMENTS
(Typical transport airplane.)

substituting $V_L^2 = 2\,W/C_{L\,max}\,S\rho$

$$V_e = 7.22\left(\frac{2\eta hp_e}{C_D\,\rho\,S}\right)^{1/3}$$

then
$$R = 7.22\left(\frac{W_0 - W_1}{hp_e C}\right)\left(\frac{2\,\eta hp_e}{\rho C_D S}\right)^{1/3} \quad \ldots\ldots\ldots [9]$$

This development makes some simplifying assumptions that cannot be applied in practice. The purpose has not been to develop a precise equation, but to establish an expression that will allow an appreciation of the important design factors.

Actually, to develop either the greatest endurance or the greatest range, the power output will be varied in order to maintain the most effective air speed for the purpose. Internal-combustion engines being what they are, the best results will be obtained at the lowest practicable rotational speed of the engine and the highest possible brake mean effective pressure that can be allowed.

Fig. 8 shows the polar curves of power required against true air speed for a typical air-carrier airplane at three altitudes. A tangent drawn from the origin will determine the air speed for most miles per gallon in still air, assuming a flat curve for specific fuel consumption. Moving the point from which the tangent is drawn to the right or left of the origin will allow for head and tail winds, respectively. The actual curve of specific fuel consumption for the engines used will alter the slope of the polar curves somewhat as will the propeller-efficiency curve. Correcting these curves with factors determined from specific fuel consumption and propeller efficiencies will make curves that are quite critical and useful for flight-control purposes.

The foregoing represents a few of the factors in the development of economic air-line equipment. There are many more, most of which are imperfectly understood, but it is felt that more discussion of the problems may lead to a better understanding and appreciation of them.

At the present moment the available air-line equipment is more economic than any that has preceded it. The best has not been developed as yet; there is still enormous room for improvement.

Discussion

WALTER F. MCGINTY.[6] The author is to be congratulated for his very complete presentation of recognized economic factors for air transportation.

A symbol or two seem to be missing, and some minor corrections are required in the equations which have to do with "speed." In Equation [3], for the maximum speed of an airplane in miles per hr, the terms of the various factors indicate that the landing speed is the limiting landing speed at sea level; therefore, in the expressions following Equation [4], the equation for the square of the same landing speed should correspondingly be given in terms of mass density of air at sea level. This will allow a correct transition to Equation [5]. In Equation [8], the atmospheric-density ratio is missing from the denominator. The next equation would be true only if the limiting landing speed were in ft-per-sec units. Due to the fact that the landing speed is defined in this paper as the limiting landing speed in miles per hour, the coefficient, 7.22, in Equation [9] should be eliminated in favor of the value 5.59.

The writer feels that any discussions of air-line economy finally come back to discussions of equipment economy. When reduced to basic essentials, Equation [3] contains every element of economical operating efficiency. An examination of this equation points to the obvious conclusion that high maximum and cruising speeds will be attained with any airplane, provided that the propulsive efficiency, the maximum-lift coefficient, and the landing speed are made as great as possible; and that total-drag coefficient, power loading, and the density ratio be made as small as possible. Landing speeds are dictated by common sense or

[6] Transair Corporation, San Francisco, Calif.

government regulation. Maximum-lift coefficients have been increased greatly these last few years with the development of special wing devices, but practical limits are indicated in this direction already. Power loadings, on the other hand, must be increased considerably over present-day figures in order to insure lowered fuel costs. The choice of a proper operating altitude that will allow intelligent increases in speed, commensurate with power-plant and passenger difficulties with high altitudes, limits the possible decrease in density ratio. What remains then is the ratio of propulsive efficiency to total-drag coefficient. This ratio must be increased if better economies are to be realized. The problem is the same now as it has been for the last 30 years. It is the responsibility, therefore, of airplane and power-plant designers to see that this ratio is made a maximum consistent with structural and maintenance limitations that might well enter.

In the floor discussion that followed the presentation of the paper, the author was asked whether he believed that air-line equipment units were going to increase greatly in size in order to minimize the number of scheduled trips for a given traffic density or whether over-all costs would be lowered if a greater equipment utilization was realized with smaller airplanes operating more frequently. In this regard, the writer feels that we shall see a much greater diversification of airplane equipment types than at present in order to increase over-all traffic by providing transportation to the smaller communities which are not served by air at present. To accomplish this, there will likely be at least three general classes of equipment: Large airplanes with moderate fuel capacity to serve large communities in densely populated areas; slightly smaller transports, designed to operate over long distances for our transcontinental services, stopping only at the larger cities or where refueling may be required; and a much smaller airplane, designed to equip the smaller air lines and to act as "parallel feeders" and "cross feeders" for the main lines.

The Flow of Water in Channels Under Steep Gradients

By W. F. DURAND,[1] STANFORD UNIVERSITY, CALIF.

In the case of water flowing down a steep slope with the upper surface exposed to the air, the usual conditions and equations for hydraulic flow under moderate velocities no longer apply. The changed conditions involve greatly increased velocities, insufflation by air, a surface in contact with the air, uneven, foamy and rolling, with consequent air resistance as an important factor in the problem.

The questions of interest involve the history of the water from its start at a zero or moderate velocity at the top of the slope until it reaches the bottom, or until a limit velocity is reached where the resistance to flow equals the acceleration, and measurably steady conditions continue. Specifically, the questions of chief interest are: With given conditions at the top of the slope, what velocity will be acquired after a given length of run or after a given period of time? The present paper gives a mathematical stepwise solution of these problems, depending on a knowledge of the initial conditions and a known or assumed value of a coefficient β, relating the resistance to flow at a given point in the run or at a given instant of time, to the square of the velocity. Values of the coefficient β await the results of observation on actual cases of such flow. With representative sets of such values, an attempt at generalization could be made. A further important question relates to the details of the way in which the air enters a stream of rapidly flowing water, thus producing the insufflation which is so important a factor in the problem.

THE PROBLEMS arising in connection with the flow of water in channels more commonly relate to moderate gradients, low to moderate velocities, and steady conditions of flow. We are not, as a rule, concerned with the introductory period during which the velocity is increasing from zero, or from some initial velocity, to its final or steady-flow value. Under these latter conditions the forces making for acceleration are balanced by the resistance to flow and steady conditions prevail, that is, over any given cross section of the stream, the distribution of velocity remains sensibly constant in time. Furthermore, the moving medium may be assumed to remain continuously in the liquid phase, that is, without sensible insufflation by air. And again, the resistance opposed to the flow may be considered as that developed between the moving liquid and the solid boundaries which constrain its motion, fluid friction so called.

The final or steady-motion velocity which is acquired under these conditions is, then, the item of principal interest and forms the subject of the well-known classical treatment of the subject.

In the case of water flowing under steep gradients, however, the preceding simple conditions of flow no longer prevail. The velocities acquired may be high and the resistance to the flow can no longer be restricted to the solid boundaries of the stream. The air boundary now begins to play a part, and gradual insufflation with air brings a change in the density of the flowing medium and in the mean hydraulic radius of the section. The surface of the flow becomes broken and irregular due to wave formation (action between air and water) and due also to the marked velocity gradient between the bottom of the flow and the top. The latter is especially marked in case the flow is relatively shallow in depth. As a result, the flow may become transformed from a liquid phase into an extremely turbulent foamy phase with a rough and irregular upper surface involving a greatly increased resistance by the air boundary of the stream.

Under these conditions of flow, we are not only concerned with the ultimate velocity which may be acquired, provided the channel is long enough, but we are also interested in the velocity which may be acquired in a given length of channel or in a given interval of time. We are, therefore, concerned with relations between velocity, distance, and time, during the period of acceleration from an initial velocity v_1 toward a final velocity $\bar{v}$.

The present treatment of this problem differs from the well-known solution by Bakhmeteff in that, with insufflation, the assumption of a continuous liquid phase is no longer tenable. Furthermore, the effect of the fluid pressure within the sheet is neglected and the slope of the flow is taken as that of the bottom surface of the channel. The simplification thus realized by throwing all variable hydraulic conditions into one factor β (as defined later) makes possible the direct solution in terms of hyperbolic functions rather than in terms of a special function, as in the Bakhmeteff solution. The present treatment is presented in no sense as a substitute for the detailed Bakhmeteff solution but rather as a relatively direct mode of approach through well-known tabular functions to problems involving insufflation, always assuming that values of the coefficient β, based on experience, may be available.

The treatment of the problem mathematically will obviously depend on the continuously varying relation between acceleration and resistance or retardation. If we know the angle of slope of the channel at any given point, we can, for a unit of mass, determine the acceleration due to gravity at that point. If the slope is uniform, so also is the acceleration.

The question then turns on the relation between resistance and velocity. For the ordinary case of channel flow we are content, for most practical purposes, to assume the resistance, or fluid friction, to vary as the square of the velocity with a constant coefficient, the value of which will depend on the circumstances of the flow, especially the mean hydraulic radius and the roughness of the surface.

In the present case we may make the same assumption as to velocity, but now with a value of the coefficient varying with the velocity instead of constant. This will give, for the resistance to the flow, a term of the form βv^2 where v is the velocity at any instant of time (or point along the flow) and β is the

---

Contributed by the Hydraulic Division and presented at the Semi-Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, San Francisco, Calif., July 10–15, 1939.

Discussion of this paper was closed September 1, 1939, and is published herewith directly following the paper.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

value of the coefficient for that value of v and for the other circumstances of the flow at that time or point. The phrase, "velocity at any instant of time (or point along the flow)," is not precise, since the velocity will vary, perhaps widely, over the cross section of the flow. As usual, however, it may be accepted as meaning the general average velocity of flow over the section.

If then we denote the angle of slope of the channel (not necessarily uniform) at a given point along the line of flow by θ, we shall have, for the general equation of flow the differential form

$$dv/dt = g \sin \theta - \beta v^2 \quad \ldots\ldots [1]$$

With the equation in this form, with θ variable from point to point along the channel and with β variable with the velocity, analytical treatment of the problem appears to be out of the question. The same is true with θ constant, as is more commonly the case, but with β variable. If, however, we know the values of θ from point to point along the channel and if we have some clue to the relation of β to the controlling conditions of the flow and to the velocity, we may then assume these values constant for a brief interval of time—one second or shorter if desired. If then we can solve the equation for constant values of θ and β, we may, knowing the values of velocity or distance at the start of the period, find those for the end of the period, and thus stepwise trace all values through as far as may be desired.

It is seen, of course, that this method of treatment is approximate only. First, the resistance is assumed to vary with the square of the velocity and second, the value of β is assumed to remain constant at some mean value over a short period of time. Justification for the first assumption is found in the fact that it is one of the conditions of a practicable analytical treatment and, further, that it is in line with the general practice in problems involving the relative motion between a fluid and its boundaries. Justification for the second assumption is found in the fact that by decreasing the time interval over which β is taken constant at a mean value, the approximation may be made as close as desired—in any event much closer, presumably, than the observational data on which the values of β may depend.

With this by way of introduction, we may now proceed to the discussion of the equation of motion.

We consider first the simple case where both the slope and β are constant and $v_1 = 0$. We then take the more general case where v_1 is not zero and where, as will be seen, the treatment will provide for a stepwise approximate solution for the case of variable θ or β or both θ and β, from point to point.

Turning then to Equation [1] we put α for $g \sin \theta$ and have

$$dv/dt = \alpha - \beta v^2$$

For $dv/dt = 0$ we have for the limit velocity

$$\bar{v} = (\alpha/\beta)^{1/2} \quad \ldots\ldots [2]$$

Put the equation in the form

$$\frac{dt}{dv} = \frac{1}{\alpha - \beta v^2} \quad \ldots\ldots [3]$$

The fraction on the right is readily separated into two partial fractions giving

$$dt = \frac{1}{2\alpha^{1/2}}\left(\frac{dv}{\alpha^{1/2} - \beta^{1/2}v} + \frac{dv}{\alpha^{1/2} + \beta^{1/2}v}\right) \quad \ldots\ldots [4]$$

This integrates immediately as

$$t\Big]_{t_1}^{t} = \frac{1}{2\alpha^{1/2}\,\beta^{1/2}} \log\left(\frac{\alpha^{1/2} + \beta^{1/2}v}{\alpha^{1/2} - \beta^{1/2}v}\right)\Big]_{v_1}^{v} \quad \ldots\ldots [5][2]$$

[2] Throughout the treatment, log means the Napierian log, or $\log_e$.

With $v_1 = 0$, that is, a start from rest at the top of the slide and with $t_1 = 0$, we have

$$2\alpha^{1/2}\beta^{1/2}t = \log \frac{\alpha^{1/2} + \beta^{1/2}v}{\alpha^{1/2} - \beta^{1/2}v} \quad \ldots\ldots [6]$$

Dividing through numerator and denominator of the fraction by $\beta^{1/2}$, remembering Equation [2], and putting

$$\mu \text{ for } \alpha^{1/2}\beta^{1/2} \text{ and } \lambda^2 \text{ for } \frac{\bar{v} + v}{\bar{v} - v}$$

Equation [6] becomes

$$\mu t = \frac{1}{2} \log \frac{\bar{v} + v}{\bar{v} - v} = \log \lambda \quad \ldots\ldots [7]$$

Here again for $v = \bar{v}$, $t = \infty$ which shows that $\bar{v}$ is reached only after an infinite time. However on the assumption of β constant we find readily the time required to reach any stated fraction of $\bar{v}$. Thus put $v = m\bar{v}$. Then Equation [7] becomes

$$\mu t = \frac{1}{2} \log \left(\frac{1 + m}{1 - m}\right) \quad \ldots\ldots [8]$$

For $m = 0.90$ this gives $t = (1/2\mu) \log 19$
For $m = 0.95$ this gives $t = (1/2\mu) \log 39$
For $m = 0.99$ this gives $t = (1/2\mu) \log 199$

Now taking exponentials and solving Equation [7] for v or Equation [8] for m, we have

$$\frac{v}{\bar{v}} = m = \frac{e^{2\mu t} - 1}{e^{2\mu t} + 1} \quad \ldots\ldots [9]$$

Equation [9] with a series of values of t will give the corresponding progressive values of v.

Equation [9] may, furthermore, be conveniently transformed into an expression in terms of hyperbolic functions as follows:

Since $\tanh x = \dfrac{e^x - e^{-x}}{e^x + e^{-x}} = \dfrac{e^{2x} - 1}{e^{2x} + 1}$, Equation [9] gives directly

$$\frac{v}{\bar{v}} = m = \tanh (\mu t) \quad \ldots\ldots [10]$$

Thus with a table of hyperbolic tangents and any assumed values of t, the values of m and hence of v may readily be found.

Again in Equation [10] putting $v = ds/dt$ and integrating between limits of 0 and t, we have

$$S = \frac{\bar{v}}{\mu} (\log \cosh \mu t) \quad \ldots\ldots [11]$$

Here again, with tables of hyperbolic cosines and natural logarithms, the value of the distance for any value of t may be directly found.

We return now to Equation [5] and take the more general case where v_1 is not zero. Substitution of the limits t_1, t, and v_1, v, with $\bar{v}$ put for $\alpha^{1/2}/\beta^{1/2}$ gives

$$\mu(t - t_1) = \frac{1}{2} \log \left(\frac{\bar{v} + v}{\bar{v} - v}\right)\left(\frac{\bar{v} - v_1}{\bar{v} + v_1}\right) \quad \ldots\ldots [12]$$

Or putting Δt for $t - t_1$, and remembering that we may put

$$\lambda^2 \text{ for } \frac{\bar{v} + v}{\bar{v} - v} \quad \text{and} \quad \lambda_1^2 \text{ for } \frac{\bar{v} + v_1}{\bar{v} - v_1} \quad \ldots\ldots [13]$$

Equation [12] takes the form

$$\mu \Delta t = \log \left(\frac{\lambda}{\lambda_1}\right) \quad \ldots\ldots [14]$$

This equation gives the time interval Δt required for an increase of the velocity from v_1 to any given value v.

Then going back to Equation [12], taking exponentials, and solving for v, we find

$$\frac{v}{\bar{v}} = \frac{e^{2\mu\Delta t}(\bar{v} + v_1) - (\bar{v} - v_1)}{e^{2\mu\Delta t}(\bar{v} + v_1) + (\bar{v} - v_1)} \text{ or } \ldots\ldots\ldots [15]$$

$$\frac{v}{\bar{v}} = m = \frac{\lambda_1^2 e^{2\mu\Delta t} - 1}{\lambda_1^2 e^{2\mu\Delta t} + 1} \ldots\ldots\ldots\ldots [16]$$

which may be compared with Equation [9].

This equation gives the velocity v acquired after an interval of time Δt, starting with an initial velocity v_1 and knowing $\bar{v}$. See Equations [13].

In a similar manner as for Equation [9], we may express Equation [16] in terms of hyperbolic functions as follows:

Put $e^{2\mu} = \lambda_1^2 e^{2\mu\Delta t}$. Then $2\mu = 2\mu\Delta t + 2 \log \lambda_1$, and, similarly as for Equation [10]

$$\frac{v}{\bar{v}} = \tanh (\mu\Delta t + \log \lambda_1) \ldots\ldots\ldots\ldots [17]$$

With values of $\bar{v}$, v_1, and Δt, the value of v is thus found directly from a table of hyperbolic tangents.

Again putting ds/dt for v, we integrate Equation [17], giving for the space interval ΔS the value

$$\Delta S = \frac{\bar{v}}{\mu} \log \left[\frac{\cosh (\mu\Delta t + \log \lambda_1)}{\cosh (\log \lambda_1)} \right] \ldots\ldots\ldots [18]$$

This gives the space ΔS passed over in the time Δt starting with an initial velocity v_1.

By solving inversely certain of the preceding equations and collecting together, we have explicit expressions for all six possible relations between the variables v, t, and S for initial $v = 0$, and for v, Δt, and ΔS for initial $v = v_1$.

These are as follows:

General Formulas

In the following formulas, note that

$$\mu = \sqrt{(\alpha\beta)}, \quad \lambda^2 = \frac{\bar{v} + v}{\bar{v} - v}, \quad \lambda_1^2 = \frac{\bar{v} + v_1}{\bar{v} - v_1}, \quad \text{and} \quad \gamma = \frac{\mu S}{\bar{v}} \text{ or } \frac{\mu \Delta S}{\bar{v}}.$$

Where $v_1 = 0$

For t in terms of v

$$\mu t = \frac{1}{2} \log \frac{\bar{v} + v}{\bar{v} - v} = \log \lambda \ldots\ldots\ldots\ldots [a]$$

For t in terms of S

$$\mu t = \cosh^{-1} e^{\gamma} \ldots\ldots\ldots\ldots\ldots [b]$$

For v in terms of t

$$v = \bar{v} \frac{e^{2\mu t} - 1}{e^{2\mu t} + 1} = \bar{v} \tanh (\mu t) \ldots\ldots\ldots\ldots [c]$$

For v in terms of S

$$v = \bar{v} \tanh (\cosh^{-1} e^{\gamma}) \ldots\ldots\ldots\ldots [d]$$

For S in terms of t

$$S = \frac{\bar{v}}{\mu} \log \cosh (\mu t) \ldots\ldots\ldots\ldots\ldots [e]$$

For S in terms of v

$$S = \frac{\bar{v}}{\mu} \log \cosh \left(\frac{1}{2} \log \frac{\bar{v} + v}{\bar{v} - v} \right) = \frac{\bar{v}}{\mu} \log \cosh \log \lambda \ldots [f]$$

Where v_1 is not 0

For Δt in terms of v

$$\mu\Delta t = \frac{1}{2} \log \left(\frac{\bar{v} + v}{\bar{v} - v} \right) \left(\frac{\bar{v} - v_1}{\bar{v} + v_1} \right) = \log \frac{\lambda}{\lambda_1} \ldots\ldots [A]$$

For Δt in terms of ΔS

$$\mu\Delta t = \cosh^{-1} (e^{\gamma} \cosh \log \lambda_1) - \log \lambda_1 \ldots\ldots [B]$$

For v in terms of Δt

$$v = \bar{v} \left(\frac{\lambda_1^2 e^{2\mu\Delta t} - 1}{\lambda_1^2 e^{2\mu\Delta t} + 1} \right) = \bar{v} \tanh (\mu\Delta t + \log \lambda_1)$$

$$\text{or } \log \lambda = \mu\Delta t + \log \lambda_1 \ldots\ldots\ldots\ldots [C]$$

For v in terms of ΔS

$$v = \bar{v} \tanh [\cosh^{-1} (e^{\gamma} \cosh \log \lambda_1)]$$

$$\text{or } \log \lambda = \cosh^{-1} (e^{\gamma} \cosh \log \lambda_1) \ldots\ldots\ldots [D]$$

For ΔS in terms of Δt

$$\Delta S = \frac{\bar{v}}{\mu} \log \left[\frac{\cosh (\mu\Delta t + \log \lambda_1)}{\cosh \log \lambda_1} \right] \ldots\ldots\ldots [E]$$

For ΔS in terms of v

$$\Delta S = \frac{\bar{v}}{\mu} \log \frac{\cosh \log \lambda}{\cosh \log \lambda_1} \ldots\ldots\ldots\ldots [F]$$

Thus far the analytical discussion has proceeded on the assumption of constant values for both α and β. While quite commonly α might be found constant, the value of β, as already noted, may be expected to change with the changing physical conditions usually met with in flows of this character. At the start the value of β will involve the coefficient of friction between water and the surface of the conduit, the density of the flow, and the mean hydraulic radius. As the flow follows down the slope, all of these conceivably may change. Air friction will enter as a factor, especially with indraft of air and insufflation of the stream, and in particular if the flow becomes broken and irregular with boiling rolling turbulence, with wave action at the surface raveling out into spray. As the gradient approaches extreme limits, from 80 to 90 deg, there is a tendency, as is well known, for the entire flow to break up into spray and mist, provided the descent be of sufficient length.

These same physical conditions will affect likewise the average density of the flow and the mean hydraulic radius. It would seem not unreasonable to expect a continuous increase in the value of β from point to point down the flow. However, any attempt to introduce β as a function, either of distance or time, into the basic Equation [1], introduces a complexity rendering direct integration impracticable.

The same results follow with variable slope, that is, with α variable. If, however, we assume both α and β constant for any specified time, such as one second, we shall have, for this period, Equations [14] and [16] as the solution of the basic Equation [3] with the known (or assumed) initial velocity v_1. This provides a means for tracing the velocity through from second to second, with any known series of values of α and any assumed values of β. If, as in the more usual case, α is constant, we shall have only to take the assumed values of β from one time interval to another.

Thus for the first second assume a velocity of approach v_1 and for β, some value β_1. This will give v at the end of second 1. This then becomes v_1 for second 2, and with another value β_2, v at the end of second 2 is found. This in turn becomes v_1 for second 3, and so on as far as may be desired.

It now remains to discuss briefly the relation of β in Equation [1] to the more familiar quantities connected with fluid friction.

We may derive immediately the desired relation as follows: From Equation [2] we have

$$(\bar{v})^2 = \frac{\alpha}{\beta} = g\frac{\sin\theta}{\beta}$$

But v is the same v as that given by the familiar formula $v = C\sqrt{(i\rho)}$ where C is the Chezy coefficient, i the hydraulic gradient which for steady flow equals $\sin\theta$, and ρ is the mean hydraulic radius. Equating these values of $(\bar{v})^2$ and v^2 and solving for β, we have

$$\beta = g/C^2\rho \quad \ldots\ldots\ldots\ldots\ldots\ldots [19]$$

However, it will be desirable to develop this relation in such manner as to bring in the two fundamental characteristics of a fluid, viscosity (as evidenced by fluid friction) and density, and to this end we proceed as follows:

In any conduit let f be the coefficient of friction for unit velocity. That is, f is the drag in pounds force per unit area of surface for unit velocity. Assume friction to vary as v^2.

Then let w = the weight of unit volume of the fluid
a = cross-sectional area of channel
p = wetted perimeter of channel.

Then for a small length dx of the channel or conduit, we shall have

Drag for length dx at velocity $v = fv^2pdx$
Weight of contents $= wadx$
Drag per lb, $fv^2pdx \div wadx = fv^2p \div wa$

If then we put $\rho = a/p$ = mean hydraulic radius, this becomes

$$\text{Drag per lb contents of flow} = fv^2/\rho w$$

This then is the drag in pounds force on a pound weight of the contents of the flow and as such it will produce negative acceleration measured by the force divided by the mass. But the mass of 1 lb wt is $1/g$ and hence the negative acceleration produced by the drag $fv^2/\rho w$ will be $gfv^2/\rho w$.

This is represented in Equation [1] by the term βv^2. Hence we have

$$\beta = gf/\rho w \quad \ldots\ldots\ldots\ldots\ldots\ldots [20]$$

Next, if we take the familiar Chezy formula for loss of head, we have

$$h = Lv^2/C^2\rho \quad \ldots\ldots\ldots\ldots\ldots\ldots [21]$$

This is loss of energy per lb wt of fluid in traversing a distance L, and is measured by the work done on 1 lb wt in traversing this distance. Hence the resistance overcome will be measured by dividing the work by L, or, drag $= v^2/C^2\rho$.

But, as we have just seen, this is also measured by $fv^2/\rho w$. Hence equating, we have

$$1/C^2 = f/w \text{ or } f = w/C^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

This gives a relation between the coefficient of friction f and the familiar C of the Chezy formula.

Again from Equations [20] and [22] we have, as in [19] $\beta = g/C^2\rho$ giving, as before, a direct relation between β, the Chezy C and the mean hydraulic radius.

Returning to Equation [20], we may write $\beta \sim f/\rho w$.

In comparing the value of β at some point down the slope with its value at the start, we have then to query the changes in f, ρ, and w.

With high velocity, irregular water surface, and insufflation of the stream, air friction will enter as an important factor and the effective perimeter must include the air surface as well as the channel surface. The value of f for the friction between the channel surface and a mixture of air and water will also come into the picture. There seem to be no available data on such a complex value of f. The effect of insufflation, without the air perimeter, will be to increase ρ and decrease w. The inclusion of the air part of the perimeter will decrease ρ. Decrease in the values of either ρ or w, or both, will tend to increase the value of β. On the other hand, the increase in velocity will tend to decrease both a and p, but with a decrease in the value of ρ. That is, increase in v by itself will result in a decrease of ρ, insufflation by itself will increase ρ and decrease w, and including the air part of the perimeter, will decrease ρ. There seem to be available no data on which to base a judgment for any particular case as to the ultimate effect on f, ρ, or w, and still less on the resulting value of β.

Accurate observations on the values of v in any particular case would however make possible, by a cut-and-try method, the determination of a series of values of β which would fit that particular case, but there does not appear to be any theoretical method whereby such values could be generalized to extend to other cases with varying values of the slope, proportions of the flow sheet, and the like.

Such observations would, however, be of value in at least determining the facts and in making possible the determination of ranges of values of β for particular cases. An accumulation of such data would then make possible at least an approximate solution for the usual run of cases which are encountered in practical experience.

A question of fundamental interest and importance, collateral with the main problem is, how, in the course of the flow of water down a steep gradient, that is, with high velocity, does the air get into the water? What are the factors which determine such insufflation and on what conditions of the flow do they depend? In the present paper no attempt is made to deal with these important questions; there seems to be too little to go on in the way of experimental evidence; but it is hoped that the interest and importance of these questions may stimulate, by way of laboratory research, suitable investigating which may throw some light on this apparently obscure phase of the general problem.

It may be noted that the treatment in the present paper implies a continuous discharge, for the time being, of a uniform *quantity* of water down the steep sloping discharge channel, rather than the movement of a discrete gulp or wave of water. The same basic equations would appear likewise to apply even to the case of a sudden wave, but in such case the form of the wave would vary continuously down the slope with resulting increased difficulty in the evaluation, from point to point, of suitable values of the coefficient β.

Furthermore, the discussion thus far has been quite independent of reference to specific applications. One of the principal fields of such application would be found in connection with the design of means for the absorption of the energy of the water flowing down the spillway of a dam, such as the Grand Coulee Dam on the Columbia River, or the Shasta Dam on the Sacramento River. In the former, the water will plunge into the river on the downstream side of the dam, and then under the influence of a submerged curved lip—the so-called "bucket"—it will be deflected upward, with transformation of most of the kinetic energy of flow into the energy of eddies, boils, and mixed turbulence. In the latter the energy is to be absorbed in a special form of hydraulic jump. In both cases the velocities likely to be acquired in the flow down the sloping face of the spillway are of definite interest in connection with the design of the "bucket" in the one case or the hydraulic jump in the other.

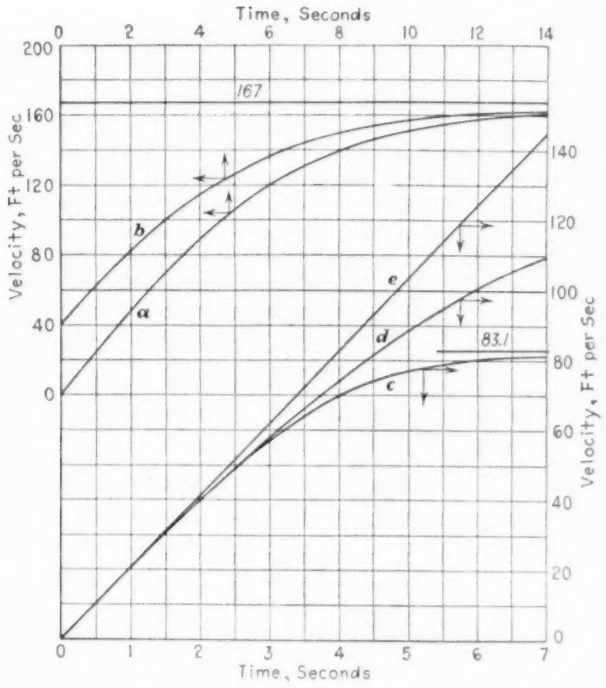

FIG. 1 VELOCITY CURVES OF EXAMPLES GIVEN

Broadly, the methods outlined in the present paper would be applicable to the determination of the velocity which might be anticipated after any given period of time or over any given length of a steep sloping run, once the controlling conditions are known or assumed, and suitable values of the coefficient β available. Such conditions may occur in connection not only with spillway dams, but with many types of hydraulic construction, where waste water is disposed of by discharge down a specially formed channel under a relatively steep gradient.

By way of illustration of the application of these equations, the following problems have been worked out on assumed conditions and values of the coefficient β.

EXAMPLES

In Fig. 1 curve *a* gives the velocity history for the following conditions: $v_1 = 0$ (start from rest), $\alpha = 25(\theta = 50$ deg), and $\beta = 0.0009$ constant. This would correspond to, say, $C = 125$ and $\rho = 2.3$ ft. Then $\bar{v} = 167$ fps and $\mu = 0.15$.

In 14 sec, with a travel of 1583 ft, v has reached a value 162 fps or 97 per cent of $\bar{v}$.

Curve *b* gives the velocity history for the same basic values except that here $v = 40$ fps. In this case, after 14 sec and with a travel of 1813 ft, v has reached a value of 164 fps or 98 per cent of $\bar{v}$.

Curve *c* gives the velocity history for the following conditions: $v_1 = 0$ (start from rest), $\alpha = 20.7$ ($\theta = 40$ deg), $\beta = 0.0009$ as before at the start, with increasing values taken arbitrarily as follows: For the first second, 0.0009; second, 0.0012; third, 0.0015; fourth, 0.0019; fifth, 0.0024; sixth, 0.0029; and for the seventh second, 0.0030.

In this case, after 7 sec, with a run of about 390 ft, v has reached a value of 81.4 fps against an ultimate for $\beta = 0.003$ of 83.1 fps or 97.8 per cent of $\bar{v}$.

Curve *d* gives the corresponding time history with no increase in β, i.e., no increase above ordinary skin friction for water on concrete, for which the limit velocity, with β constant at 0.0009, would be 151 fps.

The line *e* gives the corresponding time history with no retardation at all.

Discussion

G. H. KEULEGAN[3] AND H. N. EATON.[4] The purpose of the following discussion is to show the effect of including the velocity distribution in the equation of flow in steep channels. The author, although recognizing that this will affect the flow, leaves it out of account. However, it is a simple matter to include this effect, and it is far from being negligible in many instances. Because of space limitations, only a bare indication of the results obtained for a wide rectangular channel can be given. The notation used agrees with that of the author, except where otherwise stated.

First introduce the ratios

$$\frac{v_s' - v}{v} = a_2, \text{ and } \frac{v_s'^2 - a_1 v^2}{v^2} = 2a_3 \dots\dots [23]$$

where v_s' is the velocity of the surface filaments, and $a_1 = 1 + \eta$, η being the "Boussinesq coefficient" defined by Equation [31].

Starting with Osborne Reynolds' equation of motion for turbulent flow, we derive the following equation, in which the coefficients a_1, a_2, and a_3 involve the velocity distribution

$$\frac{\partial v}{\partial t} + (a_1 + a_3)\, v \frac{\partial v}{\partial x} + (a_3 - a_2) \frac{v}{h} \frac{\partial h}{\partial t} = - g \cos\theta \frac{\partial h}{\partial x} + g \sin\theta - \frac{\lambda}{2h} v^2 \dots\dots [24]$$

in which h is the depth, and λ is $^1/_4$ the friction coefficient λ in the rational pipe-flow formula.

We assume that the flow is steady and that the term containing $\frac{\partial h}{\partial x}$ is small; whereupon Equation [24] can be written

$$\frac{d(v^2)}{dx} = \frac{2g \sin\theta}{a_1 + a_3} - \frac{\lambda v^2}{h(a_1 + a_3)} = \alpha' - \beta' v^2 \dots\dots [25]$$

Here α' and β' are related to the author's α and β as follows:

$$\alpha' = \alpha/(a_1 + a_3), \text{ and } \beta' = \beta/(a_1 + a_3) \dots\dots [26]$$

Equation [25] can be integrated

$$S = x - x_0 = \frac{1}{\beta'} \ln \frac{\left(\frac{\alpha'}{\beta'} - v_0^2\right)}{\left(\frac{\alpha'}{\beta'} - v^2\right)} \dots\dots [27]$$

with v taken as v_0 at $x = x_0$.

At $$S = \infty, \bar{v} = \sqrt{\frac{\alpha'}{\beta'}} = \sqrt{\frac{\alpha}{\beta}} \dots\dots [28]$$

and we see that the velocity distribution has no effect upon the limiting velocity $\bar{v}$, but only upon the rate at which this velocity is reached. Equation [27] can be written

$$S = \frac{1}{\beta'} \ln \left(\frac{\alpha/\beta - v_0^2}{\alpha/\beta - v_2}\right) = \frac{a_1 + a_3}{\beta} \ln \left(\frac{\bar{v}^2 - v_0^2}{\bar{v}^2 - v^2}\right) \dots [29]$$

and the only effect of allowing for the velocity distribution is to add the factor $a_1 + a_3$ to the equation.

---

[3] Associate Physicist, National Bureau of Standards, Washington, D. C.

[4] Senior Hydraulic Engineer, National Bureau of Standards, Washington, D. C. Mem. A.S.M.E.

The values of a_1 and a_3 can be evaluated for any assumed velocity distribution. For example, if

$$v'^2 = Ay, \text{ where } A = v'^2_s/h \quad \ldots\ldots\ldots\ldots [30]$$

where v' is the filament velocity at distance y above the bed, then

$$a_1 = 1 + \eta = \frac{\int_0^{h_2} v'^2\, dy}{h\, v^2} = \frac{\int_0^h y\, dy}{\left(\int_0^h y^{1/2}\, dy\right)^2} = 1.125 \ldots [31]$$

and from Equations [23], [30], and [31]

$$a_3 = \frac{1}{2}\left(\frac{v_s'^2 - a_1 v^2}{v^2}\right) = 0.562$$

Then $a_1 + a_3 = 1.687$.

Thus the effect of a nonuniform velocity distribution is to decrease the mean velocity at a station downstream from the entrance to a channel below what it would be if the velocity were uniform over the cross section. In other words, the computed water-surface profile will be lower for assumed uniform than for nonuniform distribution. Now it has been observed in tests on model channels with steep slopes that the water-surface profiles, computed for assumed uniform velocity distribution lie below the observed surface profile. Computations made for one such channel indicate that, including the effect of velocity distribution as outlined, the foregoing accounts approximately for this discrepancy, although data are not available to test the accuracy of the assumptions made.

Problems Encountered in the Design and Operation of Impulse Turbines

By RAY S. QUICK,[1] SAN FRANCISCO, CALIF.

Because of present-day demands on high-head hydroelectric installations, calling for continuous maximum overload operation of impulse turbines, unusual problems of wear and fatigue of materials have developed. The author discusses such problems frankly and suggests solutions for them. One of the important factors influencing unit efficiency of impulse turbines is the arrangement and design of approach piping due to the effect on the jet of turbulence in the nozzle. Flow-straightening vanes have been developed to correct this turbulence. Various successful forms are illustrated and their characteristics plotted. The form of needle and nozzle tip also has a marked influence upon the appearance and form of the power jet. Another factor affecting the performance of the unit is that of the design, shape, and arrangement of buckets on the water wheel. Investigations have been made on all these elements of the impulse turbine, the results of which have been incorporated in present successful applications. Two outstanding impulse-turbine installations in California are mentioned. A comparison is drawn between field tests on one of these at the Tiger Creek Plant of the Pacific Gas and Electric Company and model tests. The paper concludes with a discussion of the governing problem.

THE DEVELOPMENT and operation of impulse turbines, particularly those for important high-head hydroelectric installations, have introduced many problems both in the selection of the most appropriate materials and in designs which will produce not only high efficiency but a satisfactory working life. In the early days of the industry loads were light and intermittent and it was often customary to shut a plant down over the week end. During the past decade transmission lines have been extended and interconnected. Loads have grown to such an extent that it is customary to operate large impulse turbines continuously at maximum overload for periods of many weeks or months without interruption. Needless to say, unusual problems of wear and fatigue of the materials have developed and, while it is most unusual for a manufacturer to report and discuss such difficulties, it will be the purpose of this paper to mention frankly characteristic problems and the methods followed in solving them.

The impulse turbine or tangential water wheel was developed in the early mining days in California. Early forms were inefficient until Lester A. Pelton about 1880 perfected the water-wheel bucket with the central dividing splitter. Seven years later the company was founded which now bears his name. Much has been written regarding the history of this type of water-turbine prime mover, while textbooks today outline and develop the theory of its operation. Consequently this work will not be reviewed at present.[2]

For many years the company with which the writer is associated has carried on an extensive research program based upon laboratory studies and upon field observations and tests. It has been customary to consider the efficiency as the ratio between the mechanical output of the water-wheel shaft and the theoretical hydraulic-power input at the entrance to the nozzle body.[3] In past years, in considering the requirements for high efficiency, no particular attention was given to the design or arrangement of the approach piping which delivers the power water from the penstock to the nozzle. Recent investigations have shown that the design of this approach piping has a pronounced influence upon the unit efficiency, due to the effect on the jet of turbulence or crossflow and eddies in the nozzle. As an example, refer to the upper jet shown in Fig. 1. This jet is produced by a needle nozzle of standard design having an inlet properly proportioned

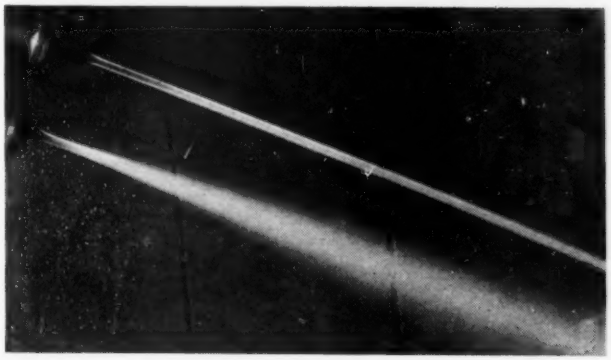

FIG. 1 COMPARISON OF JET PRODUCED BY STANDARD NEEDLE NOZZLE AND THAT PRODUCED BY SIMILAR NEEDLE NOZZLE WITH 90-DEG ELBOW NOZZLE BODY

to reduce turbulence to a minimum. A similar needle nozzle having a body formed with a 90-deg elbow is unable to produce a satisfactory power jet, the form being shown as the lower jet in Fig. 1. The spreading of the jet, due to eddies in the elbow, destroys its power value in a short distance.

Extensive investigations have been carried on in the design of flow-straightening vanes to be inserted in the nozzle body in an effort to correct this turbulence and restore the power of the jet. Fig. 2 illustrates a selected group of such vanes. Some of these vanes are far more effective than others. In general, vanes placed appreciably upstream from the power needle are of little use, while vanes combined with or surrounding the needle are most effective. Of striking interest is the type of vane shown in Fig. 3. It consists of a series of radial plates attached to the needle and stem in such a way as to divide the flow of water into parallel strips which recombine when the jet is formed. The result of

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the installation of vanes of this character is shown in Fig. 4. Comparison with Fig. 1 will show that this is the same needle-nozzle assembly but that the lower jet is now comparable to the upper in appearance and has recovered a substantial portion of its power value and eliminated most of its fringe or sprayed out covering.

A similar form of turbulence with resultant spreading jet may

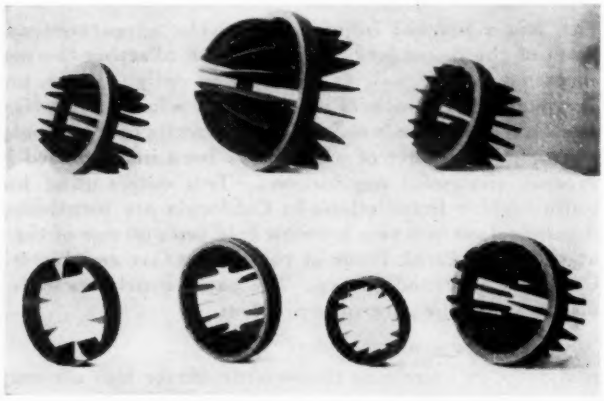

FIG. 2 STRAIGHTENING VANES FOR NOZZLE BODIES

FIG. 3 STRAIGHTENING VANES ON NEEDLE

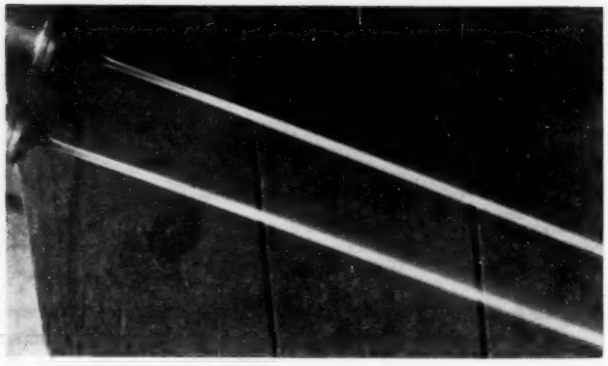

FIG. 4 COMPARISON OF JET PRODUCED BY STANDARD NEEDLE NOZZLE AND THAT PRODUCED BY SIMILAR NEEDLE WITH 90-DEG ELBOW NOZZLE BODY AND STRAIGHTENING VANES

be introduced into a needle nozzle of standard design and arrangement by an unfavorable manifold or system of elbows, wye pipes, and fittings, which otherwise would be considered satisfactory hydraulic practice. In laboratory testing it has been found that an orifice plate, inserted in the pipe line between adjoining flanges a few diameters upstream from the nozzle entrance, may introduce serious turbulence. While the pressure and velocity heads are maintained unchanged in the nozzle body, a serious loss in efficiency results, due to a disturbed stream flow at the point where the jet is formed. Fig. 5 has been taken directly from laboratory tests and shows in a very striking manner the influence of straightening vanes with and without turbulence. The performance curve, designated ① in Fig. 5, is the characteristic of a typical single-nozzle impulse turbine, using a standard needle nozzle, but with the flow in the approach piping disturbed by an orifice plate. For the purpose of the test, bucket loading is considered as the ratio between the diameter of the jet at the vena contracta, as determined by the head and quantity, and the nominal full-load-size rating of the bucket. When straightening vanes are installed in the needle nozzle, the efficiency characteristic is improved to curve ② in Fig. 5. Since the test setup is otherwise unchanged, it is apparent that the improvement has resulted from the addition of the vanes. There is also a visual improvement in the form of jet, the fringing of the outside surface being materially reduced. If the orifice plate is entirely removed and the straightening vanes are left in position, the characteristic is still further improved to curve ③ in Fig. 5. As there is little or no detrimental turbulence in the supply pipe, it is evident that

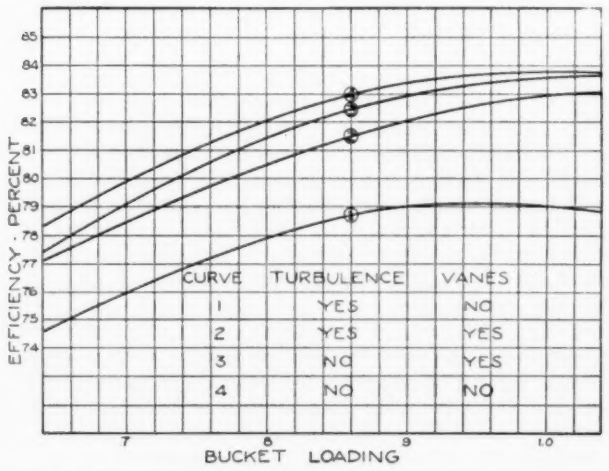

FIG. 5 EFFECT OF TURBULENCE AND STRAIGHTENING VANES IN NOZZLE BODY ON UNIT EFFICIENCY

the efficiency characteristic is approaching its best value. By removing the straightening vanes, thus bringing the assembly to the most favorable arrangement, the efficiency characteristic reaches its optimum value as shown by curve ④ in Fig. 5.

The foregoing characteristics as shown in Fig. 5 are typical and may be repeated qualitatively with other setups. The conclusions which are to be drawn from these tests may be summed up as follows:

1 The best efficiency characteristic is secured when there is neither turbulence nor straightening vanes in the supply system or nozzle.

2 If turbulence exists in the approach piping, it may be overcome or corrected materially by the installation of appropriate straightening vanes.

3 There is a mutual responsibility between all parties concerned with the selection and design of the penstock, approach piping and manifold, and hydraulic prime mover to eliminate the detrimental results of such turbulence.

Water passageways must be smooth, as straight as possible, and free of obstructions or sudden contractions and enlargements. A shutoff valve should have if possible a water passageway, forming a smooth continuation of the conduit walls. The turbulence in a well-designed nozzle is very small.

The form of needle and nozzle tip has a marked influence upon the appearance and efficiency of the power jet. Extensive tests

have been made on many combinations, both in the laboratory and in the field. While tests made under high-head conditions produce results differing slightly from those under low heads, due primarily to the change in relative velocity between the water, wetted surfaces, and the air surrounding the jet, nevertheless, in general, the nozzle producing the best appearing and the most efficient jet, when tested under low-head conditions, will be found to be preferable under high heads.[4] It is interesting to note that even at a high head, such as 2000 ft, a small jet will stay together and show a very fine appearance.

Fig. 6 illustrates a selected group of needles and nozzle tips which have been developed and tested in the laboratory with satisfactory results. The longer needles, having less contraction, require a greater stroke in order to discharge a given water quantity. Therefore, these are most adaptable to governor operation. The jet produced makes a very fine appearance and is relatively smooth and parallel on the surface. The steeper and shorter needles with greater contraction have a much shorter stroke for a given discharge and produce jets which are relatively rougher in external appearance. However, since the water has a much shorter distance to travel at full jet velocity on the wetted surfaces of the steeper needle, the efficiency is higher. This is confirmed by Fig. 7, which shows the efficiency characteristics of a given water-wheel unit, as tested in the laboratory, with needle nozzles having included angles of 45 deg and 90 deg. Other combinations of needles and tips have been tested with comparable results. The appropriate selection for a given case is determined largely by governing requirements, range in load, and general setting.

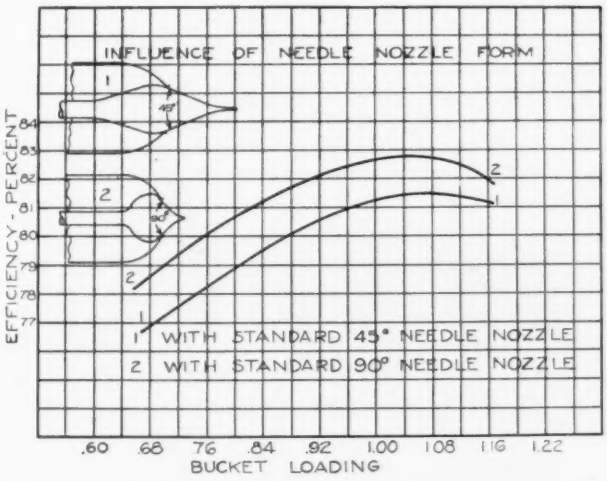

Fig. 7 Influence of Needle-Nozzle Form on Unit Efficiency

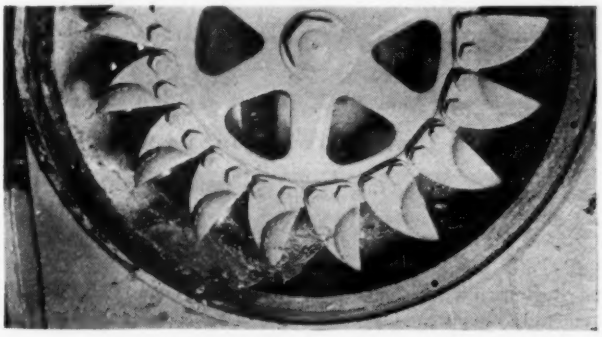

Fig. 8 High-Speed Photograph Illustrating Bucket Discharge

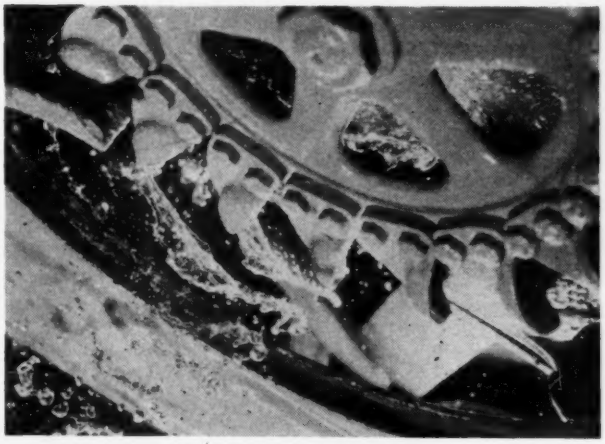

Fig. 9 High-Speed Photograph, Taken From Above Wheel, Showing Bucket Discharge

Problems of cavitation and erosion of needles and nozzle tips have been solved satisfactorily. Cavitation may be avoided almost entirely when the needle nozzle is operated throughout the normal range from say one quarter to full load. Operation for long periods near full shutoff is unfavorable, resulting in erosion and cavitation of the needle in the zone where the thin annular jet is being formed. Needles and nozzle tips made of carbon steel, stainless steel, nitralloy, bronze, and similar materials provide a satisfactory working life under average conditions. Stainless steel of the 18-8 type, used either as a forging or as a layer weld upon a mild-steel base is favored by many for severe conditions.

As the water-wheel runner is the heart of the unit, the design, shape, and arrangement of the buckets upon the wheel center exert a pronounced influence upon the performance of the unit as a whole. While the theory of reversal of the jet in the bowl of a water-wheel bucket has been developed and is fully described in standard textbooks on the subject, it has required the assistance of the stroboscope to arrest the relative motion and show clearly the action of the water with respect to the buckets. The author is indebted to H. E. Edgerton[5] for the perfection of the strobo-

[4] "Tests Conducted at Big Creek No. 1 With Experimental Nozzle and Needle Parts at Penstock Pressures," by J. F. Davenport, *Electrical West*, vol. 68, no. 6, May 15, 1932, p. 378.

scope and high-speed photography which has made possible the accompanying illustrations. A Pelton standard laboratory water motor was used by Mr. Edgerton, the glass cover plates on the housing being removed in order to provide a direct view for the camera. The water wheel was driven by a jet of water under relatively low head to avoid heavy mist and spray. The photographs were taken by instantaneous exposures when the wheel

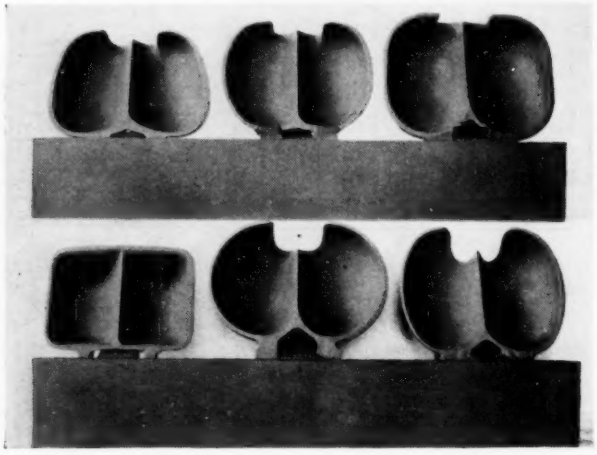

FIG. 10 GROUP OF DIFFERENT TYPES OF IMPULSE-WHEEL BUCKETS

was running approximately at normal speed. Fig. 8 is a side view showing the power jet in action on several buckets simultaneously. The bucket directly below and to the right of the shaft center line has interrupted the jet and the discharge has just started to leave the sides of the bucket bowl. The bucket to the right of this has just entered the jet and is not filled as yet. The bucket to the left is discharging its quota, while the bucket beyond is completing its working cycle. By taking photographs from above the wheel while in operation, as shown in Fig. 9, a definite clearance is indicated between the slugs of water discharging from adjacent buckets. It is also evident that the discharged water does not strike the back of the bowl of the preceding bucket, thus indicating an excellent operating condition.

The form of water-wheel bucket has undergone an evolution not only to improve its efficiency but also to increase its durability and strength, particularly for large high-capacity installations where continuous overload is the rule rather than the exception. Fig. 10 illustrates a representative group of such buckets, from the older square shape to the current ellipsoidal design with filled-in entrance. It has been difficult to secure a design of lip which will enter the jet with minimum shock and splash, while at the same time having adequate strength to resist the heavy loads and intermittent thrust. When loads are severe and the head is high, fatigue cracks may appear in the entering lip of the bucket, progressing rapidly until a portion of the bowl breaks off. Fig. 11 illustrates a bucket of older design which has failed in this manner. Due to the difficulty of making a complete analysis of the stresses existing in the bowl of a water-wheel bucket, subject to intermittent load and shock, it has been customary to design with a high factor of safety. Improvements have been made to stiffen the entrance and to distribute the load. With buckets of recent design, as illustrated in Fig. 10, the sharpened entering lip is retained in so far as possible, but the edge is rounded to minimize stress concentration and the section increases in thickness rapidly, thus providing a section of much greater strength than possessed by the previous thin and sharpened cut-out entrance.

Fig. 12 shows the efficiency characteristic of the new form of bucket in comparison with that of a previous design. It is evident that the modification of the entrance design has been accomplished without detriment. Buckets of this type are in operation under high heads and in large capacities and show great promise of having overcome the fatigue-crack limitations of the previous designs.

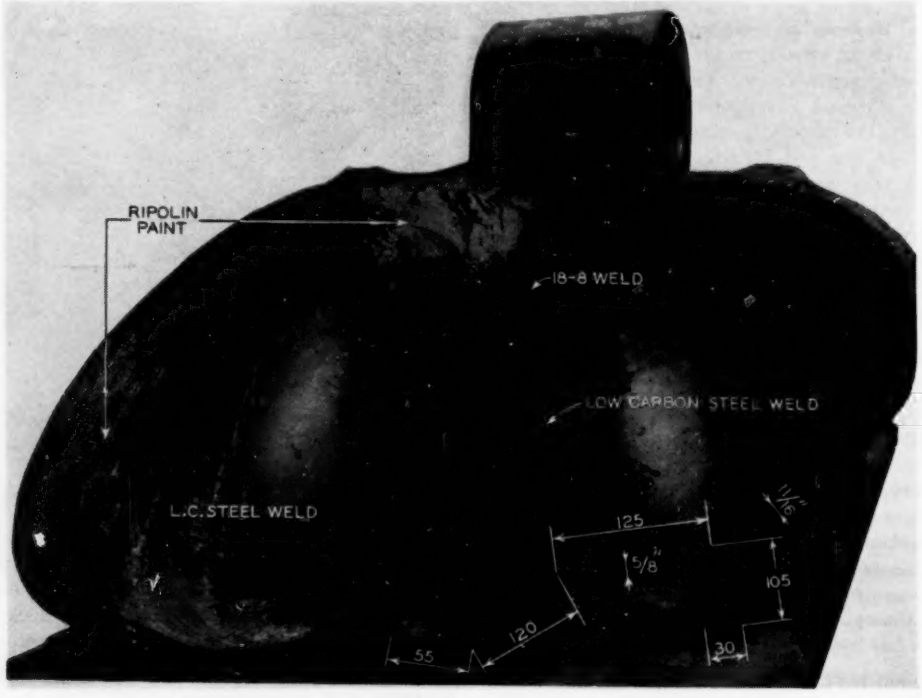

FIG. 11 SERVICE FAILURE OF A BUCKET DUE TO FATIGUE

In order to get a perspective as to the magnitude of the forces and the number of cycles of repeated stress to which a water-wheel bucket is subjected, consider an operating head of 2000 ft, an output of 25,000 hp per wheel, and a speed of 400 rpm. Calculation will show that the number of revolutions per year of the runner is about 211,000,000. Thus, a working life of 10 years requires over 2,000,000,000 working cycles for each bucket. Studies of fatigue would indicate that the material must be stressed appreciably below its fatigue limit if this working life is to be secured without failure of the material. The approximate force on the bucket each time it passes through the jet is 50,000 lb. It is apparent that the attachment of the buckets to the wheel center must be very secure and moderately stressed to avoid failure due to fatigue or to the bucket bolts working loose. The problem of bucket attachment has been solved successfully and reports of failure of bolts and lugs are very rare. The important problem in recent years has been cracking at the entering lip of the bucket.

The material used for high-head buckets is cast steel, the medium grades of carbon steel being preferred. Heat-treated alloy steel has been used to a limited extent but the practical problem in connection with this material is the difficulty in re-heat-treatment following field repairs by welding. In cases where the power water carries abrasive material in suspension, erosion may become an objectionable factor. An increase in bucket life

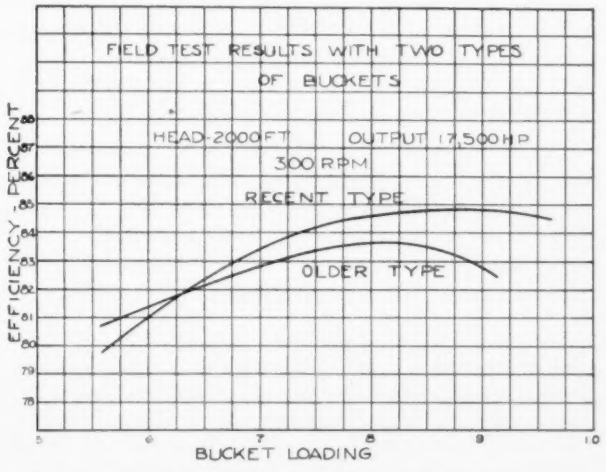

FIG. 12 INFLUENCE OF BUCKET SHAPE ON UNIT EFFICIENCY

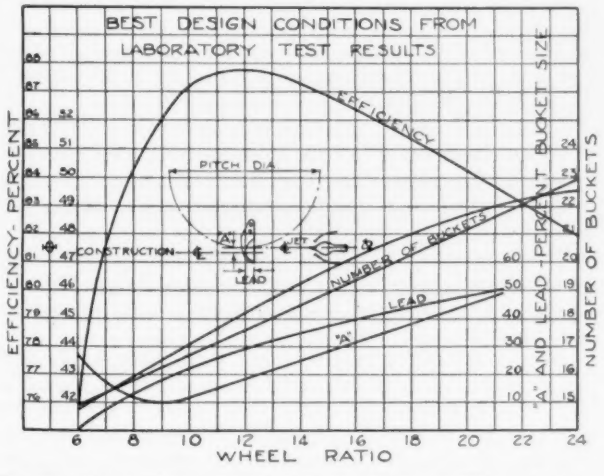

FIG. 13 CHARACTERISTICS OF ONE TYPE OF IMPULSE-WHEEL BUCKET

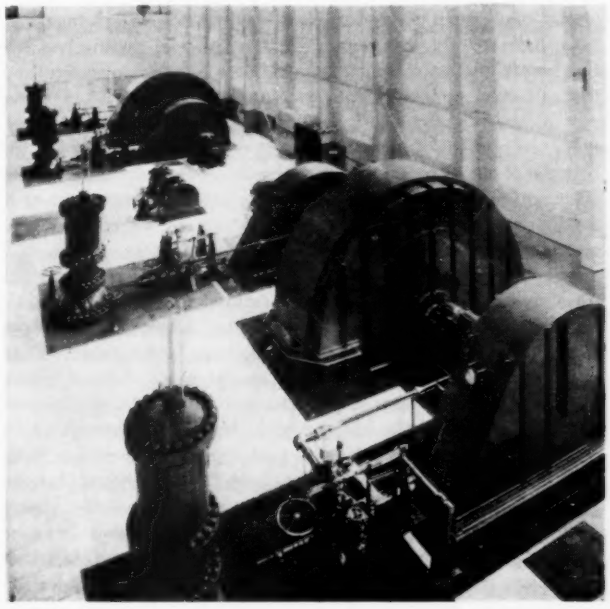

FIG. 14 TWO 40,000-HP DOUBLE-OVERHUNG IMPULSE TURBINES IN TIGER CREEK PLANT OF THE PACIFIC GAS AND ELECTRIC COMPANY

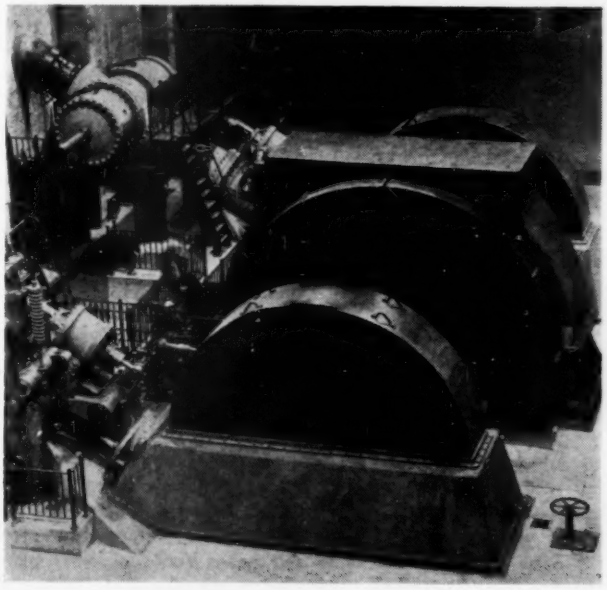

FIG. 15 ONE OF TWO 68,000-HP DOUBLE-OVERHUNG IMPULSE TURBINES IN BIG CREEK 2A PLANT OF THE SOUTHERN CALIFORNIA EDISON COMPANY

has been secured by the layer welding of 18-8 chrome-nickel stainless steel or other hard facings in the bucket bowls which are afterward ground smooth to true shape.

In the past it has been standard practice to construct water-wheel buckets as integral castings using iron for low heads and steel for high heads. Bronze has been favored for small buckets and in some cases stainless steel has been used. The complicated shape of the water-wheel bucket has made it difficult to produce castings of homogeneous physical properties. As a result, extensive study and development work have been done on the design of buckets made either as integral steel forgings or fabricated with

forged-steel bowls welded to cast-steel or plate-steel lugs. To date, however, the first cost of the integral steel casting has been the lowest and as a result, because of economic considerations, the cast-steel bucket is still standard practice. The increased cost of the forgings has been due to the special dies involved. Since the number of buckets of any specific design is very limited, because of their special nature, it has not been possible to standardize on dies. In the case of the fabricated buckets, formed by welding two or more pieces together, the increased costs of labor and heat-treatment have been the deciding factors.

In selecting the most appropriate speed for an impulse turbine for a given head and quantity, the ratio of the bucket size to the pitch diameter of the wheel is a deciding factor. Fig. 13 shows the characteristics of a bucket developed in recent years. These characteristics were established by an extensive series of laboratory tests, using a water-wheel runner so arranged that the number and position of the buckets could be altered through a wide range, while at the same time the jet could be changed in radial position and size. As a result, the characteristics shown illustrate the most favorable combination. It is evident that the highest efficiency can be secured only at the most favorable ratio.

Among the recent outstanding impulse-turbine installations in California may be mentioned the Tiger Creek Plant of the Pacific Gas and Electric Company, shown in Fig. 14, and the Big Creek 2A Plant of the Southern California Edison Company shown in Fig. 15. The units in both plants are of the horizontal, double-overhung, single-straight-flow-nozzle type, using follower-ring gate valves and penstocks carefully laid out to secure favorable approach conditions. Each Tiger Creek unit develops a maximum of 40,000 hp at 225 rpm under 1190 ft effective head, while each Big Creek 2A unit develops 68,000 hp at 250 rpm under 2350 ft effective head. The latter units are the largest-capacity impulse turbines installed in North America, and are exceeded throughout the world only by those in the Serra Plant in Brazil.[6]

Fig. 16 shows a comparison between the model and field tests of the Tiger Creek unit, using single-wheel tests. These characteristics are typical, although the stepup in efficiency between the model and the field units varies to a considerable extent with different designs. The model, which is usually tested under a moderate head in the laboratory, shows its best efficiency at a higher bucket loading than does the high-head field unit. The reason for this change in characteristics as yet has not been explained satisfactorily. Further information on this variation in characteristics, based on additional laboratory and field data, is being studied at the present time.

The systems of governing applied to impulse turbines may be divided into two general classifications, the first being those which are water-saving and the second being those discharging a constant water quantity regardless of load. The water-saving system is of course the most widely used and is best adapted to plants having forebay storage. However, many plants are located on streams where downstream water rights require an uninterrupted flow for irrigation or other use and in such cases the manually operated needle nozzle and the governor-operated jet deflector are preferable.

With water-saving controls, where the governor is connected directly to the power needle, it is necessary to accelerate and retard the water column in the pipe line slowly, in order to avoid objectionable pressure surge, which otherwise would interfere with the safety of the pipe line or with governing. Where this slow operation interferes with satisfactory speed and voltage regulation, it is customary to use a water-saving by-pass control such

[6] "Water Power in Brazil, With Special Reference to the São Paulo Development," by A. W. K. Billings, *Journal of the Institution of Civil Engineers*, vol. 3, 1935–1936 (Supplement, Oct., 1936), pp. 677–698.

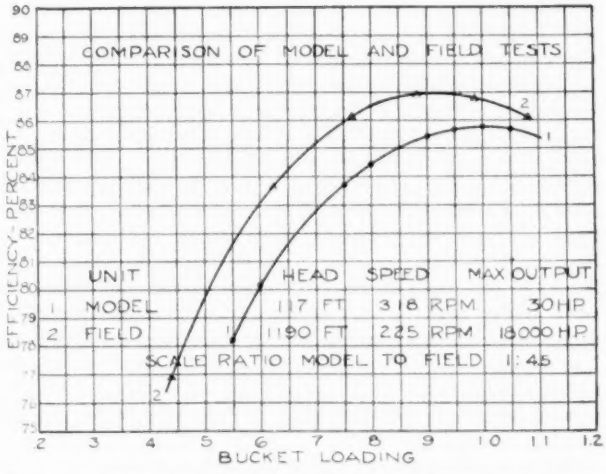

FIG. 16 COMPARISON OF MODEL AND SINGLE-WHEEL FIELD TESTS OF TIGER CREEK UNITS

as the auxiliary relief needle nozzle or a rapidly operated deflector and a slow-moving power needle. When the unit is connected to a large system and the natural stream flow must be maintained, and forebay storage is limited, a very satisfactory method of operation is to use a forebay float-control system, arranged to regulate the opening of the needle nozzle in such a manner as to maintain the forebay elevation within close limits. Governing plants, however, should have adequate forebay storage in order to average up the water supply and the required discharge through the unit.

In conclusion, it should be stated that while the impulse turbine has been developed to a high degree of perfection and reliability, nevertheless, further progress is being made, both in increased efficiency and in obtaining a longer useful working life.

Discussion

GEORGE H. BRAGG.[7] Probably no company has had more experience than the author's or has been more progressive in the development of hydraulic equipment for high-head hydroelectric systems, and so the writer ventures the statement that all the principal steps, by which the needle nozzle and the water-wheel bucket have advanced to reach their present state of efficiency and reliability, have been most ably presented in this paper.

On large interconnected hydroelectric systems, it is essential that some of the plants be designed to regulate the speed. It is not necessary for all of them to be capable of maintaining constant frequency. The needle nozzle, therefore, is indispensable in those plants which are designed to regulate the speed.

In certain plants of comparatively small horsepower rating and low head, needle nozzles are not absolutely necessary and we find in some of them the so-called open nozzle, which may be credited with a higher efficiency than the needle nozzle and a slightly lower cost.

The open nozzle would find a greater field of usefulness if equipped with some simple device designed to increase gradually its discharge from 0 to full jet, without creating disturbances and water hammer in the penstock.

It was suggested at one time that a combination nozzle might be devised which could be opened slowly and at the proper rate and, when completely open, the needle entirely withdrawn from influence to the water discharging at spouting velocity, thus forming a solid jet of maximum efficiency. Needless to say, there

[7] San Francisco, Calif.

are difficulties to overcome in designing such a nozzle, or probably there would be examples in operation today.

The effect of only a slight bend in the approach piping and also the effect of the needle in the center of the discharging jet may be observed in the graph of pressure-gage readings taken by a pitot tube in traversing a jet from the needle nozzle. Fig. 17 illustrates an actual nozzle body having a slight curvature for the needle-stem requirement and also the variation in the velocity head across the diameter of the jet, discharged by the nozzle.

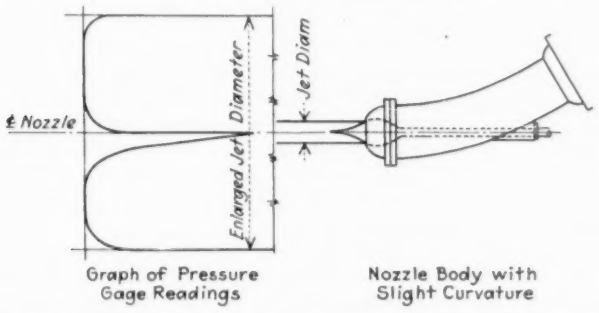

FIG. 17 GRAPH OF PRESSURE-GAGE READINGS TAKEN BY PITOT-TUBE TRAVERSE OF A JET FROM NOZZLE BODY WITH SLIGHT CURVATURE

Notice that the graph is not symmetrical about the center line of the jet and also that the needle causes a depression in the center of the jet, indicating that the power supplied by the jet is not uniformly symmetrical.

Thus far there has been no opportunity to traverse a jet from a straight-flow nozzle which is the latest development, but it is reasonable to suppose that the graph will be symmetrical about the center line of the jet but will have the characteristic depression in the center. The traverse of a solid jet, if uninfluenced by bends in the approach piping, is symmetrical and without the depression. Incidentally, the deformation of the jet has a marked influence on the rate of cavitation of the buckets regardless of the type.

The principal enemies of needle nozzles and water-wheel buckets are cavitation and erosion. Thus far no metal has been found which will resist these forces indefinitely. The hardest and highest-strength metals are the most resistant.

Although the water-wheel bucket, in plan, has been changed from a rectangular shape to the ellipsoidal shape as shown in Fig. 10 of the paper, cavitation has been found to be more rapid on some of the later designs than it is on some having the rectangular shape. There is a case, in which buckets of the rectangular type have been in continuous service for more than 40 years and yet there is little or no cavitation on the surfaces. They are made of ordinary cast steel. Perhaps the author may offer an explanation of this phenomenon.

W. A. DOBLE.[8] The development and operation of high-head hydroelectric generating units has changed merely in degree but not in kind during the last 30 to 40 years. Higher heads have been utilized, but heads of over 1000 ft were developed and placed in commercial use prior to 1897. The power output of the generating units has been increased by installing larger units, but this is also a change merely in degree. Details of design have been refined, based upon the operation of and the experience gained in regular commercial service with large-size units, under heads of 1000 ft or more.

Improved methods of governing or speed control of the units under variable load conditions have been perfected, but there again this work dates back to the years 1900–1913, to the introduction in commercial service of the needle regulating nozzle with manual or direct governor control of the needle, the use of the jet deflector, and/or the combination of the needle nozzle with the jet deflector, the needle being manually controlled, the jet deflector being controlled by the governor.

The author states: "In the early days of the industry loads were light and intermittent and it was often customary to shut a plant down over the week end."

The operating schedule of any hydroelectric public-service plant was the same in the early days as it is at present, depending upon two factors, i.e., the quantity of pressure water available at the plant to drive the water wheels and the load on the system or the power demanded from the generator units. It is the same today. So-called overloads are purely relative and bore the same relationship to the units in 1900 as in 1939. If proper factors were used in the design of the units, continuous service would result without fatigue or failure of elements. So-called overload is really meaningless, as all portions of the wheel unit were or should have been designed to carry successfully and continuously the maximum forces that could be applied. The useful life of the plant or measure of the hours of service was limited by the erosion of the active surfaces of the buckets, nozzle tip, needles, etc., depending upon the quantity and character of sand and grit carried by the water.

In those early days, reliable and continuous service was demanded by the consumer and, as requisite as it is today, the entire system must be kept continuously hot. Current had to be supplied over the week ends, as light and power were as necessary over Saturday, Sunday nights, and holidays as at any other time. The engineer, responsible for the design and successful operation of the system, developed the designs on the basis of apparatus incorporating the necessary factors of safety to insure equipment having the structural stability to develop the full power for which the units were designed and capable of giving continuous service. He could not rely on the units being subjected to intermittent service, with the idea that they could "rest up and recover" over the week ends.

The author's statement gives an incorrect impression because in the earlier days power stations that were built were generally not connected with others to form an interconnected system, but in fact served certain local areas with power. The subject of constancy of load and load factors was well known and it was necessary to maintain continuous service on practically every plant as then built; there could not be any shutdown on Saturday or Sunday.

A large portion of the load of these early plants included supplying current to drive irrigating pumps. During the irrigation season, such pumps must necessarily operate continuously, irrespective of Saturdays or Sundays.

Consider for instance the Mount Whitney power plant completed in June, 1899; this plant was primarily constructed and financed on the basis of furnishing electric current to the agriculturists for driving irrigating pumps. This plant was isolated and independent of any other plants, therefore, it was necessary to provide continuous service to the agriculturists.

As a matter of fact, the contrary situation prevails today where there are a large number of generating plants delivering energy into interconnected systems. In modern practice, it is possible to shift the load from one plant to another and in case of necessity any one of the hydroelectric units or the entire plant may be taken out of service, the load being carried by other plants of the system.

In those early days, the generator units in the large power houses in regular commercial service frequently carried maximum

[8] Doble & Doble, Patent Attorneys and Consulting Engineers, San Francisco, Calif. Mem. A.S.M.E.

full loads over long periods of time without fatigue or excessive stresses. It was absolutely necessary that these characteristics be incorporated in the design. The history of the earlier hydroelectric power plants with their records of many years of continuous service substantiates this statement.

The author also states: "In past years, in considering the requirements for high efficiency, no particular attention was given to the design or arrangement of the approach piping for delivering the power water from the penstock to the nozzle."

This is a serious and unjust charge against the many very able engineers who were responsible for the development, design, construction, and operation of these earlier hydroelectric power plants, and who also blazed the trail and developed the designs which are the basis on which the recent units referred to by the author are founded.

In the design and construction of such early power plants, the design of the pressure pipe line or penstock, including the arrangement of the approach piping or members through which the power water was delivered from the penstock to the nozzles, was most carefully worked out. It was fully appreciated that changes in the direction of flow should be avoided as much as possible and, where necessary, should be by means of curved or angle fittings providing for the least possible change in direction of flow of the power water, all abrupt changes in direction of flow being avoided. This was a fundamental requisite as the success of the project depended upon the development of the highest possible efficiency from the available water which as a rule was of relatively small volume but delivered to the wheels under a high head or pressure. A study of the layout of these earlier plants will demonstrate that these factors were most carefully considered and were provided for in the design and the layout of the plant, penstock, pressure pipe fittings, including careful consideration of the design of the pressure piping in order to insure a uniform and smooth acceleration of velocity of the power water and so designed as to avoid eddy currents, swirling, and loss of head or pressure.

Blue Lakes Water Company

In the power development[9] of the Blue Lakes Water Company, which was placed in commercial service August 25, 1897, under a static head of 1042 ft, the pressure pipe line or penstock was in plan laid on a straight line from the forebay to the steel Y branches or connecting pipe fittings at the powerhouse. The approach-pipe connections that delivered the power water from the penstock to the nozzles were steel castings designed to accelerate the power water and deliver it to the wheels with the least possible disturbance and eddy currents.

Mount Whitney Power Company

The power plant[10] of the Mount Whitney Power Company, completed in June, 1899, operates under 1300 ft static head. In this plant the penstock and special pipe-connecting members, through which the power water was delivered from the penstock to the nozzles, were most carefully designed to avoid abrupt changes in direction of flow and to provide smooth acceleration of the power water, avoiding eddy actions, disturbances, and friction losses.

The gate valves in this plant, which are of the rotatable-plug type, were incorporated in the design and construction of the nozzle body. The cylindrical plug is parallel, the water passageway through the plug was bored on a taper and registered accurately with the passageway through the nozzle body, providing continuous smooth water passageway. The valves were constructed so that the rotatable plug was lubricated and packed with a pressure grease seal.

In this plant radial antiswirling and turbulence vanes were installed in the nozzle and tips to straighten the flow of the water and improve the character of the jet. It developed, however, that regardless of how keen the entrance edges of the radial antiswirling and turbulence vanes were sharpened and, although the head of water at the nozzles exceeded 1000 ft, at times, when the power water carried fine grasses and pine needles, such grasses and needles would accumulate and build up on the radial vanes and thereby plug the nozzles. A further disadvantage was that the radial swirling vanes, being positioned in the flowing water at the point of its highest velocity, substantially increased the wetted-surface area, thereby increasing the friction loss, which more than offset any possible gain due to the improved character of the jet.

The nozzles, plug valves, and radial swirling vanes in this plant were of patented construction.[11]

In this plant, although the character of the jet was improved by the addition of these antiswirling vanes in the tip, and discharged a jet of excellent characteristics, it did not equal the character of the jet from a needle nozzle which projects a parallel jet of water with substantially constant cross-sectional velocity free from eddy action and swirling. The needle nozzle, also presenting the minimum area of wetted surface to the jet, gives a jet of higher power value than when the tip is provided with antiswirling vanes which increase the area of the wetted surface and the friction losses.

In the construction of the Mount Whitney plant, a pipe fitting was installed at the lower end of the pressure pipe line. An exact duplicate of the gate valve, nozzle, and tip was installed at this point, the purpose being to provide an opportunity for testing the character of jet discharged from the tips under this high head.

The De Sabla Power Plant of the Pacific Gas & Electric Company

The De Sabla Plant of the Pacific Gas & Electric Company was constructed by the Valley Counties Power Company. The original installation,[12] including units Nos. 1 and 2 of 2000 kw each at 240 rpm, operating under a static head of 1531 ft, was placed in service October 22, 1903. The gate valves in these two units are of the parallel transverse sliding plug or piston type.

The water passageway through the valve plug was bored to register accurately with the bore through the valve body, forming a uniform smooth water passageway through the over-all length of the valve. The branch Y fitting connecting the end of the penstock with the valves was very carefully designed to avoid eddy action and swirling losses and to insure smooth acceleration of flow of the power water.

For many months after units Nos. 1 and 2 went into commercial service, each unit carried a continuous load of approximately 2200 kw. The original buckets on units Nos. 1 and 2 are still in service, however, these units have not run more than about one quarter of the time during recent years.

In 1904, unit No. 3 was installed including a 4000-kw generator at 400 rpm. This generator was very liberally rated. It has been in service almost continuously since it was installed carrying a load of 5000 kw, during which time worn wheel buckets have been replaced.

The San Francisquito Plant No. 1

The San Francisquito plant No. 1 of the Bureau of Power & Light of Los Angeles was designed to develop the highest possible efficiency from the water available at the plant. The design of the elements carrying the power water to the wheels was most carefully considered to avoid friction losses and losses due to eddy currents and swirling in the power water. The main cutoff gate, bolted to the inlet flange of each nozzle, was of the needle type and was designed to avoid unfavorable acceleration, eddy currents, and friction losses in the power water. These needle gates were of patented construction.[13] The plant was installed about 1912 or 1913.

In view of these and many other early hydroelectric plants, it is established that the engineers in past years, considering the requirements for high efficiency, gave very careful study to the design and arrangement of the approach piping which delivered the power water from the penstock to the nozzles, so as to secure the highest possible unit efficiency, by avoiding the losses due to the effect on the jet of turbulence or crossflow and eddies in the nozzles, gate valve, and connecting piping, leading from the penstock to the water-wheel unit.

C. V. Foulds.[14] The author has given an interesting picture of the benefits to users of the routine research that has come to be practiced generally by forward-looking industries for the improvement of their products, and without which they would inevitably drop behind in the procession of progress.

The user necessarily has a double interest in such work, first as the recipient of its benefits, and second, as the one who must pay the bill. He must resign himself to the fact that, though the individual parts of a perfected machine may cost no more to produce than those of earlier models, a higher price must be paid for them to cover the indirect costs of their development. The costs of precision research are very high even for apparently simple factors; where there is sufficient quantity of production there may occur parallel improvements in manufacturing to return the research costs without price advances. However, for power-plant and similar special machinery, the manufacturing costs change but little and research can only be repaid by price increases, a single lot at times bearing a good part of the costs for its development. That the result usually justifies the charge is evidenced by the practice of many enlightened large users to encourage research by bonus, outright grant, or purchase of a model for test purposes, all with a view to removing development from the competitive business of machinery production, that would otherwise penalize the manufacturer who had done most to improve his product.

At first glance, it might seem that such intensive and detailed research would relieve the user of the necessity for initiative and careful selection in the purchase of his equipment. That it does not is because research is largely functional in character, while the user's interest is in both the functional performance and the mechanical details, as related to the period for which maximum performance will continue, the simplicity of its restoration, and freedom from petty annoyances. There are also to be considered such individual elements as transportation and evaluation of the penalties of shutdowns, compared to the costs of reducing them.

Thus, while research has assured the user of apparatus that will perform as specified and relieved him of attempting detailed specifications for the major dimensions and materials to be used, the element of competition requires that he be very specific in regard to general arrangements, replaceable wearing parts, corrosion- and wear-resistant materials, conveniences for assembly and dismantling, etc., in order that bids may be submitted on a uniform basis, as it is in those elements that the greatest variations may occur in functionally equal machines. Thus the practical specification may properly become little more than a description of the conditions to be met and the degree of refinement desired in a machine whose performance has been assured more effectively by research than anything the user might specify.

Research is a true partnership between supplier and user, of equal benefit to both, and to which every encouragement should be given.

J. D. Galloway.[15] From the context of this paper, it is evident that a close study is being made to increase the efficiency of the impulse turbine.

The use of straightening vanes to decrease the turbulence in the water as it emerges to form the jet is a new device, the value of which may be open to question. A correction in the form of the jet is obtained by the straightening vanes in some of the cases cited, but it would seem that the vanes would offer some resistance to the flow of the water and thereby act to reduce the efficiency of the unit. It would also seem likely that considerable wear would occur in such vanes, impairing their ability to form a perfect jet. However, as a means of correcting some old-time installations, where the water passages are incorrectly designed, the straightening vanes might prove to be a good device, even if occasional renewals were necessary. Experience over a term of years with the device would furnish the best evidence for or against its value. Curve four, Fig. 5, indicates that with properly designed water passages the vanes are unnecessary.

Some stress is laid by the author upon the improvement of the jet illustrated in Figs. 1 and 4. It might be questioned as to how much additional improvement in this direction is necessary, mainly for the reason that the needle is placed as close as possible to the wheel buckets and the jet is not of great length before it strikes the lip of the incoming bucket. That distance is at least only a fraction of the length of jet shown in the illustrations.

It would seem to the writer that the greatest advance has been made in the form of buckets, the results of which are indicated in Fig. 12. The recent type there shown has an efficiency of more than 1 per cent above that of the older type, which is a material gain. The efficiency curve is also much flatter at the upper portion, demonstrating that the higher efficiency holds over a wider range.

The author's remarks regarding the value of collaboration between the engineers of the power plant and the turbine designer, in order to produce the best design of the water passages, is well taken. To illustrate this point, some examples may be cited. One old-time power plant has several pipe lines leading into a manifold placed at right angles to the pipe lines. From the manifold several units are served, and none of the water passages to the nozzles takes off from the manifold opposite the pipe lines. As the units are of different capacity, one may wonder what is happening to the water in that manifold. However, it was recognized some time ago that a direct flow of the water from penstock to nozzle is necessary, and with increasing size of the power units, one penstock to each unit would be the proper design. A Y is required and also a gate valve back of each nozzle. The physical situation has an important bearing on the design of the water passages. Some plants, as at Tiger Creek, are so located that there is ample space in which to lay the penstocks in a desirable manner. On the other hand, at Bucks Plant, the situation was such that the power station was located close to a granite cliff,

[13] U. S. Letters Patent, No. 1,290,722; January 7, 1919; application filed December 27, 1913.

[15] Consulting Engineer, San Francisco, Calif.

where the horizontal dimensions were very limited. However, in all cases, collaboration between the plant engineer and the turbine designer is advisable in order to produce the best results.

High efficiency of turbine units is of value, even in a plant serving a single system. In such a plant, with several units, load changes resulting in part loads would be carried by one unit, the others being operated at or near full load. In a system of several plants, in different locations, governing is done at one plant, the others operating at full load, at least on the units in service.

The improvement that has taken place in the design and construction of impulse turbines has been well indicated by the author, who has summarized in a clear manner the recent progress and the manner in which it has been achieved.

J. P. JOLLYMAN.[16] Our experience with impulse turbines, having a wide range of heads and horsepowers, tends to confirm the author's conclusions.

The first wheels constructed for heads above 1000 ft were from 1500 to 3000 hp with wheel-to-jet diam ratios 45 to 33. Forces on the buckets were small and little trouble was experienced with bucket attachments or with bucket cracking. The need for larger units and the availability of higher-speed generators soon led to 7000-hp units with wheel-to-jet ratios as low as 10. Trouble with bucket attachments soon developed on account of the greatly increased stresses on the bucket bolts. Wheel-jet ratios have since been increased to 12 or more and the design of bucket attachments has progressed to the point where no trouble is had or expected with attachments. The hydraulic design of buckets is a problem in the relative motion of the buckets and the water. The problem cannot be solved by theoretical consideration alone, since it is impossible to predict the exact path of each particle of water after it enters the bucket. The experimental research described by the author has been of great value in assisting the hydraulic design.

The need for and the economy of large units has increased the size and loading of buckets to the point where fatigue cracking of buckets has been encountered. The hydraulic and mechanical requirements conflict at the entering lip. Hydraulically thin sections with sharp edges are desirable, whereas the necessary mechanical strength requires thicker sections and rounded edges. We are hopeful that the latest designs will largely overcome this difficulty.

The path of water in curved channels at high velocities is different from its path at low velocities, and this is recognized in Francis-turbine design. This difference may account for the change in characteristics from the model impulse turbine at low heads to the field unit at high heads.

The excellent efficiencies obtained at Tiger Creek confirm the advantages of the features of design mentioned in the paper. All of these features are included at Tiger Creek except the 90-deg needle nozzle which had not been developed at that time.

S. LOGAN KERR.[17] Two important factors affecting the performance of impulse turbines are brought forth by the author: First, the effect of turbulence in water passages leading to the nozzle and, second, the correlation between laboratory and field tests. While these two factors seem dimly related, they are, in the writer's opinion, one and the same.

Some 8 or 9 years ago, when the writer was closely associated with the inception of the research program which the author describes, the writer felt that the approach conditions in the conduits leading to the needle nozzle were left too much to the symmetrical eye of the draftsman and were given too little attention by the engineer. The transition from a single penstock to a divided conduit, thence to further divisions, all at high velocity, leading to the individual jets of a double-overhung wheel, could result only in turbulence in the free-discharging jets, causing them to reach the buckets in a manner far removed from the neat circle shown in the textbooks. One only needs to examine Fig. 1 of the paper to be convinced that the transfer of energy from the lower jet to the wheel buckets can hardly be efficient.

Coupled with this matter of turbulence is the exaggerated effect of small distortions in the needle-nozzle body when the flow is at high velocity. Each bump, crack, or minor roughness tends to distort the flow from the ideal pattern.

With reaction and propeller turbines, the relation between the model-test results and the field performance has been established so well that the Moody formula may be applied with reasonable accuracy for predicting performance of the full-sized units with assurance, so long as the conditions are held homologous with respect to flow and cavitation conditions. The agreement between true laboratory results, stepped up to full-scale units, and field performance is amazing and usually falls within the accuracy of test methods employed.

Unfortunately this same agreement is not true of impulse turbines and, as the author states: "The reason for this change in characteristics as yet has not been fully explained." Could not this be the basis for additional research? In the writer's opinion, more attention should be paid to the effect of absolute velocities on performance as compared with test velocities proportional to the square root of the head or determined from the geometric stepdown of the dimensions of the full-scale unit.

Consideration of the effect of high-velocity flow in the water passages immediately in advance of the orifice should be considered. These are the flow conditions that affect the jet directly, and approach conditions to an orifice should receive as much consideration as the approach conditions to a weir. Small disturbances at low velocity can change the flow pattern over a weir and cause marked changes in its accuracy. Is not the problem made much more acute when dealing with the discharge from needle nozzles with a usual velocity ten times or more that of the approach velocity to a weir?

Early in the research program described, the writer was able to correlate the field characteristics with laboratory tests by the introduction of artificial turbulence in the approach conduit; the point of uncertainty being only the required degree of turbulence.

Tests on a model unit under a range of heads from laboratory conditions up to field conditions should indicate the change in performance due to changes in absolute velocities. Such tests might pave the way for further improvement on large-scale units and supply a reliable basis for comparing laboratory and field test results.

E. F. MARYATT.[18] The author's comments regarding forces applied to the modern water-wheel bucket, in which he uses as an illustration the 25,000-hp wheel, each bucket of which is, in 10 years' time, subjected to 2,000,000,000 working cycles with an impulse of 50,000 lb applied to each cycle, very effectively bring to our attention, the magnitude of the problem. The question might logically arise: Why use such large-sized units? Why not buy more smaller units of the same total output and, by so doing, eliminate some of the tremendous fatigue problems. The answer is, of course perfectly obvious. The increasing size of our systems

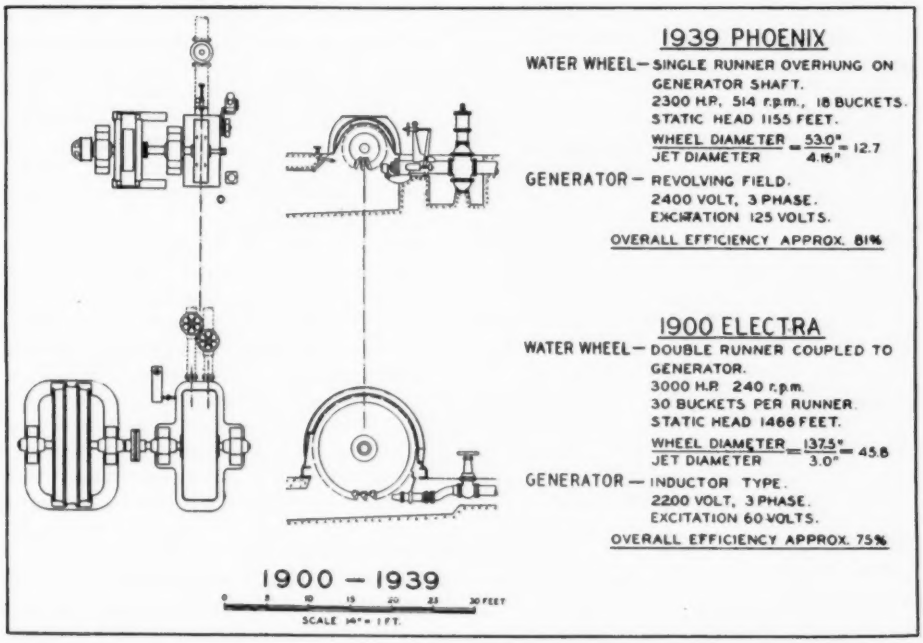

FIG. 18 PHOENIX 2000-KVA POWER UNIT AS COMPARED WITH OLD ELECTRA UNIT OF SAME OUTPUT RATING

with the accompanying increased length and voltage of our transmission lines requires these larger units.

If we build a powerhouse at the remote end of a 200-mile 220,000-v transmission line such as, for instance, the Pit lines of the P.G.& E. Co., each unit in the plant must be capable of supplying sufficient power to charge the line. In the case of the Pit lines, this amounts to approximately 50,000 kva. The Tiger Creek lines require approximately half of that amount, or 25,000 kva. Therefore, a double-overhung unit with two wheels, each of which is of the size of the one used in the author's illustration, would hardly be of sufficient capacity to charge the line if located at a site similar to Pit No. 1, for instance. Two units operating with generators in parallel are, of course, unstable for use in charging a 220,000-volt unloaded line.

The question might also be asked: Why not put a whole row of wheels on one shaft? The author may be forced to resort to some such scheme someday if the size of the required units continues to increase. In the very early stage of water-wheel development, this scheme was resorted to, but for one reason or another has grown out of general use. The most striking illustration of multiple wheels on a single shaft, which has come to the writer's attention, was at Snoqualmie Falls, Wash., where he was in 1910 on the construction of plant No. 2. Plant No. 1 had been built and placed in service in 1899. In plant No. 1 four units were installed, each consisting of a 1500-kw, 300-rpm generator driven by a so-called Doble water motor. The water motor consisted of six impulse wheels, side by side on a single shaft, each equipped with two nozzles and they were grouped with three wheels in one housing. In this unit there was a total of 12 jets, six wheels all on one side of the generator, and the rating was only 2500 hp. Those units violated many of the fundamentals of hydraulic design which the author has pointed out, and more. The head, being under 300 ft, was far more suitable for a Francis turbine. This was soon discovered, and 11 years after the original installation the impulse wheels had already been partly superseded by a horizontal single-discharge Francis turbine.

About 1 year after the Snoqualmie No. 1 plant was placed in operation, the Electra plant (now of the Pacific Gas and Electric Company), was built. In this plant the units were rated 3000 hp 240 rpm. Here the static head of 1466 ft was more suitable for impulse wheels. The Electra units consisted of a 2000-kva generator, driven by twin impulse wheels with one nozzle each. The two wheels were located side by side and in the same housing. The generators were the Stanley inductor-type, rated at 2000 kw.

At the Phoenix powerhouse, a new unit of the same output rating as the old Electra unit (2000 kva) is now being installed. Since the output ratings are identical and the hydraulic features are somewhat similar, the two installations make a very interesting comparison between the unit built in 1900 and the unit built in 1939.

Fig. 18 shows the two units to the same scale. The Phoenix unit has embodied within its design the latest known fundamentals mentioned in the paper, even to the inclusion of the 90-deg nozzle. From the drawing may be noted the straight-line approach of the needle in the Phoenix unit, while the Electra-unit needle approach includes a definite offset. However, the most striking contrast appears in the relative sizes of the two units. Attention should be called to the fact that the Phoenix unit has a direct-connected exciter on the end of the main shaft. Also space was provided for end shift of the generator stator. If it were not for these two items, the Phoenix unit would appear even smaller in the comparison.

We know that for the same unit, the speed should vary with the square root of the head. It is interesting to note that Electra, with 1466 ft static head, runs at 240 rpm, while the Phoenix unit, with 1155 ft static head, is now designed for 514 rpm. Very striking, also, is the comparison of the wheel-to-jet diam ratio, which for Electra is 45.8 and for Phoenix is 12.7. If the Electra unit had been designed with the same wheel-to-jet diam ratio as Phoenix, the Electra speed would have been increased to a theoretical speed of 830 rpm. The nearest synchronous speed is 900 rpm, which is almost 4 times the original speed.

J. D. SCOVILLE.[19] The author's discussion and illustration of the impulse-wheel jet indicate graphically the importance of proper design of the nozzle and the necessity for the introduction of straightening vanes to prevent spreading of the jet before it

[19] Assistant Chief Engineer, S. Morgan Smith Company, York, Pa.

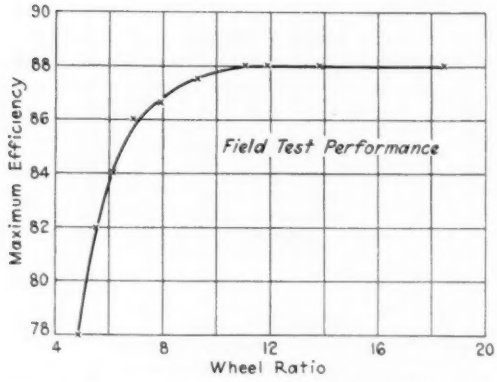

FIG. 19 CHARACTERISTIC CURVE FOR IMPULSE-WHEEL BUCKET

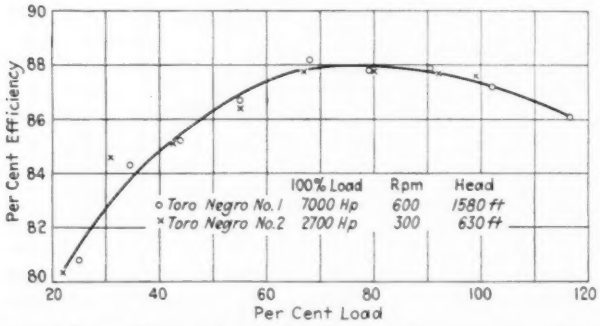

FIG. 20 FIELD TESTS OF SINGLE-JET IMPULSE WHEELS; PUERTO RICO RECONSTRUCTION ADMINISTRATION

reaches the runner. Proper design of elbows and approach passages is also required to get an efficient jet. The author illustrates various shapes of buckets and discusses briefly the importance of design on efficiency and cavitation. We think he does not dwell enough on one point which has a bearing upon efficiency, namely, the number of buckets. It is obvious that a runner with too few buckets will allow part of the water to pass without doing any work. It is also true that if too many are used, it becomes increasingly difficult to design the shape so that part of the water does not strike the back of adjacent buckets and so reduce the efficiency. Bolted construction limits the number of buckets on account of mechanical stresses. The use of solid-cast runners and very careful design of the shape permits the maximum number to be used and the maximum efficiency. This is especially important with wheel ratios below 8 on high-specific-speed runners. Fig. 19 shows maximum wheel efficiency plotted against wheel ratio. This represents tests of runners with more buckets than those of Fig. 13 in the paper.

Fig. 20 shows field tests of single-jet impulse wheels for the Toro Negro Plants in Puerto Rico. These are tests made on two different units of about the same specific speed in two plants of the Puerto Rico Reconstruction Administration. The runners of these units also have more buckets than shown in Fig. 13.

AUTHOR'S CLOSURE

The writer is indeed grateful for the many excellent ideas advanced in the discussions.

Mr. Bragg has pointed out the desirability of some form of adjustable plain nozzle which would eliminate the losses due to the needle bulb of the needle nozzle. Many tests have been conducted in the laboratory investigating the possibilities of such a nozzle but, on account of the many practical difficulties in handling the heavy loads, leakage, etc., no satisfactory design has as yet been evolved.

In Fig. 17, Mr. Bragg clearly shows the lack of symmetry of a power jet, resulting from the disturbance in the nozzle body. This disturbance becomes more acute as the relative radius of curvature is reduced, or as the elbow is made more abrupt, and is further accentuated as the velocity of approach is increased. The presence of such elbow losses has been appreciated for many years and it is now customary, for example, in the design of penstocks, to favor elbows of large radius rather than those having abrupt turns.

The problems of bucket and needle-nozzle cavitation and erosion have been studied very carefully both in models in the laboratory and in the large units in the field. Important progress is being made in correcting these difficulties both by changes in the design and in the use of tougher modern materials. The exceptionally long life of buckets found in the case of a few old units has been given a great deal of study. In all probability there was an unusually favorable combination of water, moderate loading, and homogeneous materials which accounted for the excellent performance. The efficiency of these units, however, has not been of the best and does not compare with current practice.

Mr. W. A. Doble is to be thanked for his excellent review of the early history of high-head impulse-turbine design. He has pointed out a number of interesting problems and the manner in which they were studied and solved at that time.

The practical problems of cooperation between manufacturers and users of hydraulic-power machinery has been very ably presented by Mr. Foulds. The hydraulic turbine is a custom-built or tailor-made machine designed for the particular hydraulic conditions of each installation. Consequently, model studies are of great value in verifying the results of the complicated calculations and analyses. Further cooperation covering the production and financing of model studies is to be encouraged and will do much to promote further improvements in the art of hydraulic-turbine design.

The review of past and current practice in the design of approach piping and penstock manifolds, presented by Mr. Galloway, shows the important progress made in recent years in a better understanding of the hydraulic problems involved. For example, the old practice of using a large manifold outside of the powerhouse, acting as a header from which a number of right-angle lines serve the individual units in the station, has been discontinued.

Mr. Jollyman has pointed out a difficulty confronting the designer in providing a water-wheel bucket having both high efficiency and low stresses or a long working life. Laboratory and field results demonstrate the advantages of a sharp splitter and entering lip for high efficiency. Sharp edges of this type may be nicked or damaged readily by debris in the water, thus introducing regions of local stress concentration which start further cracks and corrosion fatigue. When the entering lip of the bucket is made thicker and heavier in order to strengthen this part of the bucket against local stress concentration, the problems of entering the bucket into the power jet without turbulence and interference are greatly increased. Bucket design, therefore, must be a compromise between strength and efficiency. The trend of recent research has been to develop revised forms of bucket lips of high strength and acceptable efficiency.

Mr. Kerr suggests a more careful consideration of absolute velocities in studying the performance of model impulse turbines. Further information on the performance of a given unit when tested under a wide range in heads should throw more light on this problem. The reaction turbine and the centrifugal pump may be tested conveniently over a comparatively wide range in heads, since these two types of hydraulic machines are totally enclosed so that the flow is restricted into very definite channels and may be tested under heads varying from a few feet to 200

to 300 ft without much difficulty. However, the impulse turbine to be tested over its normal working range should be tested under heads of say from 200 to 2000 ft, which is beyond the facilities of most laboratories. These factors are fully appreciated and every opportunity will be used to explore further the influence of head.

Fig. 18, submitted by Mr. Maryatt, shows the trend of modern impulse-turbine design. A wheel ratio of about 12 is still the minimum which is most favorable for high efficiency. This is again confirmed, in Fig. 19, by Mr. Scoville. Smaller wheels with lower ratios may reduce the first cost of both the hydraulic turbine and the generator but usually are not the most economical when the entire water supply is to be converted into useful power.

In the early days of the industry, the large ratios resulted from the generator design, primarily, as it was fully appreciated even then that a ratio of 12 was advantageous.

Determining the most favorable number of buckets, consistent with high efficiency, good performance, and working life, involves problems of mechanical and hydraulic design. Laboratory testing, as carried out by the company with which the author is associated, incorporates the use of wheel centers and buckets, permitting complete flexibility in order to determine the most favorable number of buckets, lead, speed, jet position, and other such factors. The number of buckets used in the cases set forth in the paper is that producing the most favorable combination. Mr. Scoville points out that the tests with which he is familiar used a greater number of buckets. This point is fully appreciated as it has been found that the most favorable combination depends upon the bucket design, so it is to be expected that the appropriate number will change with the type.

The use of water-wheel buckets integrally cast with the wheel center is a practice of long standing and is well known to the art. Such buckets however are not satisfactory for laboratory tests as they do not permit of adjustments necessary to establish the most favorable assembly.

The efficiencies, noted in Fig. 20 of Mr. Scoville's discussion, are excellent and it is hoped that an opportunity will develop to obtain more complete details of the research which he has mentioned so that a further comparison may be made with the facts presented in the author's paper.

Joint Use of Diesel Engines and Utility Power

By EDGAR J. KATES,[1] NEW YORK, N. Y.

This paper shows that there are various ways in which a consumer of electric power may advantageously use both Diesel engines and public-utility service.

A brief review is first given of the different uses that steam and hydroelectric public utilities have themselves made of Diesel-engine power on their own systems.

The ways in which private power consumers have used Diesel engines and outside utility service jointly are discussed under the following classifications:

(*a*) Utility service as a stand-by for Diesel power; (*b*) Diesel power as stand-by for utility service; (*c*) Diesels to restrict the maximum demand on utility service; (*d*) utility service to check Diesel frequency and synchronous time; (*e*) utility service as auxiliary to Diesel power; (*f*) utility service to carry momentary load swings.

Data are given on the diversity factor of the use of utility breakdown service by a group of private power plants. The factor exceeds 10/1. The author proposes a new form of rate for breakdown and auxiliary service which he considers more equitable to all concerned than the usual forms of rate for such service.

The advantages to the power user of operating his Diesel plant electrically paralleled with the utility service are cited. The author discusses in detail the technical factors involved in parallel operation with which the power company is concerned. He concludes that if simple precautions are taken no difficulties should occur either on the utility system or in the Diesel plant. Actual experience confirms this, and such parallel operation is increasing.

Greater cooperation between private-plant owners and public-utility companies in facilitating the joint use of Diesel engines and utility service will benefit both parties.

THE ENGINEERING of steam power joined with public-utility service has been thoroughly expounded by several authors (1, 2, 3, 4, 5, 6, 7).[2] Also the use of Diesel engines in conjunction with steam engines in order to effect a balance between power loads and heating loads has been covered in a paper before this Society (9). The excuse for the present paper is that little has been said about the use of private Diesel power combined with public-utility service. While the paper has been written primarily from the viewpoint of the power user, an attempt has been made to consider the utility's aspect also.

Public-Utility Uses of Diesel Engines

Of course Diesel engines have long been used by public utilities themselves. Not only are there thousands of Diesel engines in the United States generating the entire output of public utilities (under corporate ownership as well as municipal), but Diesels have also been installed by the utilities to run in conjunction with their own steam or hydro power. Since these public-utility uses of Diesel engines combined with other sources of power are similar in some respects to the private applications to be discussed, they are here briefly reviewed:

(*a*) Diesel engines to carry peak loads in steam central stations. Here the primary object is to avoid the stand-by losses of banked boilers and idling turbines. This application has been mainly confined to Europe. There, several huge Diesel engines have been installed, such as the two 11,700-hp engines at Hennegsdorf near Berlin, Germany, the 15,000-hp engine at Hamburg, Germany, and the 22,500-hp engine at Copenhagen, Denmark (10, 11, 12, 13, 14, 15, 16).

(*b*) Diesels have been proposed for emergency "house power" in steam central stations. When a flood or hurricane completely shuts down a station and destroys its interconnections, the plant can be more quickly restored to service if a moderate amount of power is available at once to supply the station lighting, run the auxiliaries, provide initial excitation, operate the switchgear, and the like.

(*c*) Diesels for stand-by use on hydroelectric systems. The Diesels serve at times of low water and also for emergency reserve. They are particularly applicable in locations where the water flow is so irregular that the banking losses in a steam stand-by station would be excessive. The rapidity with which the Diesel plant will take over the load is an important feature. In factory tests on one of the three 3750-hp units installed in 1927 at Miraflores Locks, Panama Canal Zone, the unit took over its full load in 32 sec after being started cold (10, 11, 12, 13). This application of Diesels for hydroelectric stand-by is common; one manufacturer alone has installed ten such plants. A recent example is that of the Salt River Valley Water Users' Association at Phoenix, Arizona, where two 7000-hp Diesel stand-by units were installed last year to operate in conjunction with an eight-plant hydroelectric system.

(*d*) Diesels to carry the load of an isolated locality until the electrical demand becomes large enough to justify extension of a transmission line. During the period of utility expansion between 1915 and 1930, a number of such installations were made in the Southwest, where growing utility systems would acquire a small inefficient steam plant in outlying territory, and by serving the area at low rates by means of a Diesel plant would eventually build up enough load to warrant the investment in a high-tension transmission line from a large steam station. In fact, in some cases, such as at Paris, Tyler, and Brownwood, Texas, Diesel stations originally installed with the intention of subsequently removing them to other locations were found so to improve the operating conditions near the ends of the transmission lines that they were kept in use in their original locations for more than ten years (10, 15, 17).

(*e*) Diesels located at distant points on transmission lines to reduce peak loads in the main generating stations and on the transmission lines, reduce transmission losses, improve voltage regulation, increase power factor, and provide local service in case of transmission-line outage or main-station trouble. Diesel plants, designed to serve some or all of these purposes, long ago proved their value, and the practice, which became common in the Southwest some ten years ago, subsequently spread to other

sections such as Florida, Iowa, and Minnesota. In the latter region, the Otter Tail Power Company is operating a system comprising 36,000 hp in steam, 7000 hp in hydro, and 6000 hp in Diesel units (15, 17, 18).

Private Use of Diesel Engines With Public-Utility Service

The foregoing indicates the various uses that steam and hydroelectric utility systems have themselves made of Diesel-engine power within their own stations or out on their lines. Private power consumers, also, have already discovered ways of profitably using both Diesel engines and outside utility service in the same plant, and new uses are continually developing. The following types of applications will be discussed:

(*a*) Utility service as a stand-by for Diesel power.
(*b*) Diesel power as stand-by for utility service.
(*c*) Diesels to restrict the maximum demand on utility service
(*d*) Utility service to check Diesel frequency and synchronous time.
(*e*) Utility service as auxiliary to Diesel power.
(*f*) Utility service to carry momentary load swings.

In some of these applications it will be evident that when the private-plant owner purchases public-utility service for joint use, he obtains a large benefit while the utility company merely sells current at standard rates. The question may therefore arise as to whether the utility company should not be entitled to charge higher rates for such service. The answer is explicit in the fundamental theory under which public utilities are constituted, i.e., that public utilities are "affected with a public interest," and in return for the exclusive privileges granted them, they are charged with the responsibility of furnishing the best possible service to *all* consumers at a price commensurate only with its actual cost. The fact that private-plant owners generate power for their own use which they might have bought from a public utility is no reason, under our basic law, why this group of consumers should be expected to pay the utility company a greater profit on the current sold them than on the current sold to any other group of consumers.

(*a*) *Utility Service as Stand-By for Diesel Power*

This application, which is the oldest of all, was the natural result of the occasional breakdowns of early Diesel engines during their development stage. Of course, most power users want power available continuously, but actually the need for unfailing service varies widely, from the gravel plant which can be shut down at any time with practically no economic loss, to the lighting and elevator services in places of public assembly such as department stores.

The practice of using utility service in this manner, which is generally known as "breakdown service," varies with the circumstances, but it is probably safe to say that the proportion of Diesel plants using it is steadily decreasing. One reason is that the records of modern Diesel plants show them to have high reliability. An analysis made by M. J. Reed of the A.S.M.E. Oil Engine Power Cost Reports for 1929 to 1935, inclusive, covering over four million engine-operating hours, showed that the enforced shutdowns aggregated only 0.8 per cent of the operating time. Another reason for the lessened use of utility stand-by service is the rather surprising fact that the price for this type of service has been greatly increased in some important areas. In these areas, reserve Diesel units are now generally found to be cheaper than the stand-by charges for utility service.

Different power companies have quite different policies as to the desirability of breakdown-service customers, possibly because there is a lack of precise data on the service characteristics of this group of consumers. Little information is available even on so important a factor as the diversity of the demands of a large group of users of breakdown service. Some interesting facts about this diversity were revealed in testimony presented before the New York Public Service Commission in 1936; this showed, for a one-year period, the date, hour, duration, and the electric load for each time utility breakdown service used by 118 private power plants of all kinds, steam and Diesel, industrial and commercial (19). The greatest coincident demand at any time (which happened to be in May) was only 9.7 per cent of the total breakdown service for which the group had contracted, and the actual coincident demand in December, the month of the utility-system peak, was only 2 per cent of the total power contracted for. In other words, the diversity factor, based on the total contracted demand, always exceeded 10/1.

If this had been a group of Diesel plants only, it is probable that the diversity factor would have been even greater, in view of the fact previously cited that the average Diesel plant is out of service because of enforced shutdowns less than one per cent of the time.

Utility rate schedules for so-called breakdown service are generally faulty in form, because they do not give separate consideration to the two distinct ways in which this service may be used by the private plant: First, stand-by service, used only in case of an enforced shutdown of the private plant, which may not occur for months or years, and second, auxiliary service used voluntarily.

One common form of rate is a minimum dollar charge, based on the amount of stand-by protection contracted for, which also covers the use of energy at the regular firm-service rates without additional cost up to the minimum charge. Such a form of rate is unfair to the utility company if the customer uses auxiliary service up to or beyond the minimum charge, as in that case the utility is providing him with stand-by protection free of charge.

The other common form of rate is a minimum demand charge, in which the standard firm-service demand charge per kilowatt is applied, not to the kilowatts actually used, but to the kilowatts contracted for. If any energy is used, either for breakdown or auxiliary service, it is charged for at an additional rate. This form of rate is unfair to the customer who wants stand-by protection only, but who rarely if ever uses any auxiliary service. Such a customer pays a price for stand-by protection which is greatly in excess of its cost to the utility because of the high diversity factor of breakdown service by itself.

In the author's opinion, a form of rate for breakdown and auxiliary service which would be equitable to both parties should recognize the distinction between these two kinds of service and should consist of, first, a charge for stand-by protection and, second, a charge for actual use. The first would be a monthly charge merely for the privilege of using current if desired (but not for the current itself). It would be a fixed sum based on the amount of stand-by service contracted for, and the charge per contracted kilowatt would be arrived at upon an actuarial basis founded upon the diversity of breakdown use as shown by past experience. Assuming a diversity factor of 10/1, as previously cited, and allowing for bookkeeping and other costs, the stand-by charge might properly be, say, $0.50 per kilowatt of stand-by protection contracted for. It should be noted that this is not a demand charge, because it is the charge paid only when there is no demand.

The second part of the suggested rate would be a charge for actual use in any month, whether the use were for breakdown service or auxiliary purposes. This part of the rate could be the usual demand and energy charges in effect for general consumers, and would be applied to the actual demand and energy consumption recorded by meter for the month. If no current were

used during a month, only the stand-by charge would be paid.

Under such a form of rate each customer would pay a fair price for the particular kind of service he used, without requiring any differentiating in the metering itself. In other words, standard metering equipment could be used.

The author believes that if rates for utility service to the private plant were of this form, the use of such service would increase considerably, with profit to all concerned.

(*b*) *Diesel Power as Stand-By for Utility Service*

This application, which is the reverse of the one just discussed, is a more recent development. Its origin and growth is a tribute to the reliability, compactness, and low cost of the modern Diesel engine, and its use has been accelerated by the 15 or more unfortunate but extensive outages of utility service that have occurred since January, 1936, in important urban areas like New York, Pittsburgh, and Buffalo. These outages have caused the managements of hospitals, schools, theaters, department stores, office buildings, apartment houses, hotels, telephone companies, and airports to become concerned with the problem of providing stand-by protection for their utility service. In fact, laws are already in force, e.g., the Fire and Panic Act of Pennsylvania (20), compelling the installation of emergency lighting systems in many classes of buildings.

Among the Diesel plants acting as stand-by for utility power may be mentioned the 200-hp unit installed in 1923 in the Bell Telephone Central Office at Harrisburg, Pennsylvania, several plants installed in 1937 and 1938 in various central offices of the New York Telephone Company, a 40-kw set installed in 1938 for lighting and radio use at the Syracuse, N. Y., airport, and several installations in processing plants for motion-picture film in southern California.

(*c*) *Diesels to Restrict the Maximum Demand on Utility Service*

The purpose of this application of Diesel engines is to reduce the cost of utility service by limiting the demand imposed upon the utility lines. In addition, the engines serve as stand-by against utility outages. The engines may be used in two ways: First, where the load rises at certain times of the day, the engines absorb the hump of the curve and improve the load factor of the utility service and, second, where the utility company has a low off-peak rate, the engines take all or most of the load during the utility's peak period.

Two illustrations of this application are:

1 The Dennison Manufacturing Company, Framingham, Mass., installed in 1931 a 350-kw Diesel unit to operate in conjunction with its steam plant and utility service (21). Prior to installing the Diesel, the steam-engine load was adjusted for maximum production of by-product power, and the balance of the load was carried by the utility. However, this imposed a highly variable load on the utility lines, with a correspondingly high demand charge. The Diesel engine improved the setup by smoothing out the utility load while still permitting the steam plant to generate maximum by-product power. At the same time the Diesel provided valuable stand-by service.

2 The Union Stock Yards, Chicago, installed in 1932 a 2250-kw Diesel unit to supply power along with a 6000-kw steam-turbine plant and also utility power (22, 23). The total-load peak was 12,000 kw and the total annual consumption was 54,000,000 kwhr. Prior to the installation of the Diesel, the limited capacity of the steam-boiler plant made it necessary to purchase about 42,000,000 kwhr with a maximum demand of 6000 kw, i.e., a load factor of 80 per cent. The installation of the Diesel greatly improved the over-all performance. The Diesel supplied 10,000,000 kwhr and 2000 kw, the steam plant generated 10,500,000 kwhr and 6000 kw, while the utility load was reduced to only 33,500,000 kwhr and 4000 kw, which improved the utility load factor to 95 per cent.

In both of these plants the Diesel engines as well as the steam plants are electrically interconnected with the utility systems, which is highly desirable to simplify the allocation of load among the several power sources.

(*d*) *Utility Service to Check Diesel Frequency and Synchronous Time*

Because of the extensive use of synchronous clocks by utility customers, most utility systems maintain an exceedingly uniform cyclic frequency together with periodic correction of accumulated deviations in time. By introducing a small service from such a utility system into a Diesel alternating-current power plant, the same accurate control of frequency and time may readily be transferred to the Diesel system at a trifling cost. The Diesel-plant frequency can easily be checked against the utility system by means of the regular switchboard synchroscope, or even with a pair of lamps. Clock time can be readily checked by comparing two synchronous clocks, one connected to the utility system, the other to the Diesel-plant bus. Numerous installations of this kind are giving good service.

(*e*) *Utility Service as Auxiliary to Diesel Power*

This falls into two general classes: First, where the utility service is used at a different time from the Diesel power; second where both power sources are used simultaneously (but not necessarily electrically paralleled).

In the first class will be found many examples in office and loft buildings where such an arrangement permits the Diesel plant to be shut down at night and over week ends, when the load is small. Where this plan is adaptable, the savings in Diesel fuel, attendance, and wear exceed the cost of utility service at the light load. If the load is very small (such as for a few hall lights), and the utility rate for breakdown and auxiliary service is of an unfavorable form, it may be advisable to install a separate wiring system and purchase the current at the utility's regular rate for firm service.

In the second class are plants where the Diesel-engine capacity is sufficient to handle the normal load but utility service is used (either on a separate circuit or in parallel) to help out during the peaks. The use of utility service to carry part of the plant peak load is economical only when the utility rate schedule makes it feasible to use the same service for several other purposes as well, such as supplying the valleys of the load curve when the Diesel plant is shut down, and furnishing stand-by protection. In such cases, less Diesel capacity is needed than otherwise, and more efficient operation is obtained because of the better running-engine capacity factor. The author has elsewhere described a successful installation of this kind (24).

However, on many rate schedules it is impossible to obtain breakdown protection together with auxiliary service economically, and since utility demand charges alone are generally larger than Diesel fixed charges, it is cheaper in such cases to use a Diesel engine to carry the peak load than to buy utility service for this purpose only.

(*f*) *Utility Service to Carry Momentary Load Swings*

In some plants the load curve is uneven due to heavy current inrushes of short duration, say from $^1/_2$ sec to 4 sec, due to motor starting, electric welding, and the like. Such inrushes sometimes create momentary loads that exceed the average load. If the power is supplied by an isolated Diesel plant, it necessitates investment in excess plant capacity and also operation at a small (and less efficient) load factor. Under such conditions, utility service can be used to great advantage if the utility company will permit the Diesel plant to operate in parallel with its own service,

i.e., electrically interconnected. By suitably setting the Diesel-engine governors, the engine power is adjusted to carry the base load, and the utility lines supply the remainder. The adjustment of load is surprisingly simple, because the utility frequency is quite constant regardless of load, while the engine governors have (or can easily be made to have) a drooping speed characteristic so that the speed drops with an increase in load. Consequently, once the engine governors are set for a given load, the engines will generate the same amount of power steadily, regardless of the total load that is being supplied.

As this method of operation puts the uneven part of the load on the utility service, the layout must of course be such as to keep the swings within the limits permitted by the utility's standard rules.

Paralleled utility service was used in this way to stabilize the load on the first Diesel engine installed in 1937 in the Simonds Saw and Steel Company's file plant located at Fitchburg, Mass.

The reason why it is economical for the consumer to carry momentary load swings on utility service is that utility demand charges are based on demand-meter readings showing the integrated consumption for intervals of generally 15 or 30 min, so that the demand charge is not that of the momentary swings themselves but the integrated average of the swings and the steady load. For a simple example, suppose the only load on the utility's meter is an elevator which starts every half minute and causes an inrush of 60 kw for 4 sec. The demand meter will not show 60 kw, but only $^4/_{30}$ of this, or 8 kw. This is not unfair to the utility, though at first glance it may appear so. The utility system serves many consumers and consequently benefits by the diversity in the time of their demands. This diversity is exceedingly large in the case of momentary swings, so that the merged load of a group of consumers having uneven loads is far smoother than their individual loads. Consequently the capacity required in the various components of the utility system, all the way back to the generating station, is but a fraction of the arithmetic sum of the individual consumers' momentary swings. It is therefore entirely equitable that demand charges for this class of service, the same as for others, should be assessed on 15- or 30-min average loads instead of on momentary swings.

Parallel Operation

In several types of joint operation of Diesel engines with utility service the full benefits can be enjoyed by the power user only if the Diesel plant is electrically interconnected with the utility system. Such parallel operation is, in fact, essential in one class of service already described, i.e., where the utility service carries the momentary swings of an uneven load curve.

Parallel operation is advantageous in most situations where both sources of power are used simultaneously, or where there should be no interruption in service when changing from one to the other. This is the case where the utility supplies auxiliary service to a Diesel plant, or where Diesel engines are used to restrict the utility maximum demand. Without parallel operation it is necessary to use double-throw switches, causing a momentary interruption of service as well as voltage and frequency changes whenever the switches are thrown. If the load must be distributed between the two sources, a complicated and expensive system of multiple switching is required, and even then the load must be shifted suddenly in large blocks. Parallel operation eliminates all of this. The switching arrangements become simple, and by merely manipulating the Diesel-engine governor, the load is gradually transferred with no service interruptions and with no change in voltage or frequency.

When a Diesel plant is to be electrically interconnected with a utility system, there are several factors with which the power company is rightfully concerned:

1 *Economic Effect of Feedback*

If the total load should fall below the output of the Diesel plant, it is physically possible for the Diesel plant to feed current back into the utility system. Such feedback would be economically unfair to the utility if no precautions were taken to prevent it from subtracting from the reading of the kilowatthour meter. The effect would of course be to give the consumer an excessive price for his dump power. In cases of power interchange between utility systems and large industrials generating by-product steam power, additional metering equipment is installed to measure the feed-back energy so that it may be credited at a proper value (3, 4, 5, 6, 7). However, in Diesel plants, such arrangements are unnecessary, because the cost of Diesel generation is greater than the value of dump power. All that is required to prevent economic loss to the utility is to fit a ratchet on the meter shaft to prevent reverse registration.

2 *Electrical Effects of Feedback*

Since feedback through a ratcheted meter would be a direct loss to the private-plant owner, it would never be done deliberately. But what would be the electrical effects of feedbacks that might occur accidentally? This might happen, for example, on account of an unnoticed large decrease in power consumption, or because of a large drop in frequency of the utility service. The effects would vary somewhat with the method of distribution used by the utility.

(*a*) The most common method of distribution is by the alternating-current radial system, whereby one or several consumers are supplied by a feeder emanating from a substation. The usual protective equipment is a simple overload circuit-breaker at the substation end of the feeder, and also of course the ordinary fuse or circuit-breaker protection at the entrance to each consumer's premises. (*b*) The alternating-current network which is the more general system for large urban distribution, consists of a network of interconnected street mains fed at numerous points by banks of transformers the primaries of which are supplied by high-tension feeders. The transformer secondaries are connected into the network through network switches which automatically open if the power flow is reversed. (*c*) The direct-current networks which exist in a few cities, such as New York and Chicago, are supplied by feeders from converter substations. These feeders are protected by circuit breakers at both ends, which will open upon a reverse of polarity.

A feedback from a private plant to an alternating-current radial feeder simply reduces the amount of energy fed into that feeder from the utility substation. Other consumers connected to the same feeder continue to receive their normal service, though part of it comes from the private plant. In the case of alternating- or direct-current networks, a feedback similarly supplies part of the requirements of other near-by consumers connected to the same street mains, thus reducing the load on the feeders supplying that portion of the network. If the feedback were of excessive magnitude, there is a theoretical possibility that it would actuate the reverse-power relay at the street end of the feeder and open the circuit breaker. However, this could not occur unless all of the other consumers supplied from the same feeder were already being adequately supplied from the private plant, and therefore there would be no interruption or diminution of their service. The relatively small capacity of the usual Diesel plant compared to that of the local utility system makes it extremely unlikely that a feedback large enough to open a network switch would ever occur, and in fact the author knows of no such instance. However, if it should be deemed necessary, feedbacks

exceeding any given amount could be automatically prevented by installing a reverse-power relay on the consumer's premises which would open the interconnection between the utility system and the Diesel plant as soon as the feedback reached a predetermined magnitude.

3 *Paralleling Derangements*

Because of accident or carelessness, derangements sometimes occur which cause a momentary but heavy current inrush over a paralleling connection. For example, a heavy inrush might occur when synchronizing, if the main switch were closed while the circuits were out of phase. Such an occurrence, however, does not seriously disturb the utility system or the service to other consumers, as an excessive inrush simply opens the overload circuit breaker on the paralleling connection and disconnects the private plant's utility service. In other words, the other consumers in the vicinity would not be affected to any greater extent than they would be, under nonparallel conditions, by a short circuit on some other premises.

The possible objections to parallel operation have been discussed here at some length because some utility companies have been unwilling to permit private plants to operate in parallel with their service. As a matter of fact, inquiries made during the preparation of this paper show that different power companies have quite different policies as to parallel operation, some excluding it altogether while others have definitely provided for it in their rate schedules. Extracts from several power-company letters on this subject are given in the Appendix, to show the wide diversity of policy.

The situation in New York City is interesting. Parallel operation is now prohibited by the power company except for an instantaneous throwover limited to 1 kw. (This exception was made in order to avoid stopping electric clocks in an apartment house when throwing over.) The power company testified, in the Public Service Commission hearings previously cited (19), that in its opinion, parallel operation was not feasible under a network system of distribution. On the other hand, the author has made actual tests of Diesel power plants operating in parallel with both the alternating- and direct-current networks in New York, and in no case did any difficulties occur either in the Diesel plants or on the utility lines.

There is little doubt that paralleling of private steam and Diesel plants with utility service is growing. In fact, some five years ago, H. Drake Harkins stated (7):

> The simplest case of cooperation between utility and industrial in the generation of electrical energy occurs when the industrial secures part of its demand from the utility and operates its own generating equipment in parallel with the utility but does not feed back. So many installations of this kind exist in the United States that it may be called common practice, although a few utilities have earned the ill-will of their customers by refusing to cooperate to this extent. This attitude is untenable, as can be proved by the entire success of the numerous existing installations. The utility in one large eastern city states that it has twelve customers operating in parallel, the largest taking 6500 kw from the power company and the smallest 100 kw.

Diesel engines run as readily in parallel with utility service as do steam engines or turbines, and it is to be hoped that those power companies that have heretofore forbidden parallel operation with Diesel engines will no longer stand in the way of engineering progress.

Conclusion

There are already many instances where Diesel engines are used, or can be used, jointly with public-utility service. This joint use is increasing in several types of application because of the marked benefits it confers upon the power user in the form of improved service and lower costs. The benefits are not one-sided, as the power companies also profit from the increased business at fair rates which flow from such joint use.

Parallel operation, i.e., electrical interconnection between the Diesel plant and the utility lines, is often advantageous for the plant owner and has no harmful effects on the utility system.

The all-too-frequent antagonistic feeling between private-plant owners and public-utility officials is greatly to be deprecated, as it often prevents both parties from gaining the full benefits of joint service which could be achieved by cooperation.

Engineers engaged on power studies should carefully investigate the possibilities of joint utility and Diesel service.

Appendix

Extracts from power companies' letters in response to inquiries as to circumstances under which they permit a customer to operate his own private electric plant in parallel with their service.

1 Consolidated Gas, Electric Light, and Power Company of Baltimore, Baltimore, Md.

> We do not have any rates, practices, or plans for customer generating plants to operate in parallel with our service with the exception of our interconnection agreements with other utilities.

2 Virginia Electric and Power Company, Richmond, Va.

> The Virginia Electric and Power Company has been studying this matter in a small way for the past several years, and at the present time has a few small interconnections. In each case the customer is operating back-pressure generating equipment in order to produce steam at low pressure or hot water for process. However, no specific rates or arrangements have been developed for this type of service.

3 Philadelphia Electric Company, Philadelphia, Pa.

> Where a customer requires low-pressure steam for his actual manufacturing processes which can be most economically supplied by exhaust or bled steam from a prime mover, we permit parallel operation.
>
> You understand, of course, that our proposition with respect to such service must include the protection necessary to prevent the possible troubles inherent in parallel operation from adversely affecting our operations and consequently the service to other customers.

4 Delaware Power and Light Company, Wilmington, Del.

> Of course, it is first presumed that the customer's generating equipment is capable of being placed in synchronism with our line without any adverse effects to other customers connected to the line.
>
> Before arranging for a parallel connection, we would first make a study of the customer's economics involved. Assuming that the economics point to partial generation by the customer and partial purchase, we would be agreeable to a parallel connection on the basis that the customer would own and maintain his substation and purchase not less than 100 kw; the actual capacity of the customer's substation not to exceed the capacity in kilowatts for which he had contracted. In other words, there would be no element of free stand-by for the generating capacity used by him. Of course, if a customer desires stand-by capacity for his own generating plant, this may be purchased under the appropriate rate schedule.
>
> We now have several industrial customers whose generating equipment is, or can be, operated in parallel with our lines.

5 Commonwealth Edison Company, Chicago, Ill.

> In cases of this kind we inspect the plant and if we find it is, in our opinion, being operated with proper supervision and if the class of business will not cause trouble if operated in conjunction with our service we permit them to so operate.

6 The Detroit Edison Company, Detroit, Mich.

> I am pleased to advise that this company does permit parallel operation of customer's generating equipment with its lines under certain conditions.
>
> If the customer has a reliable operating staff and will guarantee a monthly minimum load of 500 kilowatts, parallel operation will be allowed.
>
> We do make certain recommendations that the customer provide

equipment for his protection in case of possible failure of our supply. It is further understood that under no conditions will we be held liable for damage to equipment for loss of production due to this parallel connection.

Discussion

CHARLES SNYDER.[3] We have operated several Diesel plants in isolated communities to carry loads while the load was building up to where a transmission line might be justified. We have also operated Diesels at the end of rather long transmission lines. In the ordinary case, the installation of a Diesel plant works out successfully for carrying a community until a line can be built, although it is quite costly because, usually, the load and load factor are poor. The cost of hanging engines on the end of transmission lines can hardly be justified, except where the engines are available, in which case, we have found that it helps the situation for a time, until service can be bolstered.

In Mr. Kates' discussion of utility service tied in with private industrial plants, he has taken the position that very largely the rate charged should perhaps be lower than most utility companies think it should be, because of the diversity involved. The writer cannot agree with Mr. Kates on the matter of diversity, because, on most utility systems, diversity is not felt by the utility until it gets back to the generating plant. On the local distribution system, and even in so far as networks are concerned, diversity has little or no effect.

As an example, the New York Public Service Commission, in a case with which, it is believed, Mr. Kates was identified, said in effect the same thing, that diversity was not felt until it practically got back to the generating station, and that the rate which should be charged for breakdown or auxiliary service should be different from the one which is charged for full-time customers.

The Wisconsin Public Service Commission, in the case of the municipal plant at Lodi, said the same thing, that the rate for part-time or temporary service should not be the same as the rate for full-time customers.

It seems to the writer that both of those conclusions have been based on the fact that the regular customers of the utility are paying for service on a different basis, naturally, from what the part-time customer would pay for service. In other words, they are buying service on the basis on which the utility company has made its rate, that is, full-time service. It is a well-recognized fact that the utility company cannot afford to supply stand-by service for the demand portion of its rate. Its rates are based on the use of energy. Regular rates contemplate the real use of service and are designed accordingly.

Such items as accurate frequency control and well-regulated voltage involve real expenditures on the part of the utility. The cost of these items is reflected throughout the entire rate structure. If a customer were to purchase a relatively few kilowatt-hours at regular rates merely to stabilize the operation of an individual plant, he would, in effect, be subsidizing his own plant at the expense of the regular customers of the utility. If this practice became at all common, it would, in my opinion, not be long before the utilities would be called upon by the various state commissions to answer the charge of unjust discrimination.

Now in the matter of the utility company's handling momentary swings of load, Mr. Kates pointed out that it was a matter into which diversity again entered. The same reasoning, at least in the writer's opinion, would apply in such a case, in that diversity is not effective until getting back to the power plant. For example, it would be practically ruinous to our distribution system, which serves a thinly populated area, including many scattered communities, to take such loads as mentioned in the paper.

The point the writer is trying to make is that all of these are particular cases. Each individual case requires sound engineering study from the point of view of the private plant, the Diesel plant, and the utility.

It might have been better if Mr. Kates had cited more really up-to-date cases than he has listed in his bibliography. It is also rather regrettable that the author did not go into more engineering detail, rather than the sales angle. The utility companies and the private plants have need of such information.

OLIVER F. ALLEN.[4] The writer does not remember any previous paper before this Society in which the technical aspects of the interconnection of the isolated unit with the utility system have been so clearly and broadly defined and analyzed. It can be concluded safely, partly from this paper and partly from general knowledge, that there are no technical difficulties inherent in the interconnection of isolated plants and the central-station service. There are, however, economic questions, which some Diesel enthusiasts have not always evaluated; at least some of which might prevent Diesel installations from being made. As has been pointed out, the cost of having central-station service

[3] Monongahela System, Fairmont, W. Va.

[4] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

available, as well as the cost to the private-plant owner of having his own service available all the time but used only part of the time, are features to be considered.

One private plant in the Middle West which was shut down more than three quarters of the operating week, had a load factor which was very low. Studies of this plant were made not very long ago, which indicated that the cost of operating the plant was not properly evaluated. The owner was under a misconception as to his actual operating costs.

On the other hand we all know of cases which are very successful economically, particularly where the isolated plant is of substantial size. There are also many other instances in which there is interchange of power between utilities and private plants, such as department stores, factories, and chemical or other process works, where the interchange of power goes on automatically and profitably for all concerned. In some plants there is no difference in rate. In others there is a rate differential. The meters are arranged so one set registers current coming from the private plant, while another set registers current coming from the central station. Rates are adjusted according to relative production costs.

Here again, the writer would emphasize the importance of an honest and complete study and of real cooperation between the utility, the owners, and the engineer who designs the isolated plant. The owner should have an engineering consultant to study the problem and not depend upon the overanxious salesman. The salesman is frequently a competent engineer, but obviously he is interested in making his sale, whereas a man in the author's position is able to analyze the problem and be more or less of an arbitrator. Such an independent engineer can then tell the owner whether he really should make the investment, because it is not simply a question of initial investment, labor charges, and fuel costs, but one of embarking in another business, requiring the diversion of funds from his own business. Before he enters the field of power generation, he should be sure that such a venture would be economically sound.

H. C. Forbes.[5] This paper seems to suggest that the rates of some utilities for breakdown, or stand-by service, to private plants are inequitable and, in substantiation of this view, the author refers to data submitted in a case before the New York Public Service Commission which purported to show that the diversity factor for breakdown service to a small group of customers was at least 10 to 1. From this diversity data, he infers that the cost of supplying such customers with breakdown service must be relatively low so that they ought to be entitled to special consideration in the matter of rates. Having some familiarity with the data to which he refers, the writer would like to point out that, inasmuch as the service to the group of customers in question, during the period covered by the data, was fundamentally auxiliary service rather than breakdown service, there is good reason to doubt whether it is at all indicative of the diversity which might be expected from a group of customers employing utility service as a breakdown supply in the usual sense of the term.

Be that as it may, there is no reason to conclude that, simply because under ordinary conditions the diversity among a group of breakdown customers is large, the cost of supplying them with breakdown service would necessarily be small. It must be realized that such a group of customers will not be located in a restricted area on the distribution system such as to make it possible to take advantage of their diversity to reduce the distribution-system investment. On the contrary, they may be expected to be widely scattered. It is generally necessary to install for each customer just the same distribution facilities for the customer's occasional use as would be required to deliver firm service of the same magnitude as that required for the breakdown supply. In general, therefore, it is not to be expected that the diversity will be a factor of any considerable importance in so far as distribution investment is concerned.

The author also ignores the fact that a common emergency may well operate substantially to eliminate the diversity among the breakdown customers. An interruption in the supply of Diesel fuel, due to strikes, or a general strike of private-plant operating labor, would undoubtedly have the effect of throwing the entire group of breakdown customers simultaneously upon the utility service at maximum capacity. Indeed, the recent coal strike showed conclusively enough, in the case of coal-burning private plants, that this is precisely the result to be anticipated, and the utilities must have adequate generating capacity to cope with such an emergency. Whatever the diversity may be under normal conditions among a group of breakdown customers, there is good reason to doubt, therefore, that the utilities are able in consequence to effect any substantial investment economies in supplying them with breakdown service.

From a casual reading of the paper, it might be thought that the auxiliary service, which is frequently associated with utility breakdown service to private plants, would constitute a desirable load for the utility. For obvious reasons, it often turns out to be quite the contrary. Usually the private-plant operator, in the interest of cutting down the amount of equipment required for his plant, will plan to use the utility service to carry his peak. As a general thing the private-plant peaks are likely to coincide pretty much with the utility-system peak so that the result is to impose an additional load of very poor load factor upon the utility system, causing its peak to occur at the worst possible time from the standpoint of the utility.

The author also labors to show that the parallel operation of private plants with utility systems is not undesirable. Under conditions which obtain on radial systems and, in the case of high-tension paralleling arrangements, there would seem to be no objection to such parallel operation. The operation of private plants in parallel through the low-tension networks of the utility systems, however, involves certain objectionable conditions which the author mentions in his paper without glossing them over very successfully. It is difficult, indeed, to see any reason why the utility companies should take upon themselves the duty of guarding against the possibility of harmful results which might arise through indiscriminate parallel operation, especially when their firm-service customers would be the ones to suffer in the event of a disturbance due to improper operation by the private plants.

It is to be noted finally that the breakdown rates of the utilities, of which Mr. Kates is so critical, have generally been subjected to an impartial review by the Public Service Commission having jurisdiction, before they were permitted to be put into effect, and it seems a little presumptuous to challenge them as inequitable without supplying more convincing supporting evidence than his paper contains.

Author's Closure

The author is heartily in agreement with Mr. Snyder's statement that the rates charged for utility service supplied to private-plant operators should be based on sound engineering study of this class of service. It is believed that in the majority of cases, such rates have been arrived at rather arbitrarily, and have been based more upon commercial and competitive considerations than upon the actual cost of the service.

Mr. Snyder is correct about the variations in diversity factor which may occur in different places. Certainly, on a long feeder line, serving only one or two customers in some isolated section,

[5] Consolidated Edison Company of New York, New York, N. Y.

there will be a much smaller diversity effect upon the distribution system and transmission lines than in the network system of a large city, where, within an area of a few blocks, a number of private plants are all served from the same network.

Again the author agrees with Mr. Snyder that the rate for breakdown and auxiliary service to private plants should be different from that for general consumers. With this in mind, a two-part rate for breakdown and auxiliary service was proposed. One part would be the same as the rate for general service, based on the actual demand and energy as shown by the meter. The other part of the rate would be an additional charge to the breakdown user consisting of a stand-by charge which he would pay in addition to the charge for the actual use of current. This rate for stand-by protection should be based upon actual cost, taking into account the diversity and other characteristics of that particular system.

Such a two-part rate was in fact proposed to the New York Public Service Commission in the case cited in the paper. It is gratifying to note that the Commissioner who heard the case concurred in principle, and in his printed opinion he proposed a charge for stand-by protection of two thirds the demand charge for actual use.

Referring to utility rates for swing loads, time service, low-load-factor service, etc., Mr. Snyder seems to advocate a higher charge to the private-plant operator than to the general consumer for identical service. This would be discriminatory indeed. The rate schedules for general consumers are supposed to impose fair charges, based upon actual cost, on those general consumers who happen to have swing loads, those who want time service only or those whose loads have a low load factor. If the prevailing rates to general consumers for service of such characteristics give the utility a proper return on cost, there is, in the author's opinion, no valid reason why the same rates should not apply to private-plant operators who want utility service of the same characteristics.

Mr. Forbes believes that the diversity factors of breakdown service, cited in the paper, applied to auxiliary service rather than to breakdown service. He is mistaken; the testimony upon which these figures were based are the answers received from 140 breakdown- and auxiliary-service customers to questionnaires[6] issued by the engineering staff of the New York Public Service Commission, calling for detailed data on each occasion where utility breakdown service was used by compulsion because of a plant breakdown. No auxiliary service was included.

Mr. Forbes believes the author is "presumptuous" in criticizing breakdown rates which, Mr. Forbes states, have generally been impartially reviewed by the Public Service Commissions having jurisdiction, before being put into effect. Yet in the same New York case to which Mr. Forbes refers, the Commission permitted the company's proposed rate to become operative because the Commission had no power to compel a further suspension, and it went on record[7] as follows: "The Commission has not found that the demand charge or the energy rate were just and reasonable rates. The Commission has left these matters open for later determination when it has sufficient evidence to determine what is a fair demand charge and what is a fair energy charge." Here is an instance of an unapproved rate that has been in effect for 3 years.

Mr. Forbes' discussion is itself evidence of that antagonistic feeling between public-utility officials and private-plant owners which was referred to in the paper. Surely the engineering problem of coordinating two different sources of power can better be solved by objective analysis and factual engineering studies.

An Improved System in the Application of Noncondensing or Extraction Turbines

By H. W. CROSS[1] AND E. S. WELLS, JR.,[2] CHICAGO, ILL.

The purpose of this paper is to demonstrate methods by which the electrical output of noncondensing or extraction turbines may be increased. The electrical output is definitely established by the energy drop between initial and exhaust conditions and by the quantity of steam flow. By increasing the total steam temperature at the throttle for a given pressure, the available energy is increased and consequently the electrical output. The application of a combined desuperheater and feedwater heater at the exhaust is shown to be advantageous in realizing gains from the use of higher-temperature steam. Examples demonstrating the possibilities inherent in such systems are illustrated and explained.

IT HAS BEEN the practice in the application of noncondensing turbines and extraction turbines to choose an initial steam condition, i.e., a total temperature at the selected inlet pressure, that will give the desired temperature at the exhaust or extraction opening of the turbine to suit the low-pressure system which is being served. As most applications are made in connection with old low-pressure-turbine equipment, the design of which limits the temperature at which they may be operated, or process systems where little or no superheat is desired, the total temperature at the throttle for the new turbine is thus definitely limited.

A considerable gain in the electrical output from the high-pressure, noncondensing portion of this cycle may be realized by increasing the total steam temperature at the throttle. The electrical output is definitely established by the energy drop between initial and exhaust conditions and by the quantity of steam flow. By increasing the total steam temperature at the throttle for a given steam pressure, the available energy between initial and exhaust conditions is increased and the electrical output is proportionately increased. However, the increase in initial temperature causes an increase in the temperature at the exhaust and results in an exhaust temperature higher than desired. This gain in electrical output may be obtained if a desuperheater is installed on the exhaust system to reduce the temperature of the exhaust steam to suit the low-pressure system.

In systems of this nature, it is common practice to install a feedwater heater served by the exhaust steam from the high-pressure turbine, in order to obtain a greater electrical output by utilizing more heat from the exhaust steam, thereby increasing the flow of steam through the high-pressure unit.

As an improved system for realizing this gain by the use of higher steam temperatures, the application of a combined desuperheater and feedwater heater at the exhaust is suggested. This would consist of two sections. One section would be a surface type of heat exchanger, designed on a counterflow basis and arranged for free flow of exhaust steam through it. The other section would be designed as a condensation-type feedwater heater.

The feedwater being returned to the boiler would be passed first through the heater section. If this section were of the surface type, it would be proportioned with sufficient surface to raise the feedwater temperature to within a reasonable terminal difference of the saturation temperature of the exhaust steam. This heater might be of the open type. However, the position in the system and the pumping arrangement would seem to dictate the choice of the closed-type heater. The feedwater would then flow through the tubes of the other section of the heater, where it would absorb the heat represented by the superheat in the exhaust steam. In reducing the temperature of the superheated exhaust steam, the temperature of the feedwater would be elevated above the saturation temperature of the heater. Steam of the desired temperature would be delivered to the low-pressure system, and the feedwater would be delivered to the boiler at a higher temperature than would be obtained from an ordinary saturation-type feedwater heater alone.

By transferring the high-level heat represented by the superheat in the exhaust steam to the feedwater supplied to the boiler at a temperature above the saturation temperature of the heater, the use of exhaust heat in the cycle is increased, with a consequent increase in heat flow through the turbine and a greater electrical output in conjunction with serving the necessary heat demand of the low-pressure system.

The design of the thoroughfare-desuperheater section would be determined by the temperature desired for the steam supply for the low-pressure system, which would establish the terminal difference between the feedwater entering this section and the steam leaving it. It would be desirable to design the desuperheating section to maintain a somewhat lower temperature than that required by the system, in order to provide a range for automatic control of the temperature.

Fortunately, where saturated steam is required for process work, approximate saturation is generally acceptable and a small amount of superheat does not appear to be objectionable. This is evidenced by the fact that where superheat is not controlled, the increase in temperature of the exhaust steam, occasioned by the lower efficiency of the prime mover under partial loads, is accepted. This margin in the system may be utilized to good advantage in decreasing the size and cost of the thoroughfare desuperheater by providing a higher terminal difference in the heater.

With certain choices of initial temperature and pressure, it is possible that, in absorbing the heat of the superheat in the exhaust, the feedwater to the boiler might attain too high a temperature to be conveniently handled. The temperature of the feedwater from the desuperheater can be regulated and held at the maximum allowable temperature by a by-pass around the feedwater-heater section, with a temperature control. This control would limit the temperature rise at the heater by by-passing a portion of the feedwater around it.

The thoroughfare desuperheater and the feedwater heater might be built as two separate sections working together as a

[1] Engineer, Turbine Sales, General Electric Company. Mem. A.S.M.E.

[2] Engineer, Turbine Sales, General Electric Company.

Contributed by the Power Division and presented at the Semi-Annual Meeting, San Francisco, Calif., July 10–15, 1939, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

unit, or the two sections could be combined in a single shell, depending upon physical limitations or design characteristics. In either case, it would consist of a thoroughfare-desuperheating section and a feedwater-heating section. Between the heater section and the desuperheater section, provision should be made for detraining steam condensation from the thoroughfare section, to prevent its being carried into the low-pressure system. Under certain conditions of control or certain load conditions, it is possible that a portion of the surface of the desuperheater section might act as a condensation heater, resulting in the formation of some condensate.

An appreciation of the relative outputs of these systems may readily be gained from the accompanying illustrations. The steam pressures and load conditions were arbitrarily selected as being in the realm of normal usage. The turbine efficiencies used are based on normal commercial values which vary with the steam conditions, the size of unit, and the loading of the unit.

Fig. 1 shows a conventional application of a noncondensing turbine supplying 50,000 lb per hr of saturated steam at 150 lb gage pressure to process or to other equipment. It is assumed that this 50,000 lb per hr is returned as feedwater at a temperature of 210 F from other feedwater heaters. A high-pressure feedwater heater is indicated, proportioned to heat the feedwater to a temperature of 356 F when supplied with 150 lb gage steam from the exhaust of the high-pressure turbine. With a pressure of 650 lb gage at the throttle and a turbogenerator efficiency of 64.6 per cent (turbine efficiency alone of 68.5 per cent), it is necessary to limit the total temperature at the throttle to 596 F in order to deliver saturated steam at the exhaust. This requires a steam flow of 58,646 lb per hr and gives an electrical output of 1390 kw. The heat supplied by the boiler for this combined steam-and-electrical load is 55,887,000 Btu per hr.

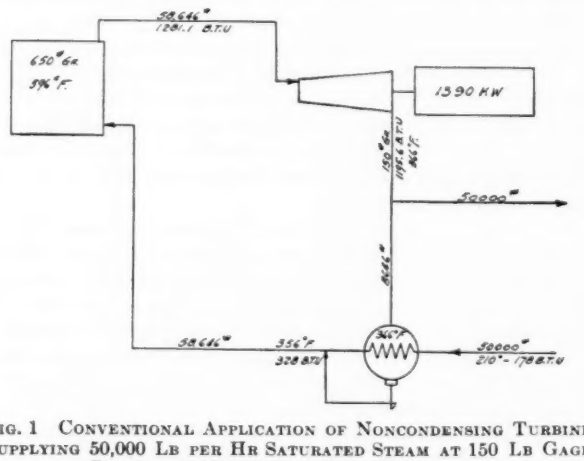

Fig. 1 Conventional Application of Noncondensing Turbine Supplying 50,000 Lb per Hr Saturated Steam at 150 Lb Gage Pressure to Process or Other Equipment

Fig. 2 shows an application to supply the same 50,000 lb of saturated steam per hr at 150 lb gage pressure, in which 650 lb gage at the throttle is used with a total temperature of 850 F. With a turbine efficiency alone of 70.5 per cent, the exhaust steam from the turbine at 150 lb gage would have a total temperature of 582 F. With a conventional type of desuperheater as shown, when supplied with feedwater at a temperature of 210 F, a flow of 44,730 lb per hr of exhaust steam would be sufficient to furnish 50,000 lb per hr of saturated steam to the low-pressure system. This requirement, together with the necessary 150 lb steam to serve the conventional high-pressure heater to heat the feedwater to a temperature of 356 F, requires a flow at the throttle of 51,527 lb per hr, which produces an electrical output of 1680 kw. This increase of 290 kw is an increase of 20.9 per cent in the power output incident to the furnishing of the same quantity of low-pressure steam, as in Fig. 1, and is obtained from this application of the increase in initial steam temperature from 596 to 850 F. The heat supplied by the boiler for this combined steam-and-electrical load is 56,930,000 Btu per hr.

Fig. 3 illustrates the application of the thoroughfare desuperheater and feedwater heater to supply the same 50,000 lb of saturated steam per hr at 150 lb gage pressure, with initial steam conditions as in Fig. 2, namely, 650 lb 850 F at the throttle. To allow for a 5-lb pressure drop through the desuperheater, the back pressure at the turbine would be increased to 155 lb gage. With a turbine efficiency alone of 72.8 per cent, the exhaust steam at 155 lb gage pressure will have a temperature of 581 F. The 50,000 lb of steam per hr, required by the process in passing through the thoroughfare-desuperheater section, is desuperheated by the feedwater and is supplied to the system at saturated temperature. Exhaust steam is absorbed in the feedwater-heater section in sufficient quantity to elevate the feed temperature from 210 to 356 F. The feedwater, in passing through the desuperheating section in contact with the thoroughfare flow of steam in counterflow direction, would be heated to a temperature of 465 F for return to the boiler, in absorbing the heat of superheat of the exhaust steam. The total flow required from the turbine is 58,646 lb per hr, which gives an electrical output of 1921 kw, a gain of 531 kw over Fig. 1, and a gain of 241 kw over Fig. 2, or 38.2 per cent and 14.3 per cent improvement, respectively. The

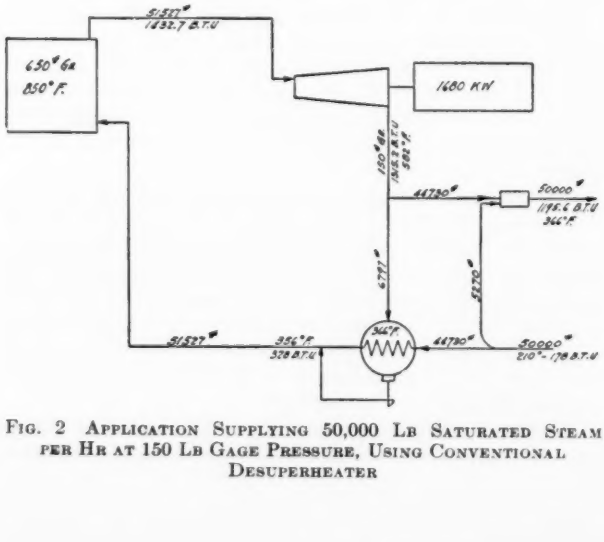

Fig. 2 Application Supplying 50,000 Lb Saturated Steam per Hr at 150 Lb Gage Pressure, Using Conventional Desuperheater

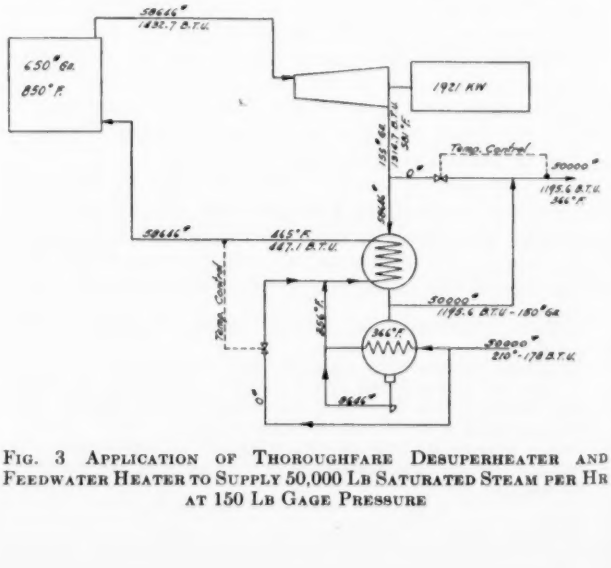

Fig. 3 Application of Thoroughfare Desuperheater and Feedwater Heater to Supply 50,000 Lb Saturated Steam per Hr at 150 Lb Gage Pressure

heat supplied by the boiler for this combined steam-and-electrical load is 57,800,000 Btu per hr.

Figs. 1, 2, and 3 are presented to demonstrate the increase in power available in connection with supplying low-pressure steam and therefore are measured in terms of electrical output. The increase in boiler capacity to accomplish this gain is small, since it is but necessary to supply the heat represented by the added kilowatt output at the rate of approximately 3600 Btu per kwhr. The relative amounts of heat supplied by the boiler, therefore, the relative boiler capacities required, compare as follows: Fig. 1, 100 per cent; Fig. 2, 101.8 per cent; Fig. 3, 103.4 per cent.

For installations where some superheat is desirable in the steam being furnished to the low-pressure system, the thoroughfare desuperheater might be designed with a greater terminal difference and equipped with a temperature control which would be arranged to control the proportion of exhaust steam routed through the desuperheater. Sufficient exhaust steam would be by-passed around the desuperheater so that, when mixed with the balance of the exhaust steam, the resultant mixture would have the desired temperature. The by-pass temperature control would be simple. It would consist of a damper or regulating type of valve which would be automatically positioned to proportion the flow through the desuperheater and around the desuperheater in a manner to give the necessary mixture to maintain the required temperature to the low-pressure system.

Similar gains and an improvement in thermal efficiency of the plant may be realized in the application of this scheme to condensing-type extraction turbines. The same proportional increase in output may be expected from the steam extracted for use in the process or the low-pressure system, which reduces the flow of steam to the condenser for a given output. In addition, the efficiency of the use of the condensed steam is improved, resulting in a gain from that portion of the flow commensurate with the gain on any condensing cycle by the increased inlet temperature.

Fig. 4 shows an application for an assumed requirement of 5000 kw electrical energy and a low-pressure demand for 50,000 lb of steam per hr at 50 lb gage, 25 deg superheat (323 F total temperature).

With 450 lb steam at the throttle, a total temperature of 625 F is required to give 25 deg superheat at the extraction opening at this load. With two stages of feedwater heating, the high-pressure heater served from the 50-lb extraction point to give a final feed temperature at the boiler of 288.7 F, and with 2 in. absolute back pressure at the condenser, a flow of 92,970 lb of steam per hr is required. The heat supplied by the boiler would be 98,455,000 Btu per hr.

Fig. 5 shows an application with load conditions similar to those shown in Fig. 4, except that a total temperature of 825 F is maintained at the throttle and a thoroughfare desuperheater is used to reduce the temperature of the 55-lb-gage extracted steam to the desired 25 deg superheat. In this case the steam as extracted from the turbine would have a total temperature of 484 F (181 deg superheat). In reducing the temperature of this extracted steam in the thoroughfare desuperheater to the desired 25-deg superheat the feedwater would be heated to 336 F. The total flow of steam required from the boiler would be 83,670 lb of steam per hr. The heat supplied by the boiler would be 93,710,000 Btu per hr.

As the steam-process load and the electrical load are held constant in the examples demonstrated in Figs. 4 and 5, the improvement in operation would be measured by decrease in fuel consumption. The saving of 4,745,000 Btu per hr in heat supplied by the boilers represents a reduction of 4.7 per cent in the fuel cost for supplying the steam-and-electrical load.

On noncondensing extraction turbines, the application of the thoroughfare desuperheater would be made at the extraction

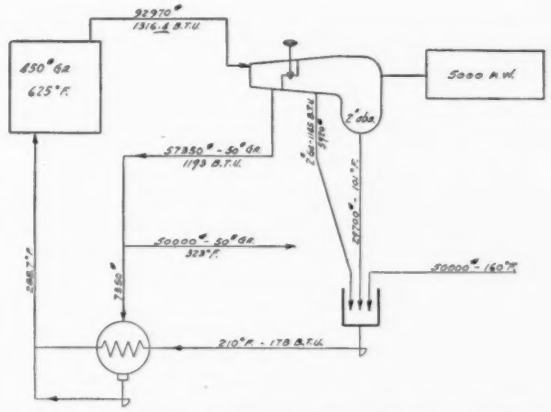

FIG. 4 APPLICATION OF CONDENSING-TYPE EXTRACTION TURBINE TO MEET REQUIREMENT OF 5000 KW ELECTRICAL OUTPUT AND LOW-PRESSURE DEMAND FOR 50,000 LB STEAM PER HR AT 50 LB GAGE PRESSURE, 25 DEG SUPERHEAT

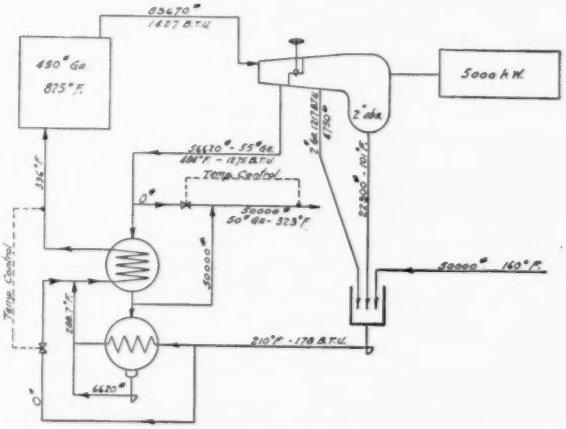

FIG. 5 SIMILAR LOAD CONDITIONS TO FIG. 4, EXCEPT THAT THOROUGHFARE DESUPERHEATER IS USED

opening or at the exhaust, depending upon which low-pressure system served to limit the inlet-steam temperature. The results from the application would be in all respects similar to the noncondensing-turbine application.

No attempt has been made to determine the economic factors in the examples given. In evaluating the applications, consideration must be given to the costs due to the modified boiler flows, the added superheat, the increased turbine capacity required, and the cost of the desuperheating equipment. As the resultant increased output from the noncondensing portion of the cycle is at a rate of approximately 3600 Btu per kwhr, the allowable cost for the suggested application could be the same, per kilowatt of increased capacity, as is found to be justified for the so-called "topping" installations. The surrounding conditions are so diverse in applications of this nature that each case must be considered on its own merits. It is recognized that a thoroughfare desuperheater designed to a close terminal difference would be large. As previously pointed out, however, the operating margin usually will permit the use of a design that will serve to decrease the size.

The thoroughfare-desuperheater and feedwater-heater combination introduces no complex apparatus and includes the customary feedwater heater. It may be equipped with all the necessary controls to hold constant temperatures of steam and feedwater from it when supplied with varying temperatures of both steam and water. The scheme shows substantial increases in

electrical power production in supplying a lower-pressure steam demand over conventional adaptations of these cycles, and merits consideration in situations where the added output is of advantage.

Discussion

W. F. RYAN[3] AND E. W. NORRIS.[4] The system described by the authors has been applied by the writers' company for several years and there is, therefore, a considerable background of actual experience supporting the mathematical demonstrations in this paper. While we have used the system in the majority of our central-station designs since 1933, the opportunity to use it in a back-pressure industrial plant did not arise until 1937. The advantages are much greater in the latter field, but its use has been restricted by a not unjustified reluctance on the part of industrial-power-plant operators to use very high steam temperatures.

The heaters required for this desuperheating cycle are usually small and inexpensive and no major difficulties have been experienced in operation or maintenance. The operating temperatures are frequently too high to permit the use of copper or copper-alloy tubes. Stainless steel is entirely serviceable but its low heat-transfer rate results in a bulky as well as expensive heater. For some high-temperature applications, chrome-vanadium steel, S.A.E. 6120, has been used. If properly heat-treated, tubes of this material are satisfactory under normal service conditions. Where it is possible to do so, the cycle should be designed to give temperature conditions which will permit the use of copper-alloy tubes in the desuperheating heater.

The authors have demonstrated the efficiency of this system for the back pressure and topping installations, but it also has marked advantages in the more limited application to the straight regenerative condensing central-station cycle. The latest installation of this type is in the South Meadow Station of the Hartford Electric Light Company, in connection with a 40,000-kw condensing-turbine generator, operating at 825 lb gage throttle pressure and 900 F total steam temperature.[5] At full load, steam is extracted from the eighth stage at 165 lb gage and 580 F (207 F superheat). This extracted steam, together with the high-pressure gland leakoff which is at a much higher temperature, is passed through a closed heater with a total heating surface of 353 sq ft and is condensed in an open feedwater heater and in the coils of the station evaporators. The feedwater is raised to saturation temperature (373 F) in the open heater and is pumped through the desuperheating heater en route to the boiler. The increase in temperature in the desuperheating heater is approximately 10 F and, due to decreasing efficiency of the high-pressure stages of the turbine at partial loads, this temperature increase is practically constant at all loads from 6000 kw to 45,000 kw, in spite of the fact that the throttle temperature drops at low boiler outputs. The use of the desuperheating cycle increases the total extraction by about 4000 lb per hr at full load, resulting in a yield of more than 150 additional kw generated as a "by-product" of the steam used for feedwater heating and make-up evaporation.

The desuperheating cycle becomes more effective as the portion of steam passing through the desuperheating heater increases in comparison to the total amount of steam in the cycle. For this reason it is particularly effective when applied to noncondensing high-back-pressure turbines or to extraction-type turbines where a large portion of the total steam is extracted. Obviously, the effectiveness of the cycle varies with the amount of superheat in the steam extracted or exhausted from the turbine. Where turbines operate at very high initial pressures and exhaust or extract at relatively low pressures, very little superheat remains, even with high initial temperatures, and the gain in power output and economy through the use of a desuperheating heater is relatively small. Conversely, in those installations, where steam is removed from the cycle at relatively high pressures and, especially, where it is impracticable to use initial pressures that are high enough to give a large amount of by-product power, considerable superheat may remain in the steam extracted, even with moderate initial temperatures. Under these conditions, the desuperheating cycle becomes very effective and enables a desirable increase to be made in the amount of by-product power generated under these unfavorable circumstances.

In many installations where noncondensing turbines are used to top existing power plants, the use of a condensing-type heater, drawing steam from the topping-turbine exhaust is considered questionable as, in effect, this heater operates on steam drawn from the low-pressure-boiler plant and transfers load from the high-pressure to the low-pressure boilers. The introduction of the desuperheating heater, however, is not subject to this criticism as the steam passing through it is exclusively from the high-pressure cycle and contributes materially to its efficiency.

The effects of the desuperheating cycle are not confined to the turbine-and-heater portion of the power plant, but also bring about some interesting changes in the design and operation of the boiler. As compared to the straight extraction plant with low-pressure heaters and moderate feed temperatures, the plant, equipped with a condensing heater connected to the extraction or crossover pressure with a desuperheating heater, operates at extremely high feedwater temperatures. While it requires the generation of a considerable amount of additional steam, due to the high feed temperature and the nature of the cycle, much of the heat in the steam is recirculated and the increased output of the boiler as measured in Btu per hr is small, as compared to the increase measured in lb per hr. For this reason the physical dimensions of the boiler remain practically constant, in spite of the fact that the high-pressure plant has materially increased power-generating capacity. A slightly increased furnace is required in order to burn the fuel needed for the increased by-product power generated. The convection water-heating surface, however, remains approximately the same, and only the superheater surface needs to be materially increased. The steam releasing space must be increased to correspond with the increased evaporation. This requires a larger drum, but usually has no material effect upon the space requirements of the boiler and relatively moderate effect on its cost.

Other changes required for the desuperheating type of plant are increased pipe sizes and increased capacity of boiler feed pumps. Fan and pulverizer sizes should remain practically the same as with the simpler cycle.

AUTHORS' CLOSURE

The discussion by Messrs. Ryan and Norris brings out several interesting features of the thoroughfare desuperheater scheme. It shows that similar arrangements have had some cases of application which had not come to the attention of the authors and apparently the cost of the equipment is not more than for ordinary conditions. The discussion is also in agreement with the claims and calculations of our paper.

Messrs. Ryan and Norris do not discuss the proposed features of automatic control. For ordinary power-station conditions, the temperature and pressure can be allowed to increase and decrease with load conditions, but for steam for process work they must be maintained fairly constant. This can be easily accomplished by appropriate control as mentioned in the paper.

Performance Characteristics of a Mechanically Induced Draft, Counterflow, Packed Cooling Tower

By A. L. LONDON,[1] W. E. MASON,[2] AND L. M. K. BOELTER[3]

Predicted and test results of a packed cooling tower are presented in this paper. The geometrical form of the air-water interface may be described as a sheet conforming to the streamlined shape of the tower packing, in contrast with jets and drops encountered in other types of towers. Tower performance is expressed in terms of its effectiveness as an energy exchanger, as compared to the performance of an infinitely high tower. The effectiveness was found to vary from approximately 0.3 at low water rates and high air rates to 0.8 at high water rates and low air rates. Experimentally determined unit conductances for diffusion vary with the 0.48 power of the gas rate, for Reynolds numbers of from 7000 to 24,000, which is in substantial agreement with published thermal-convection data for similar shapes. The height of the transfer unit (HTU) was found to vary from 3.3 to 6.3 ft, depending predominantly upon the fraction of wetted packing area and the air rate. A simple method, analogous to that employed for counterflow heat-exchanger calculations, is presented for predicting tower performance analytically. This method is based upon the integration of the energy and material-balance equations together with the rate equations, subjected to the simplification that the unit over-all conductance for thermal convection may be approximated by the product of the air-water-vapor-mixture unit-heat capacity and the unit over-all conductance for mass transfer.

THERE is a dearth of basic heat-transfer and diffusion data for cooling towers. As a consequence, rational design is in many cases impossible. The objectives of this paper are:

1 To present experimentally determined heat- and mass-transfer data together with tower performance as an energy exchanger for a particular system.

2 To show that the basic data may readily be used to predict tower performance analytically by integration of the fundamental energy and material-balance equations, together with the material and thermal-convection transfer-rate equations.

Description of the Apparatus

The tests were conducted on a mechanically induced draft, counterflow, packed cooling tower (1).[4] Figs. 1, 2, and 3, indicate the general experimental arrangement. In Fig. 4, an idealized sketch of the tower reveals the type and distribution of the packing. The equipment and instruments were arranged so that over-all material and energy balances could be readily accomplished.

Water circulation during a run was maintained in a closed system; the water from the tower basin was pumped through a shell-and-tube-type heat exchanger back to the tower distributing main. A calibrated orifice in the line to the tower was used to meter the water rate. The rate of change of basin water level with respect to time, as indicated by point-gage readings, served to determine the tower evaporation rate.

Water distribution within the tower was provided by a 3-in-inside-diam redwood-pipe distributing main, running perpendicular to the packing length. Diametrically opposed holes on the horizontal plane, as indicated in Fig. 4, directed the water jets to the grooved top-flat of the distributing deck, which served further to spread the water over the tower cross section. Only the distributing deck was provided with grooved top-flats.

A calibrated nozzle located downstream from the fan discharge yielded the necessary air-rate information. The nozzle location is indicated in Fig. 1, and Fig. 3 reveals the nozzle details. Air-flow control was obtained for runs 1 to 6 and 28 to 60, Table 1, by varying the voltage to the compound-wound direct-current fan motor, while for the other runs an a-c motor drive with damper control was used. The power supplied to the fan motor was measured by means of a wattmeter.

The cooling-tower water was heated by a shell-and-tube-type exchanger with steam as the heating medium in the shell. The rate of heat exchange was controlled by throttling the steam to a constant indicated gage pressure on the high side of a small orifice in the inlet line.

Calibrated thermocouple and thermopile arrangements were used to measure temperatures. These were:

1 Water temperature into the tower; by means of 2 four-couple thermopiles with distributed junctions.

2 Water temperatures in the tower basin; by means of 2 four-couple thermopiles with distributed junctions.

3 Temperatures of the air into the tower, wet and dry bulb; by means of single junctions located at both entrances.

4 Temperatures of the air out of the tower, after passing through the fan, wet and dry bulb; by means of single junctions located at the air-nozzle outlet.

Nomenclature

a = packing area per unit packed-tower volume, sq ft per cu ft

c = unit heat capacity of liquid water, Btu per deg F per lb

$d(\ )$ = notation indicating a differential quantity

e = base of natural logarithms

f_o = over-all unit thermal conductance for convection, Btu per sq ft per deg F per hr

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] Numbers in parentheses refer to the Bibliography.

f_c' = unit film conductance for convection, air side of interface, Btu per sq ft per deg F per hr

f_{cL}' = unit film conductance for convection, water side of interface, Btu per sq ft per deg F per hr

f_D = over-all unit conductance for diffusion, lb per hr per sq ft per (lb/lb)

f_D' = unit film conductance for diffusion, lb per hr per sq ft per (lb/lb) air side of interface

$F(\ )$ = notation indicating a functional relation

g = acceleration due to gravity, ft per hr per hr

h_{fg} = latent-heat vaporization of water at 32 F, Btu per lb water

h = air-vapor-mixture enthalpy, Btu per lb dry air (32 F datum), $h = Hh_{fg} + s(t - 32)$

h_i = air-vapor-mixture enthalpy saturated at temperature T, Btu per lb dry air (32 F datum), $h_i = Hih_{fg} + s(t - 32)$

Δh = mean-effective-enthalpy potential difference for energy transfer between phases Btu per lb dry air

G = dry-air flow rate, lb dry air per hr

H = air humidity, lb of water vapor per lb of bone-dry air

H_i = interface humidity, assumed saturated at temperature T, lb water vapor per lb of bone-dry air

ΔH = mean-effective-humidity potential difference for diffusion, lb per lb

K = dimensionless coefficient

l = height of tower packing, ft

L = liquid water flow rate through the tower, lb per hr

n = exponent

R_{DL} = difference of over-all unit resistance and gas-film unit resistance for diffusion (hr ft² lb/lb) per lb

s = unit heat capacity of the air-water-vapor mixture at constant pressure, Btu per deg F per lb; $s = 0.24 + 0.45\ H$

S = average cross-section area of air flow, sq ft

t = air-main-body temperature, deg F

t_{WB} = air-main-body wet-bulb temperature, deg F

Δt = mean-effective-temperature potential difference for convection, deg F

T = water-main body temperature, deg F

u = wetted perimeter of packing cross section in the direction of the air flow, including trailing edge, ft

V = tower volume occupied by packing, cu ft

Δ = (delta) indicates an average potential difference, generally the logarithmic mean of the terminal potentials

μ = (mu) absolute viscosity of air mixture, lb per hr per sq ft

$\cong$ = denotes sensible equivalence

Dimensionless Variables

ϵ_h = (epsilon) tower effectiveness as an energy exchanger = $\dfrac{G(h_1 - h_2)}{G(h_{i1} - h_2)}$

ϵ_c = (epsilon) tower performance as a liquid cooler = $\dfrac{(T_1 - T_2)}{(T_1 - t_{WB2})}$

η = (eta) fraction of packing-surface area, wetted by the flowing water

Re = Reynolds' number for the packing shape, $\dfrac{Gu}{Sg\mu}$

$\dfrac{f_D aV}{G}$ = number of transfer units

Subscripts

1 denotes tower conditions at water entrance and air exit
2 denotes tower conditions at water exit and air entrance
c denotes cooler and thermal convection
D denotes diffusion
h denotes energy (enthalpy) exchange
i denotes interface conditions
L denotes liquid side

Summary of Experimental Results

The range of variables included in the test agenda were:

1 Water rates L, from 3600 to 12,600 lb per hr, which correspond to rates of 8.6 to 30 lb per hr per sq ft of packing surface.

[a] Slight fogging noticed at air exit.

2 Dry-air rates G, from 2880 to 10,200 lb per hr of dry air, giving mass velocities ranging from 520 to 1840 lb per hr per sq ft of average-flow cross section.

3 Entering-water temperatures T_1, from 80 to 103 F.

4 Air dry-bulb temperatures entering the tower t_2, from 61 to 76 F; and wet-bulb temperatures t_{WB_2}, of 56 to 66 F.

5 Air absolute humidities entering the tower H_2, from 0.008 to 0.013 lb water vapor per lb of bone-dry air.

The steady-state test data Table 1, are tabulated in columns 1 through 9 and column 15. The Bulkeley psychrometric chart was used to determine the air humidities, which are entered as columns 10 and 11. The Keenan steam tables, together with the perfect-gas law, were used to compute the saturated humidities

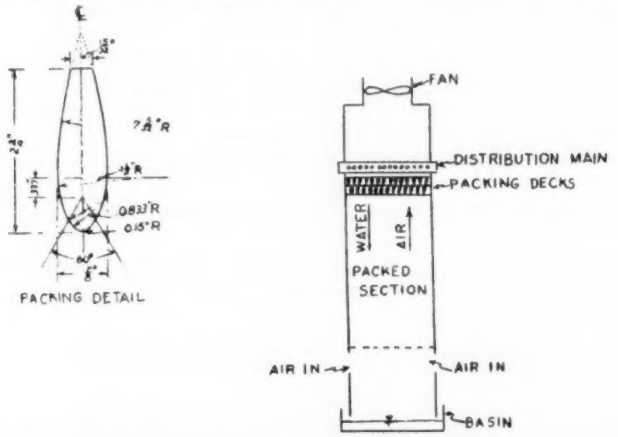

FIG. 4 SCHEMATIC DIAGRAM OF PACKED, COUNTERFLOW, INDUCED-DRAFT COOLING TOWER AND DETAILS OF PACKING USED

(Critical dimensions of the system are: Packing cross-section periphery, 0.525 ft; packing cross-section periphery, including dotted trailing edge, $u = 0.607$ ft; effective packing length, 2.67 ft; average packing area per deck, 19 sq ft, using 0.525-ft periphery; total packing area, $aV = 418$ sq ft, using the 0.525-ft periphery; number of decks, 22; height of packed-tower section, 5.75 ft; column cross-section area, 7.6 sq ft; mean cross-section area with respect to air flow, $S = 5.5$ sq ft; distance of free fall of drops, 0.302 ft per deck.)

corresponding to the water temperatures T_1 and T_2, columns 12 and 13 (2). No corrections were made for the variations in atmospheric pressure for, at the approximate sea-level conditions at the University of California in Berkeley, observations of the barometer indicated negligible deviations from the standard atmosphere. It is believed that the foregoing procedure results in humidities within 2 per cent of the values obtainable from more precise methods of calculation, which is within the accuracy of the wet- and dry-junction data.

The accuracy of the experimental results is revealed by the over-all material and energy balances, columns 14 and 16 in Table 1. The average magnitudes of both of these indicated differences are about 4 per cent.

Conductances for Thermal Convection and Mass Transfer

Unit over-all conductances for thermal convection and material transfer were computed, employing logarithmic-mean temperature and humidity potentials, corresponding to the terminal data. Interface conditions were assumed as saturated at the main-body-water temperature. This assumption yields over-all magnitudes of the conductances because there is some resistance to heat transfer in the water film and, as a consequence, the actual interface temperature is lower than the main-body-water temperature.

Use of mean potentials based on the logarithmic mean of the terminal values is exact if the variation of air-water-vapor-mixture (gas) temperature t is linear with T-t, and the humidity H varies linearly with H_s-H. These conditions do not prevail in the tower. However since the corresponding terminal differences are in the ratio of the order of 3 to 1 or less, it is believed that the logarithmic mean is a good approximation to the actual average potential.

The computed unit conductances are shown in Table 1, columns 21 and 22. Average magnitudes for each air rate, with varying water rates equal to or greater than 17 lb per hr per sq ft referred to the packing area, together with the number of transfer units $f_D aV/G$, are plotted in Figs. 5 and 6, as a function of Reynolds' number and the air-mass velocity G/S, expressed as lb of dry air per hr per sq ft referred to the average-flow cross section. Magnitudes for water rates less than 17 lb per hr per sq ft of packing area are not used for at these rates incomplete wetting of the packing led to much smaller apparent magnitudes of the conductances.

The equations defining the computed conductances are:

Material transfer

$$f_D = \frac{G\,(H_1 - H_2)}{aV\,\Delta H} \qquad [1]$$

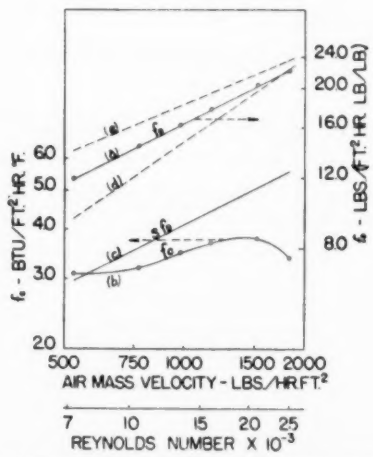

FIG. 5 VARIATION WITH AIR-MASS VELOCITY AND REYNOLDS' NUMBER OF UNIT CONDUCTANCES FOR MATERIAL AND HEAT TRANSFER f_D AND f_c

Curve (*a*) Experimentally determined f_D
Curve (*b*) Experimentally determined f_c
Curve (*c*) Experimentally determined sf_D
Curve (*d*) $f_D' = f_c'/s$ based on extrapolated thermal-convection data of Hughes (5)
Curve (*e*) $f_D' = f_c'/s$ based on extrapolated thermal convection data of Winding (6)

(Each point represents the average of 4 runs at approximately the same air-mass velocity and in all cases at a water rate equal to or greater than 17 lb per hr per sq ft.)

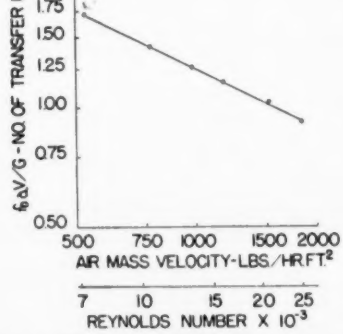

FIG. 6 VARIATION WITH AIR-MASS VELOCITY AND REYNOLDS' NUMBER OF THE NUMBER OF TRANSFER UNITS $f_D aV/G$

(Each point represents the average of 4 runs at approximately the same velocity and in all cases at a water rate equal to or greater than 17 lb per hr per sq ft.)

Convective heat transfer

$$f_c = \frac{sG(t_1 - t_2)}{aV\,\Delta t} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

In computing f_c, the indicated gain in air sensible heat and the exit-air temperature were adjusted to account for the fan-motor input.

Effectiveness of the Tower

It was found that a plot of the dimensionless modulus

$$\epsilon_h = L_1 c\,(T_1 - T_2)/G\,(h_{i1} - h_2) \quad \ldots\ldots\ldots\ldots [3]$$

as a function of the air-mass velocity G/S, or as a function of the number of transfer units $f_D\ aV/G$, served to represent by a single curve the experimental data for water rates of 15 lb per hr per sq ft packing area and greater. An additional curve was required for each fixed water rate less than this value. The experimental effectivenesses ϵ_h, given in Table 1, column 17, are plotted in Fig. 7.

If, as normally is the case, the cooling range is such that $T_2 \gtrsim t_{WB_2}$, then, $L_1 c\,(T_1 - T_2) \cong G\,(h_1 - h_2)$ and the effectiveness as now redefined becomes

$$\epsilon_h = G\,(h_1 - h_2)/G\,(h_{i1} - h_2) \quad \ldots\ldots\ldots\ldots [4]$$

That is, ϵ_h represents the ratio of actual tower energy exchange between phases to the energy exchange which would result,

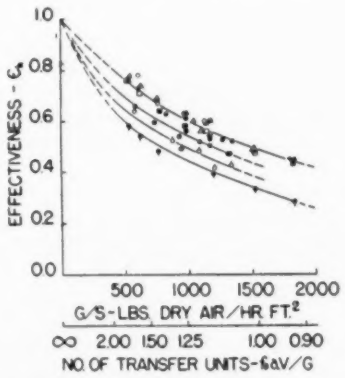

FIG. 7 EXPERIMENTAL RESULTS OF TOWER EFFECTIVENESS ϵ_h, AS A FUNCTION OF AIR-MASS VELOCITY G/S, LB PER HR PER SQ FT (The curves are the same as given by Equation [6] using the unit conductance f_D from curve [a] in Fig. 5.)

$$\epsilon_h = \frac{G(h_1 - h_2)}{G(h_{i1} - h_2)}$$

Key	
L/aV lb per hr per sq ft referred to packing area	
8.6 ♀	17.2 □
10.8 ♂	22.0 ○
12.9 ⊖	25.8 △
15.1 ●	30.0 +

provided the discharge air was saturated at the temperature of the entering water. This modulus compares the performance of the actual tower as an energy exchanger to that of a counterflow tower of infinite height and thus may be termed the effectiveness of the finite tower as an energy exchanger.

A consideration of the effectiveness concept, as will be demonstrated later, leads to the conclusion that ϵ_h may be represented empirically by an exponential equation of the form

$$\epsilon_h = 1 - Ke^{-\eta f_D aV/G} \quad \ldots\ldots\ldots\ldots [5]$$

where η represents the fraction of the packing area aV covered by the flowing water.

An analysis of the experimental data on this basis, using the magnitudes of f_D according to curve (*a*) Fig. 5, revealed a variation of η with water rate as given in Fig. 8. For water rates below 15 lb per sq ft per hr of packing area, complete coverage is not obtained and, for $(L/aV) = 8.6$ lb per sq ft per hr, the fraction covered is only 71 per cent.

The intercept of the straight-line extrapolation of the curve, representing the fraction of wetted area, shown in Fig. 8, is not 0, as might be expected, but rather about 0.40. This result is probably due to unequal water distribution to the two halves of the tower cross section from the distributing main, which was not under pressure, for the lower rates of flow. Such a condition may easily have been brought about by a slight rotation of the main on its axis, so as to make the horizontal line of radial distributing holes on one side come at a higher elevation than the diametrically opposing holes, serving the other half of the tower cross section. In this light the extrapolated line should not be straight, but curved so as to have a 0 intercept as indicated in Fig. 8.

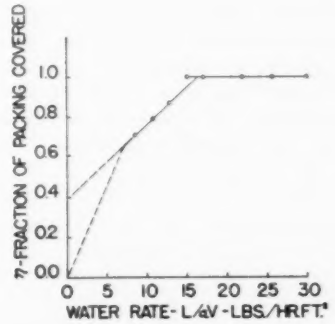

FIG. 8 FRACTION OF WETTED PACKING AREA η, AS A FUNCTION OF WATER RATE PER UNIT PACKING AREA, L/aV

The dimensionless constant K of Equation [5] was determined from the experimental results to equal 1.40 for the range of water rates covered. The following magnitudes of η substituted in the empirical equation

$$\epsilon_h = 1 - 1.40e^{-\eta f_D aV/G} \quad \ldots\ldots\ldots\ldots [6]$$

yield the tower effectiveness as an energy exchanger for the various water rates:

30 lb per hr per sq ft $\gtrsim L/aV \gtrsim$ 15 lb per hr per sq ft; $\eta = 1.00$
$L/aV = 13.0$ lb per hr per sq ft; $\eta = 0.87$
$L/aV = 10.8$ lb per hr per sq ft; $\eta = 0.79$
$L/aV = 8.6$ lb per hr per sq ft; $\eta = 0.71$

These relations, Equation [6] and the above values of η, are plotted in Fig. 7, using the abscissa scales of air-mass velocity G/S, and also the number of transfer units $f_D aV/G$.

The usual definition of cooling-tower performance is based on the ratio of the actual cooling range $(T_1 - T_2)$ to the cooling range which would obtain were the water discharged from the tower at the entering-air wet-bulb temperature $(T_1 - t_{WB_2})$. These magnitudes of $\epsilon_c = (T_1 - T_2)/(T_1 - t_{WB_2})$ are listed in Table 1, column 18. It may be seen that, when the effectiveness of the tower as an energy exchanger is low, the tower performance as a water cooler is high, and vice versa, that is, to a rough approximation

$$\epsilon_h + \frac{(T_1 - T_2)}{(T_1 - t_{WB_2})} = 1 \text{ (approximately)}$$

The tower effectiveness as an energy exchanger served to correlate the results more satisfactorily than the tower performance as a water cooler. As will be shown later, the use of ϵ_h is partially justified analytically. Further, if its effectiveness as an energy exchanger is known, the tower performance as a water cooler may be determined. Two restrictions apply to this calculation:

(*a*) The water-carrying capacity of the air stream in the infinite exchanger must not exceed the water rate, that is

$$L \leqslant G\,(H_{i1} - H_2) \quad \ldots\ldots [7]$$

which means that the water rate must be sufficiently large so that it will not suffer complete vaporization in the infinite tower.

(*b*) Cooling cannot occur below the dynamic equilibrium temperature at the air intake, which is established when the thermal convective heating of the water is just equivalent to the evaporative cooling by mass transfer. This equilibrium temperature is essentially the entering-air wet-bulb temperature, that is

$$T_2 \geqslant t_{WB2} \quad \ldots\ldots [8]$$

Any additional energy exchange which occurs in the actual tower above the amount required for the cooling range $(T_1 - t_{WB2})$ serves only to vaporize the water, reducing its enthalpy $(Lc\,t_{WB2})$ but further temperature reduction does not result.

Normal cooling-tower conditions are such that the operation is well within the limits defined by Equations [7] and [8].

Basic Equations

The differential equations for the material and energy balances and transfer rates will be stated for a perfectly insulated tower. For details of derivation the reader is referred to (2). The equations are written for a differential height of the packed section of the tower, corresponding to a differential volume dV and transfer area adV.

The energy balance expresses the fact that the gain in air enthalpy equals the loss in water enthalpy as the two streams pass counter to each other through the differential tower volume dV, that is

$$d\,[Lc\,(T - 32)] = G\,dh \quad \ldots\ldots [9]$$

The material balance yields

$$dL = G\,dH \quad \ldots\ldots [10]$$

The rate of material transfer from the air-water interface to the main gas stream is, taking V as increasing when proceeding downward in the tower

$$G\,dH = -f_D'\,(adV)(H_i' - H) \quad \ldots\ldots [11]$$

where f_D' is the unit film conductance for diffusion, defined on the basis of the humidity potential from the interface to the main gas stream $(H_i' - H)$.

The expression for the thermal-convection transfer from the interface to the gas stream is analogous to Equation [11] and may be written as

$$G\,s\,d\,t = -f_c'\,(adV)\,(t_i - t) \quad \ldots\ldots [12]$$

where f_c' is the unit thermal conductance for thermal convection.

Another equation is required to express the rate of heat transfer between the main body of the water at temperature T and the interface at temperature t_i. This relation is

$$d\,[Lc\,(T - 32)] = -f'_{cL}\,(adV)\,(T - t_i) \quad \ldots\ldots [13]$$

In addition to Equations [9] to [13], inclusive, a basic postulate usually made to relate the interface humidity and temperature is that H_i' is saturated at t_i . . . . . [14]

If over-all conductances f_c and f_D defined on the basis of the potentials $(T - t)$ and $(H_i - H)$, respectively, are used the necessity for Equations [13] and [14] vanishes and the rate Equations [11] and [12] are replaced by

$$G\,dH = -f_D\,(a\,dV)\,(H_i - H) \quad \ldots\ldots [15]$$

$$G\,s\,d\,t = -f_c\,(a\,dV)\,(T - t) \quad \ldots\ldots [16]$$

Unit Conductances

Unit conductances revealed in Fig. 5 are average over-all values. Since the packing shapes are staggered, at any tower deck approximately half the water rate will be in drop form. However, the drops for the most part were observed to possess relatively large diameters so that, even at water rates of 35 lb per hr per sq ft of packing surface, assuming a spherical drop diameter of 0.01 ft, the drop surface area would be about 6 per cent of the packing area. Also, since the results shown in Figs. 5 and 6 did not indicate any trend of f_D with water rate, if computed on the basis of a constant packing area of 418 sq ft, it was concluded that the effect of drop area was sufficiently small to be neglected.

The unit over-all diffusion resistance $1/f_D$ is the sum of the gas-film resistance $1/f_D'$, and an equivalent unit water-film resistance R_{DL}, introduced because f_D was based on H_i corresponding to the main-body-water temperature T, rather than on the interface temperature t_i.

The data on which Figs. 5 and 6 were based reveal no trend of f_D with water rate for a given air rate. This fact tends to indicate a constant value of R_{DL} with both air and water rates for, if the water-film resistance changes at all, it would be expected to change with water rate, and possibly also with the temperature conditions.

The presumption that f_D' varies as a power of G is reasonable and, since Fig. 5 also indicates that f_D varies as G^n, it follows that the magnitude of R_{DL} must be comparatively small if it is to remain constant as concluded.

There is some experimental evidence to the effect that mass-transfer coefficients vary as a power function of Reynolds' number in the same manner as do heat-transfer coefficients for similar flow systems (3, 4). Thermal convection data of Hughes (5) for a single streamlined shape, considerably more slender than the tower packing, indicated an exponent $n = 0.68$. The more recent data of Winding (6) for a bank of streamlined tubes yielded a value of $n = 0.42$. The slenderness ratio of the tube form used by Winding corresponded more closely with the tower packing than that of the shape used by Hughes. Thus the data of Winding appear to be more representative of the cooling-tower system under consideration in this paper, and the exponent 0.42 compares favorably with the slope of the unit conductance for mass transfer ln f_D versus ln G/S, curve Fig. 5, namely, 0.48.

The assumption of a constant liquid-unit resistance R_{DL}, equal to 10 per cent of the total unit resistance $1/f_D$ at a mean value of $G/S = 980$ lb per hr per sq ft, results in a unit thermal conductance f_D, varying exponentially with the 0.55 power of the Reynolds number. This magnitude appears high in comparison with the $n = 0.42$ from the data of Winding. The above assumption of the magnitude of R_{DL} also results in a logarithmic plot of f_D versus G, which possesses a slight curvature. This fact together with the larger average slope suggests that the water-film resistance is probably less than 10 per cent of the total.

The foregoing reasoning is not offered as conclusive proof of the comparatively small magnitude of the water-film resistance, but rather as an indication of its possible magnitude.

Considerable experimental evidence, obtained in part from psychrometric experiments (3), supports the Lewis equation

$$f_e' = s f_D' \quad [17]$$

for the air-water system only. The previously mentioned thermal film convection data of Hughes (5) and Winding (6) are compared with the experimental over-all diffusion data from the tower in Fig. 5, curves (*d*) and (*e*). Since the range of Reynolds' numbers for which the aforesaid data were given did not correspond to the tower values, a straight-line extrapolation of the logarithmic plot was used to determine the thermal unit film conductance f_e' over the desired range. The magnitudes so obtained were divided by the average air-mixture unit heat capacity $s = 0.25$ Btu per F per lb yielding the estimated unit film conductance for mass transfer f_D'. As may be seen from Fig. 5, curves (*d*) and (*e*) show agreement of about 10 per cent with the experimental f_D, curve (*a*). This comparison is good in view of the assumption made with respect to the magnitude of the perimeter used in Reynolds' number *Re*, and the fact that the data of Hughes refers to a single shape rather than to staggered banks.

Curves (*b*) and (*c*) of Fig. 5 reveal a comparison of the experimentally determined unit thermal conductances f_e, with the product of the mixture unit heat capacity s and the experimental unit mass-transfer conductance f_D. As may be seen the agreement is good at the lower air-mass velocities, but at $G/S =$ 1800 lb per hr per sq ft, sf_D is 40 per cent greater than f_e. An explanation of this difference may rest on the premise that small drops formed by splash are maintained or carried along by the air stream and suffer complete vaporization.

The unit over-all conductance f_e for thermal convection was computed subject to the assumption that the air-stream sensible-heat gain resulted from convection cooling of the main water body only. Thus the computed f_e may be considered an apparent value. As the complete vaporization of small drops requires the absorption of part of the sensible heat of the air stream, the net gain in sensible heat is less than the thermally convected transfer from the main water body, resulting in an apparent f_e smaller than the actual.

The small drop vaporization does not contribute to the cooling of the main water body, but merely changes the enthalpy distribution of the air stream so as to increase the latent-heat rate, $Gh_{fg}H$, at the expense of the sensible-heat rate, Gs $(t - 32)$. In effect, while the apparent unit conductance for heat transfer f_e is less than the true value, f_D as computed is greater than its true magnitude. However, as may be seen from Table 1, if small drop vaporization results, at the higher air rates, in a reduction of the air sensible-heat rate by about 4000 Btu per hr, the true f_D would be only about 5 per cent less than the computed values, whereas the true f_e would be 30 to 50 per cent greater than the apparent magnitudes, which is comparable to the product (sf_D).

The curves (*b*) and (*c*) of Fig. 5 indicate that the suggested effect of small drop vaporization increases with air rate, as shown by increasing difference between the f_e and sf_D curve ordinates. Further, at the low air-mass velocity of 530 lb per hr per sq ft, f_e is slightly greater than sf_D. At this rate, however, some fogging was apparent in the air stream issuing from the nozzle, and thus small drop condensation may serve completely to overcome the effect of small drop vaporization on the sensible-heat content of the air stream, and subsequently on the apparent unit conductance for thermal convection.

In normal cooling-tower operation thermal convection accounts for not more than 20 per cent of the energy transferred between phases. Thus an error of 20 per cent in the magnitude of f_e results in less than a 4 per cent error in the total energy exchange. If then, for the air-water system

$$f_e \cong s f_D \quad [18]$$

without any significant inaccuracy with respect to energy exchange, considerable simplification of the basic equations is possible. On this basis the rate Equations [15] and [16] combine with the energy-balance Equation [9] to yield

$$d\,[L\,c\,(T - 32)] = G dh = -f_D\,(a\,dV)\,(h_i - h) \quad [19]$$

This equation expresses the fact that the enthalpy difference $(h_i - h)$ of air saturated at the main-body-water temperature T and the unsaturated main air stream is the potential for energy exchange between phases; and f_D may be considered as the unit over-all conductance for this energy transfer. Equation [19] is not quite correct in that, when the potential is 0, thermodynamic equilibrium is not attained, for the liquid-water temperature is less than the dynamic-equilibrium wet-bulb temperature (2). As a result, the water temperature will tend to rise even though the net enthalpy transfer between phases is 0 at the 0 potential state. The temperature rise will continue until the wet-bulb temperature is reached. At this condition, a positive potential exists for which the enthalpy transfer from the liquid phase by evaporation exceeds the enthalpy transfer to the liquid phase, as a result of thermal convection, by the magnitude of the enthalpy of the liquid being evaporated.

For normal cooling-tower operation $c(T - 32)\,dL$ is about 3 to 4 per cent of $LcdT$ and, since c is constant, Equation [19], as a good approximation, may be written in the form

$$L_1\,c\,d\,T \cong G\,d\,h = -f_D\,(adV)\,(h_i - h) \quad [20]$$

This equation may be integrated if f_D = constant to yield

$$\frac{L_1 c}{G}\int_{T_1}^{T_2}\frac{dT}{(h_i - h)} \cong \int_{h_1}^{h_2}\frac{dh}{(h_i - h)} = \frac{-f_D\,aV}{G} \quad [21]$$

Equation [21] corresponds with the form of the equation defining the number of transfer units (2, 3, 7), a concept used in the design of absorption and extraction towers. The over-all values of the height of a transfer unit for the particular packing arrangement used in the tower are then

$$H\,T\,U = l/(f_D\,aV/G) \quad [22]$$

where l is the height of tower packing, 5.75 ft.

Table 1, column 24, lists the over-all values of the height of the tower transfer units, as computed from the experimental f_D. Fig. 6 summarizes the number of transfer units as based on average values of f_D at each air rate for those water rates sufficient to provide complete packing coverage.

It is seen, since f_D varies with the 0.48 power of the air-mass velocity, that the variation of HTU must be as the 0.52 power of G/S. Many of the data for gas-liquid systems, in which the gas-film resistance controls, correlate on the basis of the 0.8 power of gas-mass velocity or packing Reynolds number (3, 7, 8), rather than the 0.48 power as obtained for the packing used in the tower tested. This difference probably lies in the nature of the gas flow over a streamlined shape as compared to the flow over packings such as spiral tile, wood grid, broken quartz, and coke for which the 0.8 exponent was obtained. As is seen from Fig. 5, available thermal-convection data confirm the 0.48 exponent provided $f_D \cong f_e'/s$.

Effectiveness of Tower as an Energy Exchanger

If the water rate is infinite so that the water temperature T

remains constant, then the enthalpy at saturation h_i is constant and Equation [21] may be integrated, yielding

$$(h_i - h_1)/(h_i - h_2) = e^{-f_D aV/G}$$

or

$$\epsilon_h = \frac{G(h_1 - h_2)}{G(h_i - h_2)} = 1 - e^{-f_D aV/G} \quad [23]$$

The right-hand side of Equation [23] expresses the ratio of the gain in enthalpy rate $G(h_1 - h_2)$ of the air stream to the gain which would result in an infinite tower $G(h_i - h_2)$, for which the air would leave saturated at the entering-water condition. Since enthalpy changes represent the energy exchange between phases for the constant-pressure continuous-flow-tower system, this ratio is the tower effectiveness as an energy exchanger for the condition of constant water temperature T.

In the actual tower T is not constant but tends to approach the entering-air condition while descending over the packing. The degree of approach depends upon the potential for energy exchange and the water rate. Equation [23] suggests the form of an empirical expression which conforms to the experimental data of the actual tower. This form is given by Equation [5] and the empirically determined constants are as expressed by Equation [6]. For the experimental water rates, which resulted in complete packing coverage, Equation [6] is

$$\epsilon_h = 1 - 1.40\, e^{-f_D aV/G} \quad [24]$$

The coefficient 1.40 of this expression should not be constant but should be some function of the variation in water temperature throughout the tower, for in Equation [23], for constant water temperature, the magnitude is 1. The experimental data (see Fig. 7) are apparently of insufficient precision to reveal this variation in ϵ_h. However, the magnitudes of the effectiveness are not sensitive to the value of the multiplier K. For instance, for $\eta = 1$, the variation of ϵ_h about a mean of 0.50 is only approximately 7 per cent for $1.3 \leq K \leq 1.5$.

This consideration indicates that a single curve of effectiveness versus air-mass velocity (see Fig. 7 or Equation [24]) will serve as a performance characteristic for the tower within a limited operating range of water rates. The restrictions in the use of such a performance curve are expressed by Equations [7] and [8], and the additional fact that the water rate must be at least sufficient to give complete packing coverage.

With packing shapes which result in f_D, varying as the 0.8 power of the air-mass velocity, the variation of the number of transfer units would be to the —0.2 power of the air-mass velocity. As a consequence, a tower so packed would have an effectiveness as an energy exchanger which would not change greatly with air rate. For instance a threefold increase in air rate would result in but a 25 per cent decrease in effectiveness, ϵ_h for an initial value of $\epsilon_h = 0.5$.

Analytical Prediction of Tower Performance

The basic Equations [9] and [10], expressing energy and material balances, and the rate Equations [15] and [16], together with a knowledge of aV, f_D, f_c, c, and s will allow a prediction of tower performance for a given set of operating conditions. The solution may be accomplished in the form of a step integration, but such a procedure involves considerable labor. However, a proper algebraic combination of the equations mentioned, including the approximation $f_c \cong s f_D$, results in the expression

$$\int_{T_2}^{T_1} \frac{dT}{F(T)} = f_D \frac{aV}{G} \quad [25]$$

By plotting $\frac{1}{F(T)}$ as a function of T starting at one terminal value, say T_2, a trial-and-error solution for T_1 may be made which will give an area under the curve equal to the number of tower-transfer units at the given air rate $f_D\, aV/G$. This magnitude of T_1 establishes the tower-cooling range for the chosen operating conditions. The indicated integration can also be accomplished numerically.

Equation [25] was derived as follows: The energy-balance Equation [9] may be written, to a good approximation, as

$$L_1 c\, dT \cong G\, dh \quad [9a]$$

Integration from T_2 to T yields

$$h = h_2 + (T - T_2)\frac{(L_1 c)}{G} \quad [9b]$$

Then upon substitution into Equation [21], which combines the two rate Equations [15] and [16], the result may be expressed as

$$\int_{T_2}^{T_1} \frac{dT}{\frac{G}{L_1 c}(h_i - h_2) - (T - T_2)} = f_D \frac{aV}{G} \quad [26]$$

Since

$$h_i = s(T - 32) + h_{y_2} H_i$$

is a function of T only and h_2 is constant for a chosen entering-air condition, Equation [26] is of the form of Equation [25] where

$$F(T) = \frac{G}{L_1 c}(h_i - h_2) - (T - T_2) \quad [27]$$

The integration of Equation [26] in the manner described was performed for chosen magnitudes of air and water rates L_1 and G, entering-air state t_2 and H_2, and exit-water temperature T_2. The appropriate magnitudes of the number of transfer units $f_D\, aV/G$ were taken from Fig. 6, corresponding to the chosen value of air-mass velocity. No allowance was made for drop cooling for reasons previously mentioned. Table 2 and Fig. 9 summarize these computations made for water rates, L/aV of 17.2 and 34.4 lb per hr per sq ft referred to the packing area, for air-mass velocities, G/S, of 655, 1310, and 1865 lb per hr per sq ft referred to the flow cross section, and various initial air states and exit-water temperatures.

34.4	1310	85.0	70.0	0.01	9.4	0.565	18.9	18.6	−1.6
34.4	1960	85.0	70.0	0.01	13.8	0.455	22.8	22.2	−2.6

$S = 5.5$ sq ft.
$aV = 418$ sq ft.

The comparison shown in Fig. 9 confirms the previous conclusion that the constant K of Equation [5] depends upon the variation of water temperature T, which in turn is a function of the water rate and driving potential. At the higher water rates, the water temperature changes less than for the lower water rates with the same terminal potential at the water-exit section. Thus, as a consequence, the effectiveness ϵ_h, is higher, approaching the value pertaining to a constant water temperature, Equation [23]. With an increase in enthalpy potential, as obtained by decreasing either or both t_2 and H_2, or increasing T_2, the water-temperature variation is greater (for a given water rate) and the effectiveness is thereby reduced, approaching the magnitude given by Equation [24].

A value of $K = 1.25$ in Equation [5] ($\eta = 1$) results in an empirical expression adequately representing the predicted performance for the higher water rate, while $K = 1.5$ is required for $L/aV = 17.2$ lb per hr per sq ft.

If the logarithmic mean of the enthalpy terminal potentials, Δh, serves to approximate the average potential with respect to energy exchange between phases, then a further simplification in predicting cooling-tower performance is possible, for Equation [21] may be integrated, yielding

$$\frac{h_1 - h_2}{\Delta h} = \frac{f_D a V}{G} \quad \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

The prediction of the tower performance as an energy exchanger is then strictly analogous to the computation for a counterflow heat exchanger for which flow conditions and terminal states at either section 1 or section 2 are chosen. For instance, the following is a computation procedure which may be used:

(*a*) Choose h_2, T_2, G, and L_1.

(*b*) Determine f_D, and hence $f_D\, aV/G$ from the flow conditions.

(*c*) Estimate h_1.

(*d*) Compute h_{i1} corresponding to T_1 as determined from the energy-balance equation

$$L_1 c\,(T_1 - T_2) + (L_1 - L_2)\,c\,(T_2 - 32) = G(h_1 - h_2) \cong L_1 c(T_1 - T_2)$$

(*e*) Compute the logarithmic mean

$$\Delta h = [(h_{i1} - h_1) - (h_{i2} - h_2)]/\log_e \frac{(h_{i1} - h_1)}{(h_{i2} - h_2)}$$

(*f*) Substitute Δh in Equation [28] to verify the initial assumption of h_1. If this value does not result in an identity repeat the procedure with a new estimate of h_1.

(*g*) On establishing h_1 for the given conditions the energy exchange between phases is $G\,(h_1 - h_2)$.

The use of the logarithmic mean of the terminal potentials, while not exact, is justified as a good approximation. This conclusion may be verified by comparing the enthalpy conductances f_D, employed in the graphical integration Equation [26], with f_D computed from the logarithmic-mean terminal potentials, using the predicted conditions at section 1. The comparison, as outlined, was made for the conditions given in Table 2 and is indicated in the last three columns. As may be seen, the agreement for the most part is well within 3 per cent.

Conclusions

On the basis of the experimental results and the foregoing analysis, the following conclusions may be drawn:

1 For the cooling-tower air-water system in which the gas film presents the controlling resistance, over-all conductances for diffusion may be estimated from film conductances for thermal convection obtained from similar flow systems.

2 The correlation of tower effectiveness, as an energy exchanger versus air rate (or the number of transfer units), may be used as a performance curve for approximating either energy exchange or tower cooling. However, the application of a single curve is restricted to a limited operating range of water rates.

3 The basic transfer equations are simplified by the introduction of the approximation $f_e \cong sf_D$. Any error so introduced is not significant with respect to energy exchange in normal cooling-tower operation. This simplification results in an energy-transfer-rate equation, which uses as a potential the enthalpy difference between the main gas stream and saturated-air conditions at the main-water-body temperature. The equation so obtained may be readily integrated by graphical or numerical methods allowing a prediction of tower performance, providing the number of transfer units, $f_D \dfrac{aV}{G}$ is known.

4 The use of a logarithmic-mean enthalpy potential, based on terminal states, is a good approximation to the actual average with respect to energy exchange. This fact allows further simplification of performance calculations, the resultant procedure being analogous to the method now in general use for predicting counterflow heat-exchanger behavior.

Acknowledgments

The analysis presented herein is based upon test data obtained by A. L. London, W. E. Mason, M. L. Hilleger, and H. E. Brown. The tests form a portion of a cooperative cooling-tower research program, supported jointly by the American Society of Heating and Ventilating Engineers, the Air Conditioning Society of San Francisco, and the University of California. The tower was made available through the efforts of Edward Simons of the Redwood Manufacturers Company. The installa-

tion of the measuring equipment was performed under the direction of H. L. Eagles and T. H. Morton, assisted by WPA under the University of California Project No. 8850. Technical assistance was rendered by E. D. Howe, H. B. Nottage, and the late V. H. Cherry of the staff of the department of mechanical engineering. The authors are grateful to the cooperating agencies and the individuals who contributed to the completion of the task.

Quantitative Analysis of Single-Capacity Processes

By ALBERT F. SPITZGLASS,[1] CHICAGO, ILL.

This paper is a continuation of a previous one[2] in which the author gave methods of quantitative analysis for five types of single-capacity processes with three types of regulators. The present paper analyzes and compares the various equations obtained in the previous paper and lays the basis for critical analysis of the entire subject.

Concrete examples are utilized as a basis for the graphical analysis to complement the mathematical analysis. A number of criteria are discussed critically to emphasize the importance of each, and examples are cited to indicate the light that each of the criteria is capable of shedding on the entire problem. Derivations and solutions of important factors are given in an Appendix.

IN THE author's previous paper[2] on the same subject, "single-capacity systems" were discussed together with the "hydraulic analogy" for continuous processes. To review, a single-capacity system consists of a single storage of energy, bounded by two resistances to flow of energy and characterized by a single potential level. It has the unique characteristic that any change in supply or demand immediately causes a measurable change in the potential level. Three basic types of regulators were considered and equations were derived to characterize the reaction of various combinations of these regulators and single-capacity processes to a "standard sudden disturbance." The equations describing these reactions were tabulated and in general it was shown that these reactions depend on (*a*) the mechanical constants of the regulators, and (*b*) the physical constants of the process such as its reaction time and the degree of self-regulation.

In this present paper the solution of the afore-mentioned equations will be considered and with the aid of concrete numerical examples certain general conclusions will be drawn. It is important to keep in mind the limiting assumptions made in the previous paper, so that the results herein described will not be generalized beyond their legitimate scope.

Scope of the Mathematical Solutions to Be Studied

The reaction equations in the previous paper[2] were expressed as differential equations of the first, second, and third order. This present paper deals only with the solution of equations of the first and second order, and excludes, therefore, certain combinations of floating-plus-proportional regulators even though combined with single-capacity processes.

The nomenclature given in the previous paper is repeated here in Table 1 for convenience, but a column is added to show the equivalent symbols used by Mason.[3] Mason's work is concerned mainly with multiple-capacity processes and if accurate substitution of equivalent terms is made, exact mathematical agreement between Mason's and the author's equations will result. Note that Mason does not bring in the concept of load z or of the initial flow condition Q. This is not the result of any conflict of theory, but results merely from his using purely quantitative units for flow equations instead of dimensionless ratios.

There are certain special cases of proportional-plus-floating regulators with single-capacity processes which can be expressed as second-order differential equations. The most important

[3] "Quantitative Analysis of Process Lags," by C. E. Mason, Trans. A.S.M.E., vol. 60, 1938, paper PRO-60-1, pp. 327–334.

special case is that based on the assumption that the regulator traversing time T_s is negligible as compared to the other time factors involved. A glance at the equations in Table 9 of the previous paper[2] shows that the coefficients of the third-order term always include as a factor, T_s; therefore, when this is a negligible factor, the third-order term drops out entirely. This leaves a second-order equation which could be analyzed with the direct methods of solution. This equation

$$\phi'' + \frac{1}{\theta T_a}\phi' + \frac{1}{\theta T_a T_F}\phi = 0 \quad \ldots\ldots[1]$$

is important, but not of sufficient significance to warrant separate consideration; therefore, the entire critical analysis of floating-plus-proportional regulated systems must be reserved until the subject can be treated in its entirety.

The Solution of Third- and Higher-Order Equations

Mason[3] has suggested an extension of the hydraulic analogy which the author feels offers the best solution for this type of third-order equation as well as equations of still higher order. Instead of considering these time factors as elements of the regulator equation, they are included as elements of the process and the regulator is assumed to perform its functions instantaneously. A single-capacity process analyzed this way becomes a multiple-capacity process, and it actually makes no difference whether these reaction times or "time lags" are introduced by the process or the regulator.

This method of analysis might have been used on the proportional regulator in connection with single-capacity processes. This would give a first-order equation for all such single-capacity processes and there would be no stability problem to consider. However, since the proportional regulator is frequently used on single-capacity processes of low natural period, the traversing time T_s too often plays a very significant role; therefore, the form in which the equation is considered by the author represents a very important class of process. Since this can be analyzed by direct solution it is included in this analysis. At a later time, when all modes of solutions have been publicized, it will be easier to decide which of the two methods is the more logical approach to the solution of regulation equations.

The following combined regulator and process equations, derived in the author's previous paper,[2] will be discussed in detail.

Processes Without Self-Regulation:

Floating

$$\phi'' + 0 + \frac{1}{\delta T_s T_a}\phi = 0 \quad \ldots\ldots[2]$$

Proportional

$$\phi'' + \frac{\theta}{\delta T_s}\phi' + \frac{1}{\delta T_s T_a}\phi = 0 \quad \ldots\ldots[3]$$

Processes With Self-Regulation:

Floating

$$\phi'' + \frac{ze}{T_a}\phi' + \frac{1}{\delta T_s T_a}\phi = 0 \quad \ldots\ldots[4]$$

Proportional

$$\phi'' + \left(\frac{ze}{T_a} + \frac{\theta}{\delta T_s}\right)\phi' + \frac{1}{\delta T_s T_a}\phi = 0 \quad \ldots\ldots[5]$$

These equations all take the general form

$$\phi'' + 2c\phi' + c_0\phi = 0 \quad \ldots\ldots[5a]$$

Note that the coefficient c_1 of the previous paper has been replaced by $2c$. This change was made for convenience since this coefficient always appears as $c_1/2$ in the solutions. It is obvious that the entire characteristics of the equation and oscillation depend on the values of c often referred to as the "damping coefficient," and c_0. The relative value of these two coefficients determines all the stability conditions and the absolute values determine the other factors such as amplitude and period.

The damping coefficient of each of the Equations [4] and [5] contains the term ze/T_a which is not present in Equations [2] and [3]. This term represents the effect on the process of the self-regulation of the system. The other term ($\theta/\delta T_s$ in Equation [5]) represents the damping due to the regulator itself. Equation [4] has no regulator damping term, showing that a floating regulator depends entirely on the process for its stability.

The self-regulation of a process is defined as the tendency of a process, after it has been disturbed, to balance input and output energy flows, as a result of the change in its potential level.

Two types of self-regulation are discussed by Stein and Wünsch,[4,5] namely, (*a*) back-pressure damping and (*b*) flow damping. The latter is caused by flow resistance occurring within the system and consequently presupposes a multiple-capacity system. The former only concerns itself with condition changes (pressure, in this case) across the supply and discharge resistances, and therefore, refers to single-capacity systems. Therefore, only back-pressure self-regulation will be considered at this time.

It will be shown that the relation of the two coefficients determines the type of vibration which will occur and that this may fall into two general classes, each of which gives rise to three specific types.

Thus, aperiodic regulation results:

(*a*)	If reaction time $T_a = 0$	$c = 0$	Floating or proportional
(*b*)	If traversing time $T_s = 0$	$c = 0$	Proportional regulator only
(*c*)	If very large damping exists	$c^2 \geqq c_0$	All types

Periodic regulation (vibration) results if $c^2 \geqq c_0$, and may be either of three types. From the Appendix the solution for ϕ, when $c^2 \geqq c_0$, is given by

$$\phi = Ae^{-ct}\sin mt \quad \ldots\ldots[6]$$

Therefore, if

(*d*)	$c > 0$,	e^{-ct} decreases with time	Damped vibration
(*e*)	$c = 0$,	$e^{-ct} = 1$	Sustained vibration
(*f*)	$c < 0$,	e^{+ct} increases with time	Resonant vibration

Since cases (*e*) and (*f*) do not represent practical solutions, we will not concern ourselves with them any further. If they occur at all, the values of c must be revised until they are greater than zero.

Cases (*a*) and (*b*), in which the second-order term drops out, revert to the first-order equation

$$c_1\phi' + c_0\phi = 0 \quad \ldots\ldots[7]$$

whose solution is very easily obtained as

$$\phi = e^{-(c_0/c_1)t} \quad \ldots\ldots[8]$$

It is necessary to consider in detail then only the two cases,

[4] "Regelung und Ausgleich in Dampfanlagen," by T. Stein, Julius Springer, Berlin, 1926. Also: "Selbstreglung ein neues Gesetz der Regeltechnik," by T. Stein, *Zeitschrift des Vereines deutscher Ingenieure*, vol. 72, Feb. 11 and 18, 1928, pp. 165 and 209.

[5] "Regler für Druck und Menge," by G. Wünsch, R. Oldenbourg, Munich, 1930.

where the second-order term remains and where $c > 0$. These two cases require individual treatment and differ only in the relative values of c and c_0.

Solution of Aperiodic Processes ($c^2 \geqq c_0$)

From the Appendix we get as the solution of these aperiodic processes

$$\phi = \phi'_0 \times \frac{1}{2\sqrt{(c^2 - c_0)}} \left(e^{\omega_1 t} - e^{\omega_2 t}\right) \quad [9]$$

or

$$\phi = Ae^{\omega_1 t} - Ae^{\omega_2 t} \quad [10]$$

where

$$\phi'_0 = qz/T_a \quad [11]$$

is the initial rate of change of the variable expressed by Equation [1], and

$$\omega_1 = -c + \sqrt{(c^2 - c_0)} \quad [12]$$

$$\omega_2 = -c - \sqrt{(c^2 - c_0)} \quad [13]$$

These roots are real, since the radical is positive and ω_1 is always larger than ω_2; therefore, the sign of ϕ never changes and it always remains at one side of its equilibrium value and reaches this value, $\phi = 0$, when $t = \infty$.

It is possible to calculate the maximum amplitude of the variable deviation, which, from the Appendix, is

$$\phi_{max} = \phi'_0 \frac{1}{2\sqrt{(c^2 - c_0)}} \left[e^{\frac{\omega_1 \log (\omega_2/\omega_1)}{\omega_1 - \omega_2}} - e^{\frac{\omega_2 \log (\omega_2/\omega_1)}{\omega_1 - \omega_2}} \right] \quad [14]$$

This solution is obviously rather unwieldy, but the analysis can be very easily converted to a graphical one which gives a complete solution.

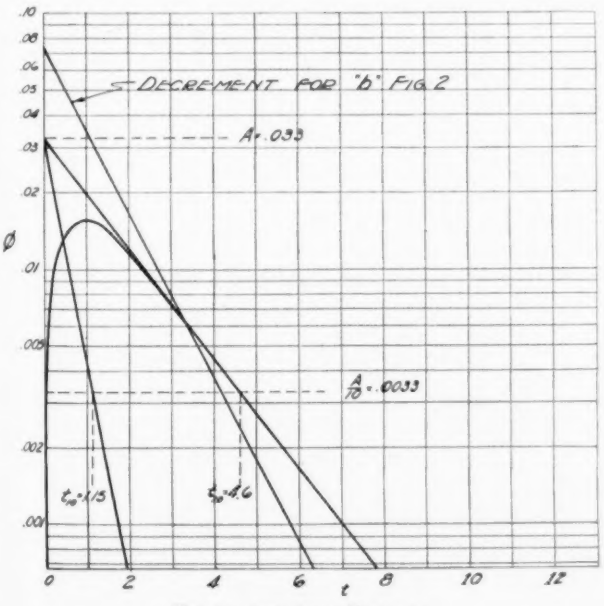

Fig. 1 Aperiodic Damping

Equation [10] consists of two distinct terms $Ae^{\omega_1 t}$ and $-Ae^{\omega_2 t}$. These exponential functions are very readily plotted on semilog paper. Fig. 1 shows a plot of example 1, a typical single-capacity process, which is solved as follows:

Example 1: Proportional Regulator—No Self-Regulation. Let $\theta = 0.25$, $\delta T_a = 0.10$, $T_a = 10$, $z = 0.5$, $c = \dfrac{\theta}{2\delta T_a} = 1.25$, and $c_0 = \dfrac{1}{\delta T_a T_a} = 1.0$. Then

$$\phi'_0 = qz/T_a = (1 \times 0.5)/10 = 0.05$$

$$A = \phi'_0 \frac{1}{2\sqrt{(c^2 - c_0)}} = \frac{0.05}{2\sqrt{(1.25^2 - 1.0)}} = 0.033$$

This represents the value of ϕ when $t = 0$, and is plotted as the initial ordinate.

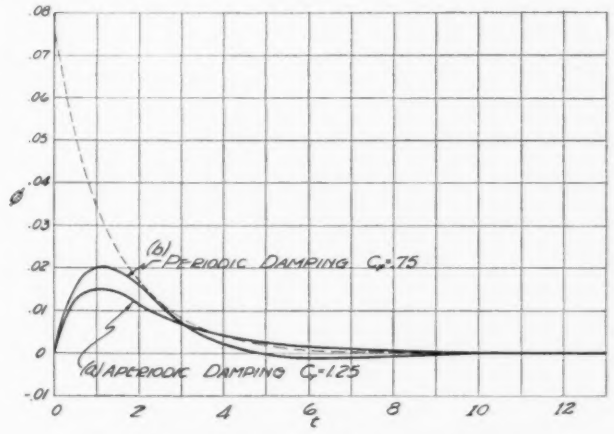

Fig. 2 Aperiodic and Strong Periodic Damping

The slope of the two curves is easily determined by solving for the time (t_{10}) required to reduce the variable to one tenth its initial value. Since the initial value of $e^{\omega t} = 1$, when $t = 0$, the time for $e^{\omega t} = 0.1$, or t_{10}, is obtained by solving directly for t in this last equation. That is, since $e^{\omega t} = 0.1$

$$t = \frac{1}{\omega} \log_e 0.1 = -\frac{2.3026}{\omega} \quad [15]$$

Now

$$\omega = -c \pm \sqrt{(c^2 - c_0)}$$

Therefore, in the example

$$\omega_1 = -1.25 + \sqrt{(1.25^2 - 1.0)} = 2.0$$

and

$$\omega_2 = -1.25 - \sqrt{(1.25^2 - 1.0)} = 0.5$$

Therefore

$$t_1 = \frac{-2.3026}{-2} = 1.15 \text{ sec}$$

and

$$t_2 = \frac{-2.3026}{-0.5} = 4.6 \text{ sec}$$

These values are plotted for values of $\phi = A/10$ or 0.033 and the total value of ϕ is obtained by subtracting the first curve from the second giving the resultant curve below from which any derived data may be taken directly.

Fig. 2 is a replot of this resultant curve on standard coordinates to bring out the more familiar contour of the aperiodic vibration.

Solution of Periodic Oscillating Processes

By far the most common and most significant group of proces-

ses are those that fall between the limits $c > 0$, and $c^2 \leqq c_0$, and whose equation of change is characteristic of a damped periodic oscillation.

The solution of this equation differs from that of the aperiodic process in that the roots are imaginary (see Appendix) and is represented by the typical equation for a damped oscillation, that is

$$\phi = Ae^{-ct} \sin mt \quad [6]$$

In Fig. 3 a typical process following this law is plotted. In the figure, the three factors fundamental to every damped vibration are clearly shown. These are

A, the initial or zero intercept of the decrement curve.

e^{-ct}, the "logarithmic decrement" or the curve representing the damping effect.

$\sin mt$, the factor that imparts the periodic character to the vibration, where $m = \sqrt{(c_0 - c^2)}$ radians per sec.

The constants c and m are determined directly by referring to the coefficient of ϕ' in the combined equation.

Note that the value of e^{-ct} reaches zero only at $t = \infty$. Therefore, in all regulator motions that damp out (periodic or aperiodic), the regulator continues to vibrate indefinitely, although with constantly decreasing amplitude. The fact that in practice the regulator actually stops in a finite time indicates the presence of a "dead zone" within which mechanical forces such as friction are sufficient to overcome the residual working forces in the power element of the regulating mechanism.

The Initial Coefficient A. This coefficient is obtained by analyzing the conditions that exist when $t = 0$, at which time

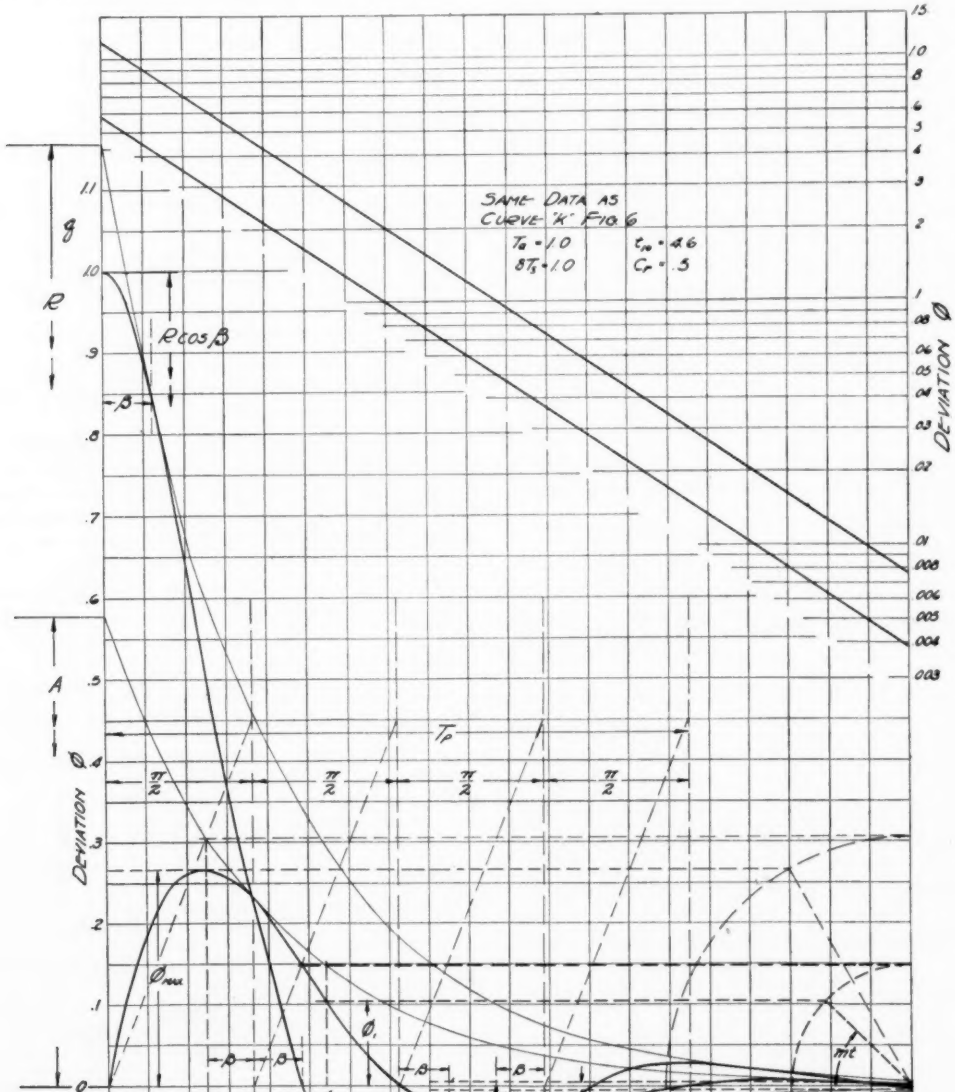

FIG. 3 GRAPHICAL ANALYSIS OF REGULATOR VIBRATION

$\phi = A$. The rate of change of ϕ or ϕ' is obtained by differentiating Equation [6] thus

$$\phi' = -Ace^{-ct} \sin mt + Ae^{-ct}\, m \cos mt \quad [16]$$

and at $t = 0$, $\sin mt = 0$, $e^{-ct} = 1$, $\cos mt = 1$, and $\phi' = \phi'_0$.

Therefore

$$\phi'_0 = Am \quad [17]$$

or

$$A = \phi'_0/m = zq_0/mT_a \quad [18]$$

The plotting is simplified greatly by first drawing in the decrement curve Ae^{-ct}. To do this an auxiliary curve is first drawn on semilog paper to the same time scale, as in Fig. 3. Ae^{-ct} is represented by a straight line in these coordinates, starting at A, for $t = 0$, and passing through $A/10$ at a time t_{10} sometimes referred to as the "time for tenthing," or "interval."[6]

Time for Tenthing. This time t_{10} is determined by calculating the time required to give 0.1 A. Thus

$$0.1\,A = Ae^{-ct_{10}} \quad [19]$$

or

$$0.1 = e^{-ct_{10}}$$

therefore

$$t_{10} = \frac{\log_e 0.1}{c} = \frac{2.3026}{c} \quad [20]$$

This defines the straight-line decrement on the semilog paper and the points can be projected along the time ordinates to the standard coordinates. The periodic curve is then generated graphically, the individual points being determined by multiplying the ordinate at any time t by its corresponding sine function.

The mathematical solutions for the various critical points of the curve will be given together with the discussion of its qualitative aspects.

Maximum Deviation. This deviation Q_{max} is sometimes the most significant quantity we have to determine, and is not quite as simple a function to calculate in the case of damped vibration as it would be if the variable followed an ordinary sine curve. Its value is obtained by differentiating Equation [16], which gives the following form, and equating ϕ' to 0. Thus, Equation [16] becomes

$$\phi' = Ae^{-ct} \cos(mt + \beta) = 0 \quad [21]$$

where

$$\beta = \tan^{-1}(c/m) \quad [22]$$

Therefore, mt must equal $(\pi/2 - \beta)$ in order that $\phi' = 0$, and β is the angle by which ϕ_{max} precedes the tangent point to the decrement curve, which occurs at $\pi/2$.

Solving Equation [6] for this value, $t = (\pi/2 - \beta)$ gives

$$\phi_{max} = Ae^{-\frac{c}{m}\left(\frac{\pi}{2}-\beta\right)} \cos\beta \quad [23]$$

where $\cos\beta = m/\sqrt{c_0}$.

The Period T_p. This is the time for 2π radians, or one complete cycle, that is, $mt = mT_p = 2\pi$. Therefore

$$T_p = \frac{2\pi}{m} = \frac{2\pi}{\sqrt{(c_0 - c^2)}} \quad [24]$$

[6] "Automatic Regulators, Their Theory and Application," by E. S. Smith, Trans. A.S.M.E., vol. 58, 1936, paper PRO-58-4, pp. 291-303.

The period is a constant quantity for a damped vibration, regardless of the disturbance or the time, although the vibration is not symmetrical. The zero intercepts occur successively at 0, π, 2π, etc., but the maximum amplitudes precede the points $\pi/2$, $(3/2)\pi$, etc., by the angle β. It actually takes the variable longer to get back to equilibrium than to reach its maximum departure, even though the cycle is perfectly isochronic.

This, incidentally, is true for all processes with continuous-type regulators, which represents another point of distinction between them and the discontinuous types, such as the two-position regulator. The period of such a discontinuous regulator varies with time as well as with the extent of the disturbance.

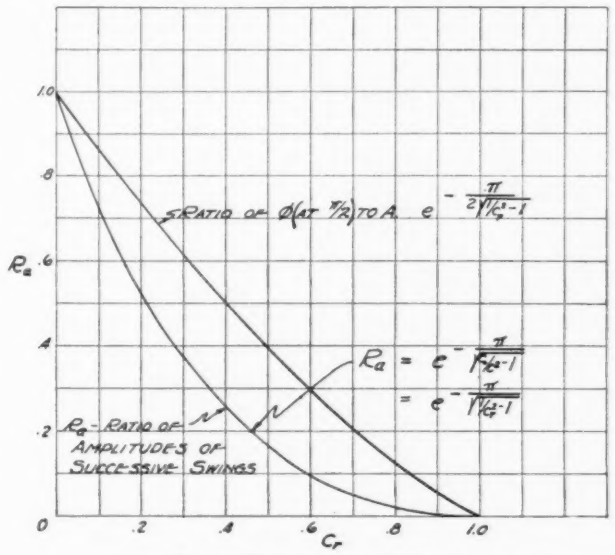

FIG. 4 RATIO OF AMPLITUDES

Ratio of Amplitudes. The ratio of any two successive amplitudes R_A is a very good criterion for stability, and may be represented by the two values ϕ_2/ϕ_{max}. This ratio is equal to the decrement for t = one half swing = $T_p/2 = \pi/m$, that is

$$R_A = \phi_2/\phi_{max} = e^{-c\frac{\pi}{\sqrt{(c_0 - c^2)}}} \quad [25]$$

$$R_A = e^{\frac{-\pi}{\sqrt{\frac{c_0}{c^2} - 1}}} \quad [26]$$

Damping Constant C_r. To simplify matters, the ratio of amplitudes R_A is plotted against a damping constant $C_r = c/\sqrt{c_0}$ as in Fig. 4. This constant C_r is a much simpler function to calculate than R_A and it has therefore been suggested by Wünsch[5] as the logical single criterion for the stability of a process (as a substitute for the more involved function R_A).

Fig. 4 presents the case where C_r is 0.5 and R_A is 0.16, which according to Wünsch[5] is a convenient criterion for good damping. If R_A is 0.16 then a disturbance is reduced to $(0.16)^2$ or 2.56 per cent in one full oscillation (two half swings), which can usually be considered as satisfactory damping. We shall investigate, however, to determine whether this is a sufficiently general criterion by which to judge the entire regulation process.

The values of C_r for typical regulator and processes are

Regulator	No self-regulation	Self-regulating process
Floating.....	0	$\frac{ze}{2}\sqrt{\frac{\delta T_a}{T_a}} = C_r$

TABLE 2 DATA FOR FIGS. 5 AND 6[a]

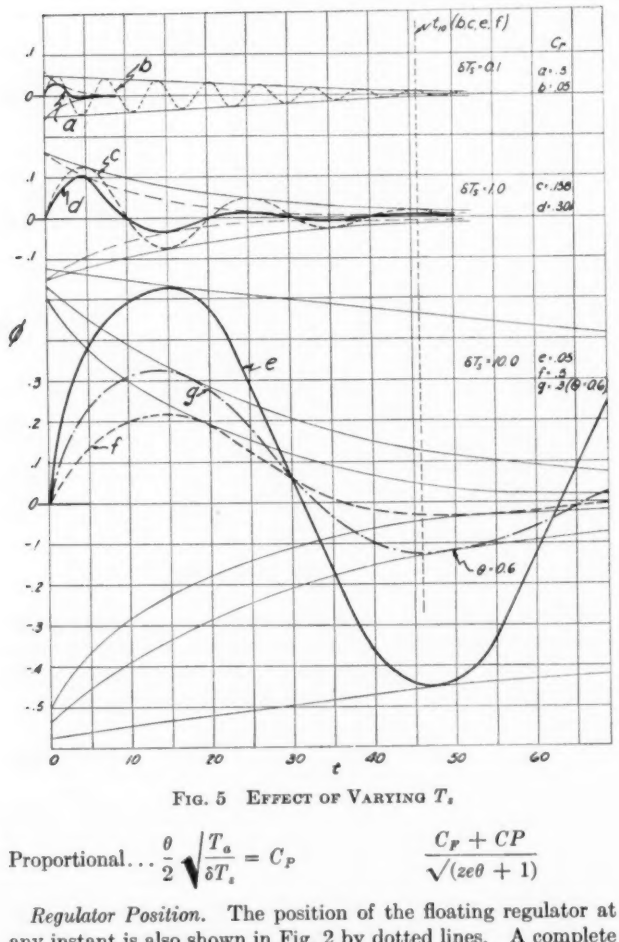

FIG. 5 EFFECT OF VARYING T_s

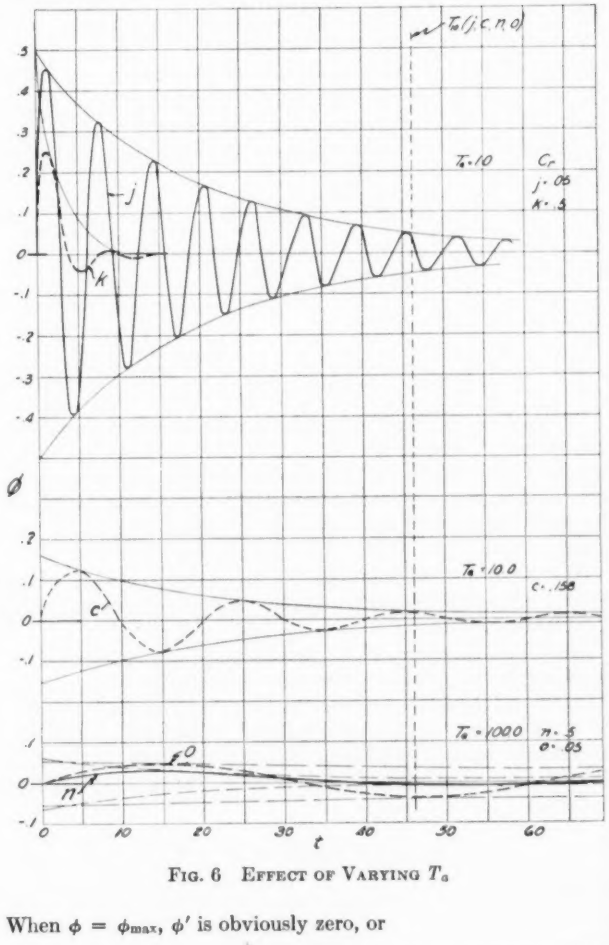

FIG. 6 EFFECT OF VARYING T_a

Proportional... $\frac{\theta}{2}\sqrt{\frac{T_a}{\delta T_s}} = C_P$ $\qquad$ $\frac{C_P + CP}{\sqrt{(ze\theta + 1)}}$

Regulator Position. The position of the floating regulator at any instant is also shown in Fig. 2 by dotted lines. A complete discussion of the regulator position is not possible here, but several interesting aspects are worthy of note.

The phase relation between the position, which is referred to in terms of the supply flow q, it produces, and the variable ϕ, is not 90 deg as might be expected, but 90 deg — β. The angle β is negligible only when the damping is negligible, as in a sustained oscillation.

Another point to notice is that the regulator does not go through its equilibrium position when the variable reverses, or ϕ_{max}, because the nature of the process has made the supply flow decrease, and the discharge increase, each by an amount depending upon the change in ϕ. Where $e = 2$, that is, when supply and discharge self-regulation effects are equal, ϕ_{max} corresponds to a position of the valve $q = \phi e = 2\phi$ from the equilibrium position. This valve position can be checked from the process equation

$$T_a \phi' = q - \phi e \qquad [27]$$

When $\phi = \phi_{max}$, ϕ' is obviously zero, or

$$q = \phi e \qquad [28]$$

If no self-regulation existed and a proportional regulator were shown, then the regulator would go through zero at ϕ_{max}.

EXAMPLES OF REGULATED PROCESSES

The more the question of regulation is investigated, the more it becomes evident that the process and regulator are part of one inseparable problem, and that their reactions must be studied together to lead to the most useful conclusions. To illustrate this, Fig. 5 has been drawn so that several regulator characteristics are compared with reference to a single process, and Fig. 6, so that a variety of processes are compared for a single regulator. Data for Figs. 5 and 6 are given in Table 2.

The curves show the effect of a sudden "supply" disturbance, caused by unbalancing the regulator an amount equal to q, and then letting the system come back to equilibrium. Therefore,

there is no change in load. It must be kept in mind that the change in the variable with load for the proportional regulator cannot be detected on these curves although its effect on the vibration is taken into account.

These curves have been verified experimentally by several observers and substantial agreement established, well within the required limits of accuracy.

Effect of Regulator Speed or Traversing Time T_s. The traversing time T_s which is the reciprocal of the regulator speed and δ, the pilot valve or speed characteristic, are found together in all the equations. Their combined effect will, therefore, be considered under the heading of effect of regulator speed.

Since δ is the value of ϕ at which the regulator will travel at full speed, discontinuity results whenever ϕ is larger than δ, and the speed does not increase any further. This happens only when very large disturbances occur but if it does, the reaction that takes place is neglected in the calculations while ϕ is greater than δ. As soon as the regulator has traveled sufficiently to bring ϕ within this range, then the equations are applicable. This imposes another set of limitations on the analysis. It is not a serious one, since, even under extreme conditions, the process gets back into this range in a relatively short time. If it does not, then the value of δ itself should be increased even though the product δT_s is satisfactory.

The term δT_s is the theoretical time per 1 per cent of stroke when $\phi = 1.0$. Of course, this time is never attained because ϕ never gets larger than δ, which is always a fraction, but it is an important quantity because as long as ϕ stays within δ we can imagine that the maximum regulator speed will finally go to this value, and treat it as the theoretical maximum speed.

Proportional Regulator Speed. Fig. 5 shows six cases for the same process having 10 sec reaction time, in which both extremes of stability and accuracy are obtained by varying the regulator characteristics. Thus, curve *a* shows a very stable regulation process with a proportional regulator that also gives a good deviation characteristic. An extremely fast regulator is required, however, one with a δT_s of 0.1 sec or a speed of 1 sec per stroke.

Curves *c* and *e* illustrate what occurs when the proportional regulator is slowed up 10 times and 100 times, respectively. The last two curves show a much lower stability, longer period and "time for tenthing," and much larger ϕ_{max}. These curves emphasize the importance of speed in proportional regulators and show why it cannot be neglected as a factor.

Curve *n* in Fig. 6 shows what the regulator of same T_s as curve *c*, or 10 sec, does on a process with longer reaction time. Obviously, the result is much improved, since the speed of the regulator, relative to that of the process has been increased. Therefore, it becomes obvious that the regulator speed must be considered in its relation to the other constants of the process.

Floating-Regulator Speed. If the process possesses self-regulation and a floating regulator is to be used, then the effect of the speed on damping is quite the opposite to the effect for proportional regulators. Thus, curve *f* in Fig. 5 shows that with the slowest of all the regulators in the figure, very strong damping results. As a matter of fact, speeding up the regulator has the effect shown in curve *b*, namely, the regulator is acting so fast that the self-regulation of the process has insufficient time to take effect strongly; consequently, a bad oscillating condition results.

Combined Effect of Proportional Regulation With Process Self-Regulation. When a proportional regulator is used on a system having strong self-regulation, as in curve *f*, the added damping due to the proportional characteristic is negligible. Likewise, if the proportional damping is very strong, then the added damping due to the self-regulation is negligible.

The third case, however, in which both regulator damping and self-regulation are rather weak, is shown in curves *c* and *d*. The factor $\theta/\delta T_s$ for the proportional-regulator damping coefficient equals 0.1 and ze/T_s, the self-regulation damping coefficient equals 0.1. Consequently, the two curves are identical and do not exhibit great stability, as shown by curve *c*. Curve *d* shows the effect of plotting the sum of these two effects, or a combined coefficient of 0.2; the result is considerably more stable than curve *c*.

This does not happen if we combine the damping of curve *b* with *a* because it is so negligible compared to *a* that it would not change the characteristic of the more strongly damped curve. A simple calculation bears this out.

It must be kept in mind that we cannot always use the combined equation since not all processes exhibit self-regulation due to discontinuity in the process, even though the constants of the process appear to be favorable. A process having pressure drops greater than critical is a case in point. Therefore, we may state the following as a practical and general résumé of the foregoing comments:

(*a*) If the damping due to self-regulation of the system be strong, the addition of a proportional characteristic will not improve the result but will merely introduce the error due to the band (droop or characteristic).

(*b*) If the damping due to self-regulation be weak, and a strong regulator damping be required, then the effect of the self-regulation of the system would be negligible and disregarding it in the calculation would introduce no serious error.

(*c*) If the self-regulation of the system be moderate (C_r = 0.15 to 0.3) and a regulator damping of about the same amount be required, then the total damping would be approximately the algebraic sum of the two.

For example, in curve *c* the C_r of the process exhibiting self-regulation equals 0.158, and the C_r of the regulator damping equals 0.158. For the combined process the value of C_r is 0.302, or approximately the sum of the two.

On the other hand, C_r for curve *e* equals 0.05 while for curve *f* it is 0.5, and the vector sum equals 0.52 which would give practically the same curve as curve *b*.

Effect of Reaction Time T_a. Fig. 6 presents a parallel analysis in which a single regulator characteristic is applied to three processes having widely different reaction times. As in the first figure, we see that the larger time constants of the process cause an appreciably larger period of vibration. Again the effect of the reaction time is considerably different depending upon whether a floating or proportional regulator is considered. Curve *j* shows how unstable a proportional regulator would be on a quickly responding process. Of course, this does not mean that a proportional regulator could not be made to work on this process, but its speed in order to be satisfactory would have to be increased about 100 times. For the speed shown, which is fairly high for normal regulator practice, the regulator hunts considerably.

On the other hand, with a large reaction time of 100 sec the proportional regulator gives a very small deviation and strong damping, although a very long period. Again this is largely due to the fact that the relative speed of the regulator is very high.

Where self-regulation is present, the floating regulator curve *k* damps out very quickly although the relative speed is still such that considerable deviation of the variable occurs. As a matter of fact, on a process having such a low reaction time, tremendous speeds of a different order entirely from those customarily used would be required if in addition to strong damping it was necessary to hold the maximum deviation of the variable within narrow limits.

On the system shown in curve *o*, the floating regulator shows practically no damping at all and ordinarily would continue this oscillation indefinitely. The oscillation is not very large, it is

true, but this is merely because the system has such large capacity that it would change very slowly even if no regulator at all were applied. Although the variable does not oscillate much, the regulator itself moves almost wide-open and closed. As a matter of fact, the results shown in curve *o* would not be the best solution even if they were not objectionable, since the simpler two-position regulator could be made to give results which are equally as good, if not better, provided the load variations were not too great.

The Effect of Proportional Characteristic θ. When the speed of a proportional regulator is insufficient and the process exhibits no self-regulation, then the values of θ must be increased as shown in curve *g*. Curve *g* shows a fair stability characteristic but a θ of 0.6 is required and this, of course, introduces considerable variation of the variable with change of load. This is not nearly so satisfactory a solution as speeding up the regulator as illustrated in curve *a*. Even curve *c*, which is relatively unstable, is better in some ways than curve *g*, due to the shorter period, since the actual deviation is less and of shorter duration.

Sometimes a pressure drop within the system can be utilized to introduce a proportional characteristic into the equation without necessitating its presence in the regulator mechanism. When this is possible a floating regulator may be used, but its effect is practically that of a proportional regulator. This type of damping is known as "flow" self-regulation, but the full discussion of it belongs under the heading of "Multiple-Capacity Processes."

Effect of Load. The load factor *z* as used here refers to the ratio between the equilibrium flow at the given time and the maximum flow to which the process may be subjected without introducing any discontinuity in the process reaction. It affects the various processes in several ways:

(*a*) With a proportional regulator the equilibrium value of the variable varies directly with the load by an amount determined by the characteristic θ. This is not brought out by the examples which are all taken at constant load.

(*b*) With a proportional regulator, the damping and the decrement are independent of the load.

(*c*) While the reaction time T_a is a constant, the "apparent" reaction time T_e actually decreases with load. It obviously takes the process longer to react for a given percentage of change at low loads than at high loads and this is confirmed by the equation for the damping constant

$$C_r = \frac{ze}{2}\sqrt{\frac{\delta T_a}{T_a}}$$

for self-regulating systems, which indicates that the damping is directly proportional to the load.

This is another limitation on the floating regulator. Unless the damping is so large at high loads that it is still sufficient at low loads, some proportional characteristic may be required merely to take care of the low-load condition.

Judging Quality of Results

Many attempts have been made to judge the quality of a regulation process by simple criteria such as stability or deviation. These will be discussed to determine whether any one of them is a true criteria of quality.

Stability. Stability refers to the ability of the regulator to damp out its oscillation quickly. This can be considered to mean either that the damping per cycle is strong, that is, C_r is large, or that the damping per unit time is strong, that is, t_{10} is short.

Now, curves *a* and *k* satisfy both these criteria, that is, C_r is large and t_{10} is small, and obviously they are examples of stable strongly damped vibration.

Curves *n* and *f* have large values of C_r but their period is so large that the t_{10} is also large; therefore, they would not satisfy the conditions of a fairly rapidly changing process, because the vibration though well damped might not damp out entirely between load changes. In fact, six of the curves in Figs. 5 and 6 have the same t_{10} value (46 sec) and yet there is no similarity between any of them in so far as their effect on the process is concerned.

It can hardly be said, therefore, that the t_{10} value forms a logical criterion for regulator operation. This does not mean that it is not a significant figure. It is a valuable index if only for the fact that it is very useful in preparing the rest of the graphical solution.

The damping constant C_r is a more informative criterion, although as has been pointed out, it is not safe to judge the process by this value alone. However, none of the processes with a large value of C_r is likely to cause much disturbance to the process, as this criterion is definitely associated with the tendency of the process to return to a normal position within one or two cycles.

When $C_r = 1.0$ or more aperiodic damping exists and while this is often very desirable there are many cases where it is preferable to have a slight oscillation. In Fig. 2, a second curve *b* has been drawn for the same set of conditions as the main curve *a*, except that $\theta = 0.15$ instead of 0.25. This gives a C_r of 0.75 instead of 1.25, or a very strongly damped periodic oscillation instead of one that is aperiodic. Curve *b*, the less damped, actually returns the variable to its equilibrium value much sooner, and though it overshoots it slightly, its average value after about 3 sec is much better than that of curve *a*. Furthermore, its final value is apt to be more accurate than in the case of the aperiodic curve, since it is more likely to stop in the middle of the "dead zone" while the aperiodic vibration usually stops at the edge of the dead zone.

Period. The period of a damped vibration, it has been pointed out, remains constant for a given process regardless of the magnitude of the disturbance. It depends almost entirely on the product of the regulator traversing time and the process-reaction time. With a large-capacity process, a large period is unavoidable unless the regulator traversing time is made extremely low. Very often, however, this is not undesirable since large capacities are usually present, at least partially, for the purpose of preventing sudden changes from occurring. It is important to note that if the period is large due to the slowness of the regulator, as in curves *e* and *f*, considerable deviation of the variable results. If it is the process-reaction time that is very large, relatively small deviation results even though the period is large, as shown by curves *o* and *n*.

Again, if C_r is very large, a very small period is helpful. However if C_r is small, a small period causes a fast vibration as in curves *b* and *j*.

Maximum Deviation ϕ_{max}. This quantity is a little more involved to determine mathematically but in a graphical analysis its value becomes self-evident. There is again no general rule which can indicate the extent of this deviation. Obviously, it is a direct function of the disturbance or change in load. Its relation to the other constants, however, is quite indefinite and is entirely different with a self-regulating process from that with a process with proportional regulator damping.

Graphical Methods. If instead of trying to determine individual criteria the entire results are plotted as in Fig. 3, the solution becomes evident at a glance. All the factors that enter in the picture are embodied in the resultant curve and it only remains to judge the process on the basis of the results required.

Requirements of the Process. The entire analysis so far has been made on the basis of a standard disturbance which consisted of moving the supply valve an amount necessary to change the flow by a value of *q*. It has been pointed out in the author's previous article[2] that this disturbance is typical of all types of

disturbances for single-capacity processes. This means that if the process will satisfactorily damp out a sudden disturbance in supply, it will take care of any other type of disturbance at least as well.

The actual disturbance against which we must compare our result is always, in some manner or other, the equivalent of a change in load. Any change in condition can be translated in terms of its equivalent in input flow or load.

The load factor then is plotted against time, and sections of the curve selected to represent both typical and extreme load disturbances. On these is superimposed the curve already obtained for equivalent standard disturbances, and the final decision, as to whether "satisfactory" regulation of the process exists, becomes a matter of judging the results and comparing them with the ultimate requirements.

Usually it is sufficient to perform these last-named operations mentally as a visual comparison of the load curve and the sudden-disturbance analysis should tell the whole story.

Résumé of the Complete Analysis of a Single-Capacity Process

1 Determine T_a, z, and e of the process (check to determine that the process is single-capacity and is not discontinuous or involving critical supply pressure drop).

2 Assume values of δT_s and θ to test the process.

3 Calculate the following coefficients:

	Floating	Proportional	Proportional with self-regulation
(*a*) c	$\frac{ze}{2T_a}$	$\frac{\theta}{2\delta T_s}$	$\frac{ze}{2T_a} + \frac{\theta}{2\delta T_s}$
(*b*) c_0	$\frac{1}{\delta T_s T_a}$	$\frac{1}{\delta T_s T_a}$	$\frac{ze\theta + 1}{\delta T_s T_a}$

(*c*) C_r or

$$\frac{c}{\sqrt{c_0}} \qquad \frac{ze}{2}\sqrt{\frac{\delta T_s}{T_a}} \qquad \frac{\theta}{2}\sqrt{\frac{T_a}{\delta T_s}} \qquad (ze\theta + 1)\left[\frac{ze}{2}\sqrt{\frac{\delta T_s}{T_a}} + \frac{\theta}{2}\sqrt{\frac{T_a}{\delta T_s}}\right]$$

4 From 3(*c*) determine which type of regulator to analyze first.

5 Calculate

(*a*) $m = \sqrt{(c_0 - c^2)}$
(*b*) $T_p = 2\pi/m$
(*c*) $T_{10} = 2.3026/c$
(*d*) $A = zq/mT_a$
(*e*) $\cos\beta = m/\sqrt{c_0}$

Of assistance but not necessary for calculations are

(*f*) $R_A = e - \dfrac{\pi}{\sqrt{\left(\dfrac{1}{C_r^2} - 1\right)}}$ (or see Fig. 4)

(*g*) $\phi_{max} = Ae - \dfrac{c}{m}\left(\dfrac{\pi}{2} - \beta\right)\cos\beta$

6 Plot e^{-ct} on semilog paper as straight line defined by

(*a*) $t = 0$, $\phi = A$
(*b*) $t = t_{1/10}$, $\phi = A/10$

7 Transfer to standard coordinates and multiply by periodic factor $\sin mt$.

Conclusions

There is no property or combination of properties of the process that justifies the assumption of the existence of an "index of controllability" or of satisfactory regulation. The true solution lies in the complete representation of the entire process reaction, and the recognition of the fact that once a regulator and process have been combined, they must be studied as a unit.

Certain generalizations are possible (with reference to single-capacity systems) but they must be restricted carefully to the limitations imposed on the problem. A few of the more important of these are:

(*a*) Certain processes exhibit a property of self-regulation, so as to impart an inherent stability to the process.

(*b*) When self-regulation is present in sufficient degree, a floating regulator will operate in a stable manner.

(*c*) When self-regulation is not present, then no stability exists unless it is supplied by the characteristics of the regulator itself, as in the case of a proportional regulator.

(*d*) Stability may be present at the expense of other desirable characteristics such as speed and accuracy; therefore, it is not alone a satisfactory criterion of operation.

(*e*) The dynamics of process regulation follows the well-known principles which govern all vibrating systems and then, by applying the principles of dynamic similarity, a general statement of the problem is possible through the use of dimensionless ratios and time constants.

(*f*) Knowing the constants of a particular process and those for the regulator, the characteristics of the regulated process can then be determined by applying the methods discussed in this paper. The results obtained will be sufficiently accurate for all practical purposes.

It is not always possible to determine the constants of the process with accuracy. This, however, need not impose too stringent a limitation to the broad application of the method herein outlined, since the results need only be approximations in order to be of value to the process designer. Very often it is sufficient merely to know the order of the quantities involved in order to make a satisfactory approximation.

Considerable literature dealing with the qualitative aspects of process regulation has been published, and the great need is for comprehensive quantitative data. It would be of invaluable aid to the future development of regulation technology, if those who are discussing the application of regulators to specific processes would describe these processes in terms of the time constants involved, and help form the basis for a quantitative approach to the whole subject.

The reasoning utilized here may be extended to multiple-capacity processes and to other types of regulators giving equations of the third and higher order. It is hoped that this extension will be published soon under the auspices of the Committee on Industrial Instruments and Regulators.

Appendix

General equation

$$\phi'' + 2c\phi' + c_0\phi = 0 \qquad \text{[A-1]}$$

Let

$$\phi = e^{\omega t} \qquad \text{[A-2]}$$

Substituting in Equation [A-1], dividing through by $e^{\omega t}$

$$\omega^2 + 2c\omega + c_0 = 0$$

Solving this quadratic equation gives the two roots

$$\omega_1 = -c + \sqrt{(c^2 - c_0)} \qquad \text{[A-3]}$$

and

$$\omega_2 = -c - \sqrt{(c^2 - c_0)} \qquad \text{[A-4]}$$

If $c^2 > c_0$ there is aperiodic damping.

The general equation for ϕ from Equation [A-1] is

$$\phi = Ae^{\omega_1 t} + Be^{\omega_2 t} \quad \text{[A-5]}$$

where A and B are constants of integration.

The values of A and B are determined from the initial conditions. Thus, when $t = 0$, $\phi = 0$, and $\phi' = \phi'_0$.

Then from Equation [A-5]

$$\phi = 0 = A + B \quad \text{or} \quad A = -B$$

and

$$\phi' = \omega_1 A e^{\omega_1 t} + \omega_2 B e^{\omega_2 t}$$

Let

$$t = 0, \ \phi'_0 = \omega_1 A + \omega_2 B \quad \text{[A-6]}$$

$$\phi'_0 = A\left(-c + \sqrt{c^2 - c_0}\right) - B + c + \sqrt{(c^2 - c_0)} = 2A\sqrt{(c^2 - c_0)} \quad \text{[A-7]}$$

Therefore

$$A = \frac{\phi'_0}{2\sqrt{(c^2 - c_0)}} \quad \text{[A-8]}$$

Likewise

$$B = -\frac{\phi'_0}{2\sqrt{(c^2 - c_0)}} \quad \text{[A-9]}$$

Substituting in Equation [A-7]

$$\phi = \frac{\phi'_0}{2\sqrt{(c^2 - c_0)}} (e^{\omega_1 t} - e^{\omega_2 t}) \quad \text{[A-10]}$$

If $c^2 < c_0$, then vibratory process exists.

Let

$$m = \sqrt{(c_0 - c^2)}$$

Then

$$\omega_1 = -c + im \quad \text{[A-11]}$$

And

$$\omega_2 = -c - im$$

where

$$i = \sqrt{-1} \quad \text{[A-12]}$$

Then the integrated value of ϕ in Equation (A-1) is

$$\phi = Ae^{-ct + imt} + Be^{-ct - imt} \quad \text{[A-13]}$$

where A and B are again constants of integration. Also

$$\phi = e^{-ct}(Ae^{imt} + Be^{-imt}) \quad \text{[A-14]}$$

Replacing the unit vectors e^{imt} and e^{-imt} by their sine and cosine functions

$$\phi = e^{-ct}[A(\cos mt + i \sin mt) + B(\cos mt - i \sin mt)]$$

$$\phi = e^{-ct}(K_1 \sin mt + K_2 \cos mt) \quad \text{[A-15]}$$

where $K_1 = i(A - B)$ and $K_2 = (A + B)$.

Let

$$K_1 = a \sin \theta \text{ and } K_2 = a \cos \theta$$

then

$$\phi = e^{-ct}(a \sin \theta \sin mt + a \cos \theta \cos mt)$$

or

$$\phi = ae^{-ct} \cos (mt - \theta) \quad \text{[A-16]}$$

where θ = angle at $t = 0$, or initial phase angle, measured from the peak of the first vibration.

Transferring the time axis $-[(\pi/2) - \theta]$ gives

$$\phi = Ae^{-ct} \sin mt \quad \text{[A-17]}$$

Discussion

H. L. MASON.[7] The author has well coordinated a number of theoretical quantitative treatments of the critical stability of a regulator-managed process. The equations can be widely used, but will become so only to the extent to which engineers and process designers can furnish numerical values for the process constants which enter into them. Hence, it seems pertinent to emphasize the basic concept—flow, which underlies all understanding and measurement of these constants, and point out that our present terminology may usefully be broadened.

Fluid passing through a typical industrial process, whether the "fluid" quantity be cubic feet of liquid, pounds of gas, or heat units of thermal energy, encounters two hindering actions —resistance and storage. The rate at which it gets through the resistance depends on the "head" across such resistance and is in many cases proportional to it. This head may be a difference of liquid levels, a difference of pressures, or a difference of temperatures between entrance and exit, and it may be expressed in feet of water, pounds per square inch, or degrees Fahrenheit. The constant of proportionality may be termed a "conductance" and expressed in units of fluid quantity passed per unit time per unit head; when multiplied by head it becomes flow.

The rate at which the "fluid" accumulates in a storage depends not on any property of the storing element, but solely on the inflow to and the outflow from it. We are more interested in the "level" of the stored "fluid," measured from an arbitrary datum and expressible as feet of water, pounds per square inch, or degrees Fahrenheit, because it is generally the variable we seek to control. Quantity stored is proportional to the "level," and the constant of proportionality may be termed "capacitance," and expressed in units of fluid quantity per unit level.

With the terms "fluid," "head," and "level" generalized in such fashion, the fundamental dynamic relation

Rate of change of level = inflow — outflow

will be useful for a variety of industrial processing systems. Each of its three terms represents an obvious physical reality, the numerical value of which is the product of obvious physical quantities, determinable both by computation and by direct experiment. The relation appears to be basic to a rational explanation of the so-called "time constants," and valid for any value of self-regulation, whether of supply or discharge, and (if limited to small deviations) for any process in any medium involving temperature, pressure, or flow. It may readily be extended to complex systems with a number of storages and resistances by applying it in turn to each storing element in combination with the resistive elements adjoining it. A plea is made, therefore, for the use of the foregoing concepts in arriving at numerical values for process constants.

C. P. BOSOMWORTH.[8] One of the author's primary assumptions states that "standard sudden disturbance" in a single-capacity system can be simulated by an instantaneous change in supply caused by the movement of the supply valve. It is doubtful whether such a disturbance can be found in the normal operation of process equipment. Generally, the disturbance occurs over

[7] Director of Research, Taylor Instrument Companies, Rochester, N. Y. Mem. A.S.M.E.

[8] Akron, Ohio.

a definite time interval and the change occurring in the characteristics of the system does so at a varying rate.

The author takes this into account in his further analysis of a single-capacity system when the time characteristics of the controller and process are made a part of the equation shown. It may be that the difference in the answers obtained to the problem using "standard sudden disturbance" assumption instead of the more or less gradual load change which occurs is relatively unimportant. Perhaps the author would give his opinion on the analysis if such a standard disturbance was assumed to occur in a specified time with a uniform change of demand.

A previous paper[2] by the author stated that Dr. Ivanoff used a standard disturbance consisting of ".....a continuous sinusoidal change in demand. This standard disturbance leads to a solution which is difficult to apply and generalize." It is probably true that such a type of change would be difficult to incorporate in a simple mathematical form; however, it appears to the writer that there should be something between the two assumptions of standard disturbance which would be a little more consistent with the usual simple single-capacity process.

WALLACE D. WOOD.[9] The author is to be commended for making available in English the work of Stein[4] and Wünsch[5] and for ably extending the work of control analysis through fundamental concept and mathematical development. The paper rightly emphasizes that the quality of control depends upon the combined influence of the characteristics of the process and of the controller.

The writer feels that if the author had chosen his "sudden standard disturbance" as one of load rather than supply that his equations would have been more useful. They would then have represented the actual changes that occur in practice. The quality of droop which is a characteristic of proportional control and not floating control would have been brought out in the mathematics. The proportional-control equations would then have indicated the factors which affect droop and the quantitative effect of the factors on the amount of droop. In extending the analysis to multiple-capacity systems, it will be preferable to assume a load disturbance. Therefore, it seems desirable to analyze the single-capacity system under similar assumptions.

It is the opinion of the writer that the author in his previous paper[2] did not choose the most representative type of proportional and proportional-plus-floating controllers. It is the experience of the writer's company that only in a very small percentage of its proportional-control installations is the traversing time of the valve slower than the speed of changes in the process, i.e., the rigid connection between the valve position and the pen position on the chart is maintained during motion of the pen. Should this be generally true, then the author's second- and third-degree equations for proportional and proportional-plus-floating control become first- and second-degree equations. This would alter the scope of the critical analysis as well as lead to somewhat different conclusions. For instance, a proportional controller regulating a single-capacity process could not produce periodic damping as the general equation of control would be of first rather than second degree.

The writer is not in agreement with the author's acceptance of the Wünsch damping constant C_r. In practice R_A, the ratio of the amplitudes, is simply observed and serves as a logical criterion of damping. Those who are making a mathematical analysis of control will find it only slightly harder to calculate R_A than C_r. Also the use of R_A is in keeping with log decrement as used generally in vibration phenomena.

[9] Research Engineer, Taylor Instrument Company, Rochester, N. Y.

With reference to the purpose of control analysis, it may be argued by some that the easiest way to "synchronize" an instrument to a process is to install the instrument and adjust it by cut and try to the optimum control that it will give, and that generally it will be easier and more economical to install an instrument in this manner than to first determine the constants of the process and then apply a preadjusted instrument. But, one must not lose sight of a goal of this group which is to analyze and classify processes and instruments so that when a manufacturer desires an instrument to control a particular process and maintain a quality of product within given limits, he will know whether to choose a floating, a proportional, or more complicated type of controller.

With such an end in view, the author, at the close of his paper, emphasizes the need for comprehensive quantitative data of existing processes. The work of this group may well be directed to the determination of what data should be known about processes and how it should be obtained. A collection of such data representing a good cross section of existing processes would then be available for a complete analysis. The author has set up factors which describe the characteristics of a process. It would be useful to have other papers presented on this same subject with alternate methods of describing process characteristics. From these factors this group might select those most easily and generally measurable and use them as a basis for data leading to analysis. C. E. Mason[3] and the author have made a fine start in this direction.

E. S. SMITH.[10] While the author's two papers[2] involve a great amount of work and constitute a definite advance in the art, they may be criticized as being too short, particularly in their failure to set up the physical reasoning back of that useful tool, the Anlaufzeit. To the writer, this concept is a physically meaningless abstraction for the case where no self-regulation is involved, the "area" only being there needed. The author's closure could well include a brief introduction of the Anlaufzeit from a physical standpoint. For the occasional user, it would seem better to use Mason's more direct approach[2] instead of the ratio notation followed in these papers. The ratio treatment tends to weaken the use of dimensional analysis, i.e., use of the π theorem of Buckingham, in attacking the physical problems involved; but this is not of much consequence since regulation is more a matter of the mechanics of damped oscillating systems than of physics.

Some of the general conclusions of the paper under discussion appear to be limited to the particular sort of regulator illustrated, e.g., one should apply the analysis with caution to self-operating devices. The treatment of the dead zone due to mechanical friction is inadequate and should be expanded to bring out the advantage of the earlier response (to a change) due to a narrower dead zone.

AUTHOR'S CLOSURE

The discussions on this paper deal mainly with qualitative rather than quantitative concepts which the paper has attempted to emphasize. The author feels that this is a general tendency in the field of automatic control and is overemphasized in most of the discussions taking place.

The author's aim was to stimulate discussion of the results of all types of quantitative analyses, so as to promote a study of the quantitative constants involved and to begin to talk on the subject of regulation in terms of numerical values. Furthermore, we must get away from the realm of our personal experiences, since the tendency to view regulation problems against one's own

[10] Mechanical Engineer in charge of Patents, C. J. Tagliabue Manufacturing Company, Brooklyn, N. Y. Mem. A.S.M.E.

limited experience often blinds us to the broader generalizations that are possible.

H. L. Mason offers the statement "the rate of change in level equals inflow minus outflow," and asks that it be accepted as a fundamental dynamic relation "for a variety of industrial process systems." He also suggests that the processes equation given by the author will come into wide use only to the extent that numerical values can be obtained for the "process constants" which enter into these equations.

The two remarks seem to be contradictory since the first is purely qualitative and places no significance on the dimensions or properties of the processes. Generalizations such as this in which the dimensions of the process are omitted entirely are more apt to confuse than clarify the problem. We all know that the rate of change in level is not the same for different processes, even if the inflow and outflow are exactly the same.

The author feels that less attention should be given to names and qualitative concepts, and more attention to the concise mathematical definition of each element. The names can well be selected by a Committee on Terminology, once we have decided upon the physical dimensions of each quantity. It matters little if we call a certain property the "reaction time," "Anlaufzeit," "capacity time constant," or any other term. After all, the important thing is to realize that we are talking about the ratio of q to ϕ', if we know exactly where q and ϕ' are numerically. The best test is the one so often quoted by C. E. Mason in his well-known "let's put some numbers in it, then we will all understand it."

Mr. Bosomworth's objection to the "standard sudden disturbance" on the ground that it does not often occur in practice is again an evidence of a qualitative point of view. What difference does it make whether it occurs in practice as long as it is a satisfactory mathematical test and one that can be checked experimentally? The reasons for this approval have been covered in previous papers by the author and others.

The objection raised by Mr. Wood to the use of the "supply" disturbance instead of the "demand" or "load" disturbance was seriously considered by the author before deciding on the method finally adopted. It is quite possible to bring in the effect of a sudden permanent change in load and derive an equation or plot a curve in which there is a permanent change or "droop" in the control point. This introduces further complication into the analysis, however, and adds nothing to our knowledge of the regulator action except what could be very simply determined by a simple and separate calculation using the "static" regulator equation, namely

$$\mu = k\phi$$

which tells us that the static value of the variable, or the control point, varies with the regulator position, or the "load," when a proportional regulator is used.

Frankly, this is a question on which opinion may very justifiably be divided and the author would gladly accept either method if it were to promote consistency between various writers in studying this subject.

There does not seem to be much validity in the statement that the regulators chosen in the analysis were not the most representative type. In the first place, these regulators were of no "type" whatsoever, the equations being perfectly general to *any* floating or proportional regulator, whatever the speed. This discussion in referring to proportional regulators of one type introduces a limitation which was never present in the paper itself.

The statement "It is the experience of our Company that only in a very small percentage of its proportional-control installations is the traversing time of the valve slower than the speed of changes of the process," indicates, first, a limited range of application and, second, a misconception of the effect of speed. In all turbogovernors and in many flow and pressure controls, high speed is of vital if not controlling importance. The writer knows of many problems where δT_e values of about 0.10 to 0.25 second were needed.

Furthermore, even if the speed is greater than the speed of change of the process, poor regulation may result when the two are about the same order of magnitude. This confusion results from generalizing from observations based on temperature-control problems where the process changes so very slowly due to the relatively large capacities involved, that the relative regulator speed is very high.

Obviously, certain single-capacity processes with proportional regulators of high relative speed reduce to a first-degree equation and will not vibrate. But this follows from the general equation very clearly and has been brought out in the paper, and it is not necessary to alter any conclusions or stretch any theory to be completely consistent.

E. S. Smith criticizes the failure to set up a physical reasoning back of the term "Anlaufzeit" and calls it a meaningless abstraction. If the writer could have supplied a photograph of this "time constant" of the process, it might be clearer, but time constants, while they cannot be seen, are very concrete, real quantities, and irrevocably related to and characteristic of all single-capacity processes. In the hydraulic analogy it is the time it would take to fill a tank of area A to a height h, at a rate of flow Q, or as stated in the simple Equation [4] of the first paper

$$T_e = \frac{Ah_2}{Q}$$

Mr. Smith notes that only certain regulators are treated and the treatment appears to be limited. The author purposely limited his treatment to "inertialess regulators," as clearly brought out in the first paper,[2] and this obviously eliminates any practical consideration of self-operating regulators.

As to the nomenclature, the author has no great preference, having used dimensionless and ratio nomenclature only because it tends to generalize the equations and simplify them. If the A.S.M.E. prefers other notations, the change-over is easily effected, and to this end a table has been included to relate the author's nomenclature with that of C. E. Mason, who uses quantitative units throughout.

Finally, it is hardly to the point to criticize the treatment of "dead zone," since this factor was assumed to be zero in this discussion and the treatment carefully omitted with malice a forethought.

In conclusion, the author wishes to point out that this work represents the merest introduction to the study of processes treated as vibrating systems, and the general quantitative approach to the whole problem of process analysis. He hopes that discussions of processes will gradually become more quantitative. Only in this way may the "art of process control" gradually develop into a "science of process operation."

Some Problems in the Design and Operation of Merchant Vessels

By ROBERT C. LEE,[1] NEW YORK, N. Y.

This paper presents certain technical aspects of ship design and operation as viewed from the standpoint of the executive administration of the merchant marine. The author evaluates the recent developments in hull and machinery design and construction in terms of economics. From the records of the Scantic Line and the American Republics Line, operating-cost figures are cited to demonstrate the relation of the various factors involved in ship operation. A review of shipbuilding costs and sales values of ships is included. Among other important matters discussed in the paper are safety provisions, crew training and personnel relations, and finally mention is made of the need for better and more efficient methods of cargo handling. The problems are proposed without solutions being available for many of them, in the hope that subsequent discussion may develop answers.

NO APOLOGIES need be offered for modern marine machinery. The industry is keeping well abreast of power developments. The average shore engineer would be favorably impressed with the power plant aboard any modern ship. Of course, in viewing a ship's installation one must keep in mind the limited space and the inevitable conflict which must occur in reconciling the different demands upon that space and the weight allowance for machinery in any given model. Certainly the fundamental axiom of ship construction is that each demand must be compromised in order to arrive at a buoyant, stable, and workable ship. Furthermore, it should be axiomatic that there must be employed afloat much larger factors of safety than are needed in shore design.

Just as in shore establishments, afloat there are steam plants, Diesel plants, combination steam and Diesel, and a constantly increasing use of electricity for the distribution of power to distant units, and for reduction gears.

For the main propulsive units, which account for 80 per cent or more of the power utilization, there are steam plants driving turbines through mechanical reduction gears; steam plants driving generators, which in turn drive the propeller through a motor or so-called electric drive; the straight Diesel drive; the Diesel drive through mechanical reduction gears; and the Diesel drive through electrical reduction gears, if they may be so termed. The race between the Diesel and the turbine is so close, from the standpoint both of reliability and economy, when the twenty-year life of a vessel is considered, that the choice between them becomes largely a matter of personal preference. The same condition is not quite true of the choice between mechanical or hydraulic reduction gears and electrical coupling. There is no question but that electric losses of such connections are somewhat greater than the friction losses of well-made reduction gears. On the other hand, the author is of the opinion that the flexibility and the elimination of vibration inherent in the electric gear more than compensate for the difference in efficiency in the case of many merchant ships and afford the electric connection much attraction for military purposes. It is assumed, of course, that the matter of reducing by gearing or other means the high rotative speed of the propelling units to the necessarily slow revolutions of the ponderous propellers of a modern ship, in order to secure reasonable efficiencies, is a familiar one.

In departments of the ship other than the engine room, there seems to be slight justification for any but electrical equipment. Electric winches, electric steering engines, electric galleys, because of the flexibility of electric-power conduits, as compared to the awkwardness and risks of conducting steam about a ship, have left the steam-driven winch and the oil-fired galley range in the limbo of the past.

Early Days of the Turbine in the Navy

As a young midshipman, the author vividly recalls a sunny morning at sea, leaning over the engine-room hatch of the old cruiser *Chicago*, while a friendly first-class man explained the rudiments of the steam turbine. At the time we were watching the slow turning of the weird-looking horizontal reciprocating engines. By the time of graduation from the Academy, two battleships, sister ships of the dreadnought class, had been placed in commission. One, the *Delaware*, was driven by reciprocating engines, and the other, the *North Dakota*, was propelled by turbine machinery. The author was ordered to the reciprocating ship, the *Delaware*. The *North Dakota* spent much of her first year of service at various Navy yards undergoing turbine-reblading operations. It almost seemed that the steam turbine could be discounted as a marine propulsion system. However, wise heads saw that the fault in the machinery of the *North Dakota* was structural and not one of principle. The *Delaware*, in spite of her performance and economies of operation, was one of the last reciprocating-engined ships built for the Navy.

Less than twenty years ago, the author knew of a case, where some very wise and able shipping men refused to consider any form of propulsion for ships of their fleet except reciprocating engines and Scotch boilers. Looking back now, it seems incredible that such a view could have been so tenaciously held by intelligent men and engineers.

Developments in Hull Construction

In hull construction great progress also has been made. The *Titanic* disaster, of course, brought about a complete revision of bottom construction and led to the adoption in the merchant marine of the double bottom long after that design had been applied to naval vessels. Flooding curves are now carefully studied and ships are compartmented with careful consideration of stability in a damaged condition. Practically no material is used in the construction of a ship these days that is inflammable. The author is by no means prepared to subscribe to the press

Prepared for presentation at the Marine Transport Session at the canceled Fall Meeting of The American Society of Mechanical Engineers which was to have been held jointly with The Institution of Mechanical Engineers of Great Britain in New York, N. Y., September 4–8, 1939. Presented at a meeting of the New Jersey Division of the A.S.M.E. Metropolitan Section and the Stevens Engineering Society, November 9, 1939, Stevens Institute of Technology, Hoboken, N. J.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

releases and other publicity which have recently proclaimed the advent of "nonsinkable, fireproof ships." That situation is still a long way off and probably always will be from the very nature of the enterprise. Nevertheless, great progress has been made in ship construction not only from a practical point of view, but in most cases from the artistic point of view as well.

When the average shipowner wants a ship built, he calls in his naval architect and advises him of the general characteristics and the limitation of cost. Then the freight department demands voluminous cubic and large deadweight carrying capacity; the passenger department demands all outside staterooms with bath; both departments demand top speed; the operating department demands machinery which will achieve the lowest possible fuel consumption, as well as innumerable auxiliaries, winches, booms, and other cargo-handling gear. The architect knows that there is no way in the world to provide such a ship and he begins to trade among the different departments in the owner's establishment, from which effort the final compromise emerges as a workable vessel. Most of the formulas used in designing a ship are inevitably arrived at by the trial-and-error method; therefore, the marine fraternity is a very conservative one, going forward only a little at a time. Changes are by slow evolution.

Less than three months ago, the new Cunarder *Mauretania* made her maiden voyage to New York. Though of comparable size to her famous predecessor, she is considerably slower. To be sure, there are the *Normandie* and the *Queen Mary*, superliners which dominate the Atlantic service, with both owners engaged in building or planning larger and faster ships. In the author's opinion this trend is likely to prove only a passing phase. The amount of power required to drive a vessel varies approximately as the cube of the speed. Excessively high speeds, therefore, become very costly. Also, there is no question but that a ship driven at high speed, in anything except good weather, causes considerable inconvenience to the passengers. The owner of one of these very high-speed ships told the author recently that, for at least one third of the running time, they were unable to use the full power of the vessel. It is the author's belief that the *America*, now under construction for the United States Lines, and other similar-type vessels of various shipping companies, are pointing the way for the future. Modern cabin liners of moderate size and moderate speed, compared with the superliners, are becoming increasingly popular. Transatlantic passage by air on a commercial basis is now an actuality, with every indication of increasing service. Probably overseas transportation of the future is likely to be conducted by moderate-sized, dependable, medium-speed vessels, leaving air transport to those passengers who would otherwise be the patrons of three-day ships, when and if they become an engineering possibility.

While the world tonnage of today, comprising some 30,000 craft of various sizes and refinements as to the means of propulsion, probably offers a fairly complete picture of the evolution of marine machinery from the simplest to the most complex type, the immediate interest and concern are in the advantages and limitations of the more modern machinery of the three principal types, the steam reciprocating engine, the turbine, and the internal-combustion engine. While the main competitors in the field of higher powers are the turbine and the Diesel, the reciprocating engine is still in the running and cannot be left entirely out of the picture.

Considerations in Selecting Propulsion Machinery

The modern shipowner, while constantly gambling with uncertainties characteristic of his business, cannot afford to gamble in the selection of his ships. He is conservative in his choice and will insist upon proved reliability and economy of his equipment. This is especially true of his marine power plants where failures are not only costly to repair but also can be very expensive in the matter of disrupted service and accompanying dissatisfaction of the shipping and traveling public. A wise shipowner will, undoubtedly, even sacrifice a certain amount of economy to obtain unquestionable dependability of his ships.

The combination of reciprocating engine and Scotch boiler, which so long appeared to be inseparable, is apparently at the end of its long trail of service. This is particularly true in the field of higher powers.

It is true also that the reciprocating-engine builders have made many valiant attempts to regain the lost ground but, if the supremacy of the turbine is being challenged, the effects of such a challenge are imperceptible. To overcome the thermodynamic disadvantages of the reciprocating engine the uniflow steam principle has been utilized, as well as the double-seat poppet valve, which is cam-operated and suitable for superheat. Preheated, low-pressure and exhaust steam turbines have also been interposed between the low-pressure cylinder and the condenser. To overcome the disadvantages of high weight-to-horsepower ratio, there have been refinements of design and materials, as well as a stepping up of engine speeds. Needless to say, all this, while reducing the operating cost of engines, at the same time has increased their purchase price.

This type of installation is unquestionably dependable and can stand a great deal of abuse. Furthermore it may be repaired readily in any part of the world. In these and other ways it embodies many features of desirability to the shipowner. Nevertheless, it is difficult to overlook the disadvantages of poor thermal efficiency, mechanical losses, and high weight per horsepower inherent in this type of machinery. The use of higher pressures and superheat introduces difficulties of cylinder lubricants in the feedwater. Consequently, in the present-day trends toward bigger and faster ships, the reciprocating engine is being left behind to do its work in the lower-power class, where the characteristics and economics of this type of marine power plant still offer certain advantages and serviceability.

With the advent of higher steam pressures and temperatures, steady progress has been made by geared-turbine machinery. The high dependability and economy of such a power plant renders it very desirable in marine work. Better and better economies are being obtained with installations of this type. Undoubtedly, the progress will continue for many years to come, as the metallurgist finds new and better materials which will insure unfailing reliability at higher pressures and temperatures. At the same time, developments must be forthcoming in the future which will cut down maintenance costs by eliminating the more common failures in the blading, packings, gears, shafts, and casings. Water-tube boilers have been developed to a high state of efficiency and dependability.

Speed-Reducing Systems for Propulsion Machinery

In order to take full advantage of the excellent efficiencies which the high-speed turbine offers, which must be combined with the low-speed propeller, various ingenious systems of gearing have been utilized. Of the three principal methods used, mechanical gearing is the most common, while strong claims have been put forth for hydraulic coupling. The electrical method, while having advantages of its own, apparently for the time being must be restricted to special cases.

Mechanical gearing may be either single- or double-reduction, the advantages to the shipowner being in the economies. Both types are reliable. While the double-reduction gear may be slightly less efficient than the single and involve more of an engineering risk, the higher turbine speeds permissible with double-reduction result in better over-all efficiency. This system of gearing makes possible the use of a turbine of smaller size, fewer

blades, greater rigidity, and one that is less likely to be susceptible to distortion, misalignment, and defective workmanship. As against this, must be considered the slightly greater reliability of the single-reduction gear. Also, because of the practical limits to the gear size, the application of single-reduction gears becomes more suited to cases where high revolutions and high powers per screw are desired.

The turboelectric drive has a high degree of maneuverability. It also reduces engine-room noise and helps to eliminate vibration, since torsional vibration is practically absent from this type of machinery. At reduced speeds, turbine efficiencies are poor and, consequently, where operation at low speeds and powers is required for any considerable length of time, it may be of real advantage to cut out one turbine while the others run at high efficiency. In the turboelectric drive, the astern element with its mechanical problems is also eliminated. Turboelectric drive is therefore of considerable value in naval vessels.

On the other hand, the first cost of the electric drive is apparently higher and the requirements of floor space greater. The fuel consumption is higher than that for the mechanical gear drive as a result of transmission losses, excitation, ventilation, lubrication, etc. Only special conditions of service would seem to justify the higher capital and running costs of this type of installation. Particularly it can be recommended for large passenger ships where elimination of vibration is of importance.

This type of marine installation, when compared with the geared turbine, has provoked many heated arguments among the experts. Whatever the outcome of these discussions, the shipowner must as usual decide the matter for himself. He cannot afford to overlook the basic value of any type of power plant, since it may help him to survive in his hazardous and highly competitive business.

Developments in Marine Diesel Engineering

It seems to be generally agreed that, if the Diesel had no other justification for coming into being, it has fully earned its place by providing healthy competition for the steam turbine, thus forcing the art of steam engineering into more advanced and efficient stages. In the course of its development, this type of power plant has progressed from the heavy, single-acting, four-stroke-cycle engine to the lighter, single- or double-acting, two-stroke-cycle type. During the course of its evolution many refinements in design have been made. As in the case of the steam turbine, inherent metallurgical problems will have to be solved to make possible further and more telling advances.

Diesel engineering has reached a high state of dependability. There are many Diesel installations which have rendered excellent service for many years. While in the United States the adoption of this type of power plant for marine uses has been comparatively insignificant and behind most of the European maritime nations, notably Norway, Denmark, Sweden, and Holland, where the motorship tonnage has reached roughly from 60 to 75 per cent of their respective totals, American shipowners cannot afford to overlook some of the real economic advantages which the Diesel affords.

Since its efficiency is equally high for all sizes and because it is adaptable for direct, mechanical, electrical, or hydraulic drive, the range of serviceability of this type of machinery is unusually wide. The excellent thermal efficiencies can be increased further by the utilization of exhaust heat for auxiliaries, as is being done regularly with varying degrees of success and economy. Proposals have been made to use multiple, high-speed, Diesel-electric units where high powers are required, since it is merely a question of time until the practicable limits for Diesel size will be established. Such installations undoubtedly will be made in the future. As the engines grow in size and power, the heat problems grow with them. Consequently, there are certain metallurgical and engineering limitations upon size, and new ways of utilizing the efficiency of the Diesel will have to be found if it is to continue into the field of higher powers.

At present, the first cost of a Diesel ship in this country is higher than that for steam. In certain cases, the weight and floor-space requirements of this type of power plant appear to be greater than would seem to be desirable. Because of the comparative inexperience of some of the Diesel-engine builders of the United States, there may occur an occasional failure of cylinder covers and crankshafts; there may also be some instances for reasonable complaints as to liner and piston-ring wear, fractured bedplates, or misalignment of shafts. However, the difference in maintenance cost between Diesel and steam drives is apparently not too great.

Fuel economy for the Diesel may vary somewhat according to the heat content of fuels used and the design of the engine. The Diesel will always have some advantage over steam in the matter of fuel consumption, regardless of how greatly steam machinery is improved, for the obstacles to further economies appear to be common to both types. Too often, however, the Diesel has been compared with some older steam installation and a false value derived.

During the present program of rehabilitating the American merchant marine, the problem of proper choice of marine machinery is being placed acutely before the operator. The question of steamship versus motorship must be decided. While the engineering profession can supply voluminous technical data on the two types and thus aid in arriving at a proper answer, the operator cannot overlook certain broader aspects of marine-machinery economies.

While the question of fuel itself appears to be neither a serious nor troublesome factor of operation, its importance in determining the relative advantages of the motorship and the steamship is undeniable. Experience indicates that the price differential between motorship- and steamship-fuel grades is important in the comparison of the two types, and that this differential never remains constant.

In Europe, where the fuel-price differential has been smaller than in America, the motorship with its favorable fuel-consumption rate has been economically more desirable. Therefore, the Diesel engine as a power source has been much more widely adopted on the Continent than in America. The fuel-price differential apparently is increasing in Europe; what it will be in the future is unpredictable. This differential will largely determine which of the two types of power will have the advantage and to what degree.

The strategic value of fuel oil cannot be denied; also its availability is apparently not limitless. Undoubtedly, political and economic factors of the future will have a profound influence upon the economics of ship operation. Enthusiasm for either steam or Diesel propulsion should be tempered by this consideration. It would be necessary to penetrate the future, to find the answer with regard to these two types of power plant.

Power as a Factor of Operating Costs

Among ship operating costs, the cost of power is not the greatest nor the most troublesome. During the design and construction stages of a vessel, the broad aspects of power selection, as they affect the economic life of the vessel, undoubtedly are of great importance, demanding considerable study. When the operating stage is reached, however, the cost of power is a stable factor requiring a lesser degree of vigilance on the part of the operator than other operating items. A typical example of the breakdown of the operating-expense dollar for an 8500-ton, deadweight, 12-knot cargo vessel in American Scantic Line service is:

Crew wages	15¢
Crew subsistence	3
Supplies and equipment	4
Repairs and maintenance	6
Insurance	7
Port charges and other port expenses	12
Cargo expenses	33
Agency expenses and brokerage	5
Fuel	15
	100¢

The cost of power, as made up of fuel, lubricants, engine supplies, engine-room crew, and repairs and maintenance of machinery, aggregates roughly 29 cents of each operating dollar expended and, consequently, is next in importance to the cargo-handling expenditures.

In the American Republics Line, where a de luxe passenger service to South America is conducted with modern turbo-electric vessels of 17,000 shp, developing sea speeds of 18 knots, a typical example of the breakdown of the disbursement dollar is as follows:

Crew wages	21¢
Passenger and crew subsistence	13
Supplies and equipment	6
Repairs and maintenance	6
Insurance	6
Port charges and other port expenses	10
Cargo expenses	17
Agency and brokerage expenses	9
Fuel	12
	100¢

The cost of power in this instance constitutes only 23 cents of each operating-disbursement dollar.

For tramp tonnage, handling bulk commodities, for tankers and similar tonnage, power costs, of course, may assume quite different proportions, going as high as 50 per cent of the entire costs. This largely accounts for the popularity of slow-moving ships, usually with reciprocating steam machinery.

Of the cost of power components, the fuel expense is the greatest but, while important in itself, only routine vigilance is required to control it. The same applies to the problem of repairs and maintenance.

Generally speaking, it may be said that the question of whether or not the cost of power is to become troublesome from the viewpoint of economics depends largely upon the wisdom and judgment of ship operators in the selection of ships to fit the requirements of various trade routes. The tools must fit the job if the job is to be well done. There is no such thing as a ship satisfying the requirements of all routes. Consequently, in a broader sense, good engineering, as applied to the field of marine transportation, may be considered as not being confined merely to the measure of thermal and mechanical efficiencies of marine power plants, but to the degree with which these efficiencies meet the economic dictates of the multitude of arteries through which the life blood of international commerce flows.

Ship Construction Costs

Needless to say, one of the principal factors entering into the design of any vessel, and one not to be found in textbooks of naval architecture, is that of construction cost. By all odds this is the most puzzling factor in the United States. Undoubtedly shipowners in all parts of the world think that their shipyards are charging too much. It is an established fact that wages and living conditions are on a higher scale in the United States than elsewhere. From this it may readily be deduced that American ships operating on the high seas in competition with unrestricted foreign tonnage must be subsidized. The amount of this subsidy can be fairly well established by a comparison of wages and similar costs, with those of competing foreign lines. It is the author's opinion that the differential is a good deal higher at present than it will be in the future, owing to the gradual leveling of wages and living conditions throughout the world. The subsidy is higher than it need be under any circumstances, if and when the American public actually begins to support its own flagships. It is hoped that the taxpayers, from whom these subsidies emanate, eventually will awaken to the advantage of supporting to the fullest extent their own merchant marine, which is indeed a part of their national defense.

When it comes to establishing the cost differential between an American ship and a similar ship built in a foreign yard, the matter becomes more confusing and there cannot help but be a feeling in the minds of many shipowners that all is not as it should be in our shipyards. Our shipyards build good ships. They are the equal of ships built anywhere in the world, and the superior of many. An explanation has been offered that, since most of the building has been Navy work, there have been very few ships commercially built in the United States and that part of the excessive cost is attributable to the application of Navy requirements to commercial construction. There is not much to this argument. When the United States Maritime Commission sent out its first invitations to bid on commercial tonnage, some startlingly high bids were received. The favorite explanation was that many unusual requirements were specified. The author is reliably informed that the Maritime Commission promptly met this situation by asking what reduction in price would be offered for the revision or elimination of any or all items or restrictions which imposed unnecessary expense. The resulting prices from the shipyards indicated that the effect of naval requirements on the bids had been negligible.

The National Council of American Shipbuilders, presented a very interesting document[2] to the Committee on Merchant Marine and Fisheries of the House of Representatives on February 29, 1928. In this document, it was stated:

"The principal reason for the greater cost of American vessels is the high wages paid American labor, which are nearly double those paid in Great Britain. . . . . There is some difference in the cost of material in the United States and Great Britain, but this difference is not as great as the difference in cost of labor. As shown by the *Iron Age*, steel plates, as of February 9, 1928, are only 10 per cent higher f.o.b. Pittsburgh than f.o.b. mill, Great Britain, while shapes and bars are 20 per cent higher."

In this valuable document,[3] the cost of building a 10,000-ton deadweight 14-knot cargo ship, equipped with high-pressure-steam machinery, is broken down. A figure of $171 per deadweight ton is deduced of which 50.2 per cent is material and 39.94 per cent is labor; the remaining 9.86 per cent being for customary miscellaneous items. At another point[4] in this document, a price of $125 per deadweight ton is given for a 10-knot freighter. At that time, namely, 1928, the building price of this class of tonnage in Great Britain varied between $42 and $45 per ton, which leaves in the author's mind, at least, an unexplained discrepancy of excessive cost in American yards of about $25 a ton. The National Council of American Shipbuilders further stated:

"Upon the assumption that both the foreign and American shipyards have a normal amount of work on hand, so that the efficiency of the employees of each class of yard is substantially the same, and upon the further assumption that each class of yards has the same percentage of overhead expense, the National Council of American Shipbuilders, after careful investigation, finds that it costs 59 per cent more to build a 10,000-deadweight-ton cargo steamer in the United States than in Great Britain. . . . Under present conditions the above assumptions do not exist, because there is no shipyard in the United States now engaged

[2] "Statement of Conditions of the Shipbuilding Industry in the United States," by H. Gerrish Smith, vice-president of the National Council of American Shipbuilders, New York, N. Y.

[3] Ibid, Exhibit VII, p. 38.

[4] Ibid, p. 15.

in new construction that is operating at over one third of its normal capacity. Therefore the present-day prices show an even greater differential than the percentages given above."

This might seem at firsthand, at least in some degree, to account for the unexplained $25 per ton. However, on May 10, 1938, one of the major shipyards in the United States signed a contract for a very fine ship, the first of a group of fifty or more being built by the United States Maritime Commission, at a fixed contract price of $2,080,292. From then on began a tremendous upswing in the volume of tonnage being built, not only by this yard, but by all the major shipyards in the United States. So great became the building program that the Maritime Commission has taken steps to encourage the expansion of shipyard facilities in order to proceed in an effective manner with its program. In view of this condition, it would seem that a point had been reached at which American shipyards might be considered to be operating under what should be their maximum efficiency. From personal inspection, it is a fact that this shipyard had every way filled on July 11, 1939, a little over a year later, when a bid was entered upon a similar ship but 1000 tons smaller and about 2 knots slower. The price submitted was almost identical with the earlier contract price cited, namely, $2,020,000.

The Merchant Marine Act of 1936, under which these ships are being built, definitely limits the top salaries that can be paid to anyone in the yard or, at least, that can be charged against the ship. Further, it requires that there shall be paid back to the government any profit in excess of 10 per cent of the total contract price. The motive is therefore not excess profits. If any remedy is to be found for the seemingly excessive high cost of tonnage, it must lie entirely in a more economical operation of our yards.

It is not proposed that there should be any change in the standard of wages or living conditions, either in United States shipyards or on American ships. The remedy cannot lie there. As a matter of fact, perhaps this idea of standard of living is a little out of perspective. Measured by automobiles and radios, it is high, but measured by many of the other things that go to make up the life of a family, there may not be so much to boast of concerning living conditions in America. As previously noted, a leveling-off process in living standards is undoubtedly occurring throughout the world. The International Labor Office at Geneva, probably about the only department of the League of Nations which still functions, has for its avowed purpose that objective.

Support by the American public can cure the situation afloat. In the case of the new American Republics Line, this support has been given by the traveling public. It is hoped, eventually, that similar support will be received from the shipping public. Correcting the high cost of shipbuilding, however, is an internal problem and one to which the general public may not contribute. The National Council of American Shipbuilders has said: "Give us some ships to build and then we will get the cost down." That has been done and the reverse has happened.

There seems to be but one answer to this high cost of American shipbuilding and that is the incompetency of the shipyards themselves. This incompetency does not apply to the quality of their work, but only to their ability to organize themselves so that economical work may be performed.

Admitting that a ship is probably the most complicated, comprehensive, and difficult creation of modern civilization; admitting that all the difficulties which enter into any kind of construction are encountered in the construction of a ship, to which must be added the difficulties of dropping the ship into the water; and understanding fully that the vessel must be so complete she can sever all ties with the land for a long and arduous voyage far from any help except her own; admitting all the problems thus presented, there still seems, to the average layman visiting the usual American shipyard, a lack of organization and a certain amount of inertia between the several departments which are wholly unreasonable.

The capital costs of a ship are inescapable. Whatever else happens, these costs go on and on. A ship earns money only when her wheel is turning over with pay load aboard, but she can lose money with alarming rapidity tied to a dock and charged only with interest and depreciation. Therefore, one of the vital elements of a successful maritime industry is the matter of capital cost.

A noteworthy technical efficiency has been developed in the United States. The genius of men like Henry Ford has revolutionized the world in the last forty years; and what a strangely different civilization it would be were it not for the automobile industry. Some thirty years ago, there was grave danger that the automobile industry would develop into just a small enterprise turning out a few high-priced cars a year—almost in the class of museum pieces. Today, despite all the high costs of American labor, the major factor in the export trade of the United States is the finished product of this industry, the American automobile. It is the best and the preferred car in any market in the world and presents an amazing value for the dollar paid. It is the author's hope that the technical efficiency which has produced the American automobile will be applied to produce an American merchant marine.

Range of Ship Prices in Great Britain

The fluctuation of price in building ships has been ably illustrated recently in a British publication.[5] The steamer for which the diagram was prepared, and which may be considered as typical, is a single-deck type, with bare specifications, having a bridge, poop, and forecastle, and carrying about 7500 tons deadweight. From this diagram, the building cost at the beginning of the World War, that is, the second half of 1914, was something over £7 per deadweight ton. It rose rapidly as the war progressed, so that by the end of 1915 it had doubled to about £15. The following year it went to £23 then to £26, and actually reached its peak at the end of 1920, when the price rose to £30. The slump of 1921 brought it to £13 by the end of that December, and to £9 by December 1, 1922. It stayed in that vicinity for the succeeding fourteen years, so that, in June, 1936, a price of £9 12s prevailed. It rose slowly through 1936 and 1937 and by June, 1938, had reached £14 8s. By June 30, 1939, it slipped back to £13 6s 8d.

On the same chart another curve is drawn showing the sale values of similar tonnage during the same period of time. While this follows in general the building cost, the sale cost being affected not only by the cost of building but also by the state of the market when built, it occasionally fluctuated considerably above or below the actual cost of replacement tonnage. For example, in 1932 and 1933, when there was almost no cargo in the world to be moved, this tonnage had a sale value of £32,000 although it cost to build in the same period £62,000 to £63,000. The diagram shows clearly that in periods of poor freight markets, the sale price of tonnage is less than the replacement cost; while in good periods it may greatly exceed replacement cost. For example, it is well known that a spurt of shipping activity occurred during the second half of 1937. For a few months then it was impossible to get tonnage. The building cost showed from £78,000 to £100,000, but in about the same period the sale price advanced from £60,000 to £125,000.

In the same article[5] the rather significant statement is made:

[5] "Fluctuations in Shipping Values," *Fairplay*, July 6, 1939, supplement, p. 23.

"We asked a well-known shipbuilder what he thought the future held, and he replied, 'So long as we have a continuous demand for armaments I cannot see much hope for any reduction in the price of ships over the next year or two. The cost of social services is always increasing and there is never any hope of getting alleviation from this part of the cost of a ship as time goes on.'"

Personnel Relations a Vital Factor

As previously noted, the marvelous creation which is a ship has reached a high state of development. Opportunities for advancement in the art of ship construction still remain, but probably far greater opportunities lie in that field of endeavor having to do with human relationship.

Incorporated in a modern vessel are fireproof materials, watertight bulkheads, smothering equipment, and even machines for steering the vessel automatically, but in the end disaster can come and a ship will fail to function without the skillful guidance of a trained crew. Suppose an absolutely fireproof ship were built. Before she could move it would be necessary to introduce into her highly inflammable fuel. Before she could earn revenue her holds would have to be filled with inflammable cargo, and her public rooms with passengers careless with cigarette butts, careless with cleaning fluids, careless with electrical fixtures, all of which are necessary. Therefore, no matter how fireproof the ship may be to begin with, by the time she is loaded and ready to embark, she has added all the hazards which in building were so carefully avoided.

Essentially, the crews which man merchant ships have been more or less allowed to develop themselves. In the United States this is particularly true where no effort at all is made to train any except a handful of officers in the two or three state training ships which are in commission, although the Maritime Commission has recently attempted to develop an extensive training program.

A practical application of the social sciences and more enlightened personnel relations are the evident needs of the immediate future. Among personnel there is a general lack of understanding of the problems of management which confront a ship operator. It is not possible to blow a whistle at noon on Saturday and go home and leave the ship until Monday morning. Because of some dispute with the management, the ship may not be abandoned in some foreign port, or in mid-ocean until the dispute is settled. In the teeth of a gale, there is no opportunity to discuss overtime demands. A ship goes for days and weeks, and seemingly nothing happens and then, in an instant, disaster threatens. There must be complete organization, military in its authority, inexorable, and inflexible. The Soviet, attempting to operate its vessels by committees, encountered one disaster after another, and finally gave up the idea. Much that is perfectly fair and proper and reasonable to be considered in the relationship between employer and employee, or boss and workman on shore, must be abandoned entirely by the sailor. A new social science must be devised.

There is also much yet to be done in the matter of systematic management. The unknown factors in operating ships will always be numerous. The reduction of known factors to a workable understandable basis should be prosecuted with all haste. Discussions of this kind assist. Probably more effective than anything else is the rapidly increasing availability of sound practical university courses in various phases of the marine-transportation industry. Young men completing these courses, if given proper subsequent training at sea, can eventually become of utmost value in the shore establishments. They are needed for analyzing the effect of all the factors that enter into the operation of a ship; for studying fuel consumption, the loading and discharging of a ship, her scheduling and turnaround, and the accumulation and disposition of cargoes.

Cargo-Handling Problems

Probably the problem that has had the least attention, or at least has undergone the fewest changes, is that of loading and unloading cargoes. At least 25 per cent of a ship's revenue goes into this operation, if she operates in the usual trades. In addition, while the vessel is being loaded or discharged, she is necessarily idle at a dock. The methods of loading, stowing, and discharging are in about the same state as they were generations ago. The winches are a little faster and may be electrically driven, making them easier to control, but the old burton is still dropping down into the hold where a few men with hooks, crowbars, or their bare hands manage to hook on a sling load for hoisting and discharging on the dock. Or a sling load comes down to them, is dropped in the middle of the hatch, and is lugged by the men to some corner for stowage. There is a better way to do most of this that will occur to someone some day. Some experiments have been tried, but these have been limited to peculiar situations. For example, in the *Seatrain*-type ships, an entire carload of freight is loaded into the ship, car and all. Some cargo has been strapped to platforms which can be lifted out of railroad cars by spade trucks, run over the dock to the ship's side, and easily slung on board, where frequently another truck picks it up in the hold.

In the "Good Neighbor Fleet" of the American Republics Line, escalators are used, for discharging and loading fruit and coffee, in conjunction with continuous roller conveyers. A cargo elevator is now being installed in the blind hold of each of the three ships. Some cargo is now being handled by the line in containers. Of course, the railroads, particularly abroad, are doing a very large container business. However these are only isolated cases, pointing the way to better methods which will be developed in the future. Now, only an infinitesimal part of the world's cargoes are handled by methods which in any way may be considered efficient.

Discussion

George H. Rock.[6] The author and the writer had similar assignments after graduating from the Naval Academy, as each was assigned at different periods to the same ship, the U.S.S. *Chicago*. When the writer graduated in 1889, she was the flagship of the "White Squadron." Probably the author did not have the same interesting experiences, however, when wanting to go ashore and asking permission from the executive officer, who was an exceptionally fine and able seagoing officer but gloried in being something of a martinet. On being asked for permission to leave the ship, he would look at the writer quizzically for a full minute and then ask: "Tell me how you would pump out A-19 in the event of damage in that compartment." If the correct answer was not forthcoming, there was no shore leave that day, nor the following day, unless the question propounded then was answered. It was always sure to be a different problem.

The author makes the inference in his paper that it is his belief the *Titanic* disaster resulted in double bottoms being incorporated in the designs of later ships. To correct the record, it is necessary to state that double bottoms were fitted in ships long before the *Titanic* was built. She had a double bottom extending throughout her length. In the wake of the machinery compartments, the double bottom extended up the sides to a height

[6] Rear Admiral (CC), U. S. N., Retired; President, Webb Institute of Naval Architecture, New York, N. Y.

of about 7 ft above the keel. The height of the inner bottom elsewhere was in general about 5 ft. The *Titanic* had been advertised as an unsinkable ship, but of course such advertisement would be taken with reasonable understanding of the design. Her damage, when she struck the iceberg at about 10 ft above the keel, extended over six compartments, i.e., the two forward boiler rooms and the four compartments forward of them. With these compartments full of water, no ship built at that time, nor at the present time, could remain afloat. Whether a double bottom, extending up the sides beyond the line of damage, would have confined the water to the outboard compartments, or whether, if the bulkhead deck had been watertight instead of weathertight, she would have remained afloat until the arrival of rescuing ships, are matters which we cannot know, but certainly they would have had some effect.

The writer is in sympathy with superliners and in that particular does not agree with the author. It is his belief that superliners are here to stay, and that the *America* only points the way for the ships of the future. If history is any guide, the *America* is far from the last word. The length and other dimensions of ships have increased at a slow but an unvarying rate from the beginning, and the changes looking to smaller ships have been for a short time only, when the increases in size again have been made. This trend was so well established in the minds of the Navy Department that some 12 or 13 years ago, when asked by the War Department for opinions as to the size of the new Panama Canal locks, the recommendations of the Navy Department were that they should be about 1300 ft long by 150 ft wide by 45 ft draft, in order to provide for what appeared to be the inevitable size of the ships about the end of the current century. Studying the records over the last 100 years discloses a steady and fairly uniform increase in length and breadth of 8 ft in beam and 80 ft in length for each period of 10 years. Probably sizes will not increase as rapidly in the future as in the past, due to considerations of cost, depth of harbors, etc. The Navy Department estimated an average increase of 5 ft and 50 ft, respectively, per decade during the remainder of the century. Incidentally, it should be noted that the *America* is appreciably larger than the *Washington* and *Manhattan*.

The author refers to the efforts of naval architects to produce nonsinkable and fireproof ships. We do not say that we can build nonsinkable ships, but we do say that we can build fireproof ships in so far as all materials entering into the construction are concerned. This, of course, as the author points out, does not make the cargo or the fuel oil fireproof, but ships are fitted with very efficient smothering devices for extinguishing fires in the cargo holds and, furthermore, the principal disasters at sea, due to fire, are not those in which the fires have started in cargo holds or fuel-oil compartments. They have been fires due to the use of combustible materials in the constuction of the ships, such as was the case in the *Morro Castle*.

The speaker refers to the slight justification for other than electric power for auxiliaries, and mentions the steering gear and galley ranges. It seems such a short time ago, about 25 years actually, when we in the Navy had to remove the electric-galley installations that had been made because they failed so quickly and completely in use. Fortunately, the electric-supply companies, by studying the particular requirements of galleys on board ship, succeeded in designing resistances, connections, etc., which made them practically foolproof. After a brief interval of time, the electric galleys were reinstated, until now, as the author informs us, they have almost completely displaced the oil-burning type of galley.

As to the steering gear, it seems also but a short time ago when we were spending so much time and energy in making the telemotor gear function, but, fortunately, before we had to give it up as an impossible job, the electric steering gear came into general use.

The speaker stresses the advantage of electric drive because of the elimination of vibration. That does not appear to have applied to the *Normandie*.

J. F. METTEN.[7] The author apparently has presented this paper as a résumé of the present conditions and trends in operation, design, and building of ships and some of the causes responsible therefor. Such papers naturally represent the considered opinion of the author, and their value largely depends upon the integrity of the basic facts which are used to support these opinions.

Under the heading "Developments in Hull Construction" reference is made to the *Titanic* disaster, which is stated to have brought about a complete revision of bottom construction, leading to the adoption of double bottoms in the merchant marine long after that design had been adopted by the Navy. The *Great Eastern*, completed in 1859, was provided with a double bottom carried up to the lower deck. Double bottoms were adopted in transatlantic liners built long before the *Titanic* was thought of. The *Paris* and *New York*, completed in 1890, had double bottoms with advanced transverse subdivision, no access openings of any kind being provided through transverse bulkheads below the main deck. The *Titanic* was provided with a double bottom. The disaster resulted from contact with ice above the inner-bottom margin, thereby opening up a series of compartments. All the transatlantic liners of that day were vulnerable in this respect as, when wing coal bunkers were provided in the wake of boiler compartments, it was recognized that power-operated watertight bunker doors were of doubtful value in such emergencies. The change from coal to oil fuel and elimination of open bunker doors was the development which permitted a more rational approach to the matter of effective subdivision.

Reference is made by the author to "the elimination of vibration inherent in the electric gear." He states: "The turbo-electric drive has a high degree of maneuverability, reduces engine-room noise, and helps to eliminate vibration, since torsional vibration is practically absent from this type of machinery."

This reference to the matter of vibration is somewhat misleading, since there is no inherent advantage in this respect possessed by the electric drive over the geared-turbine drive. Both, so far as the driving end is concerned, are completely balanced units provided that they are properly designed and constructed. Uneven torque at the propeller, arising from variable wake conditions in the propeller path, may cause torsional vibration in line shafting regardless of whether the shafting is driven by turbogeared or turboelectric propelling units. Moreover some of the most serious cases of vibration in the wake of passenger quarters arise from this variable propeller condition. The *Normandie*, a turboelectric-drive ship, is a good example. The very satisfactory correction of the vibration, experienced on the first trips of that vessel, involved the correction of unfavorable propeller conditions and interrelated structural factors.

The author's analysis of the cost of American-built ships and his claim that the differential between foreign- and American-built tonnage is largely due to the incompetence of American shipyards, seems to be based principally upon the fact that American automobiles are built as cheaply as foreign cars. He apparently feels that the quantity-production methods, special tool investments, conveyer assembly lines, etc., permitted in building 500,000 or 1,000,000 duplicate automobiles should be applied in a shipyard which is lucky indeed if it can get 4 dupli-

[7] President, New York Shipbuilding Corporation, Camden, N. J.

cate ships to build at one time. A proper and unbiased analysis will show that the differentials in cost between American and foreign flagship operation are not as great as the differentials in cost the American shipbuilder has to face in comparison with a foreign builder. Therefore, if the author's contention in respect to American shipyards is based upon sound reasoning, the writer would suggest that he might dispense with any form of government subsidy to the steamship lines he represents, by applying the same measure of efficiency to their operation.

B. E. MEURK.[8] A serious situation facing the shipowner, which has not been commented upon by the author, and which the writer believes should be given some thought, is the conditions of regulation and inspection of vessels imposed by the government on the shipowner. Shipbuilding and ship operation are of greater interest internationally than any other industry in existence. It has been found, therefore, of advantage to make rules and regulations in connection with the construction and safe operation of vessels somewhat uniform among nations. To create a mutual and common understanding of these problems, international conferences are held at which technical experts from the various maritime nations seek agreement upon construction features of ships and machinery in line with advances in the art. The most important conference of recent years was held in London in 1929. In the United States, however, there has been a tendency during subsequent years to exceed greatly the standards of safety agreed upon at that conference.

When accidents or catastrophies occur at sea, it is the practice of American newspapers to report the incidents in a sensational manner, which tends to play on the emotional side of the public. Senators and Congressmen feel it to be their duty to submit bills to Congress for the purpose of preventing the recurrence of such disasters. The laymen and average citizen never realizes that ships at sea constitute the safest means of transportation in existence and that these accidents are relatively small considering the magnitude of the business of ship operation. Of late, Congressional investigating committees have caused excessive regulation in construction of ships and control of steamship lines, which has resulted in increased shipbuilding and operating costs. Furthermore, it has interfered with the design and construction of a proper ship to meet strictly competitive trade conditions with foreign ships, particularly with reference to suitable cargo holds and the net registered tonnage which can be obtained for a certain cubic or cargo-lift capacity.

Due to the fact that the United States has imposed a far greater burden and responsibility on the shipowner than, for instance, the government of Great Britain has done, embarrassing conditions are likely to occur when chartering vessels of that country's flag. To illustrate this point, at the present time the author's company is having an important case tried in the U. S. Federal Court, in which the cargo underwriters are prosecuting an American steamship line as charterer of a British ship, for the loss of their cargo. After the casualty had occurred, the shipowner, the seaworthiness of the vessel, and the conduct of its crew were investigated by the British Board of Trade, and the vessel was declared seaworthy, while the shipowner was exonerated and exempted from responsiblity. However, as the cargo was owned by American interests and the party issuing the bills of lading was an American steamship company, the seaworthiness of this particular vessel and the owners' responsibility must now again be established in court under the American laws. It is easy to understand how embarrassment may occur if the laws and regulations of one nation establish different requirements from the laws governing steamship operation in another. Inevitably this will occur if we depart too greatly from international opinions in regard to seaworthiness and regulations of safety of a vessel.

E. H. RIGG.[9] Referring to the section, "Developments in Hull Construction," the author states that the *Titanic* disaster brought about a complete revision of bottom construction and led to the adoption in the merchant marine of the double bottom long after that design had been applied to naval vessels. This is a somewhat misleading statement. The earliest forms of merchant-ship double bottoms go back to about 1855; the modern double bottom is recognizable as far back as 1875, since which date they have been fitted in increasing numbers and improved forms. At the time of the *Titanic* disaster in 1912, they were well-nigh universal in deep-sea passenger ships, whatever may have been the case as to coastwise vessels. At that time, there doubtless were many single-bottom deep-sea survivals but not so for ships then or recently building. Warships may well have been ahead of merchant ships in this respect; it is doubtful if many double bottoms of date prior to 1860 could be found in warships. The widely known *Great Eastern*, 1858, was built to a design involving much that was ahead of its time, among other things, a full double bottom.

The author refers to flooding curves, inferentially, as a modern, post-*Titanic* development. They have been used and applied in their present form since 1890 and doubtless in earlier forms before that, especially in warships.

Stability in damaged condition has always been with us; in recent years, oil fuel has increased the dangers and complicated their determination, but practical methods of assessing the adverse effects of damage on a ship's stability have been devised and made available.

The author draws a picture of the difficulties of the naval architect in satisfying all the demands of the owner's different departments, in one comprehensive design; one reply is that the owner should know enough of his business to talk directly to his architect and handle his department heads himself. Leaving it to the hapless architect to "trade" one departmental chief against another does not help the owner much in getting a good ship; it might well increase the costs.

The statement is made that "most of the formulas used in designing a ship are inevitably arrived at by the trial-and-error method." That word "inevitably" is well placed. For a ship floating in smooth water, we need little or no "trial and error;" like the bridge engineer, we can design quite closely; then our troubles begin. Even harbor vessels bump against piers—how hard? A clumsy tugmaster can, in an instant, make the cleverest mathematics look sick. He does not necessarily have to be clumsy; he may have the bad luck of wind, tide, fog, and other vessels getting him in a tangle with but little, if any, fault of his own.

Just what margins over and above "accidentless" operating stresses is the owner willing to pay for? This still leaves our old friend "corrosion" out of the picture entirely. The big trial and error is in the inconsiderate action of the ocean. Any clever skeptic, who goes to sea and watches a first-class Atlantic storm, will come home considerably sobered as to his ability to calculate the stresses set up in the hull structure by the action of the supporting water.

Improved educational and training facilities have been giving us a steady stream of well-educated young men for many years past. In spite of this, we still hear from time to time, that our old friend the sea has caused "cracks" to develop in ships. The main point is that the clever young men are not quite clever enough yet and the "conservatives" still have their uses in ship structural design.

[8] Superintendent Engineer, Isthmian Steamship Company, New York, N. Y.

[9] Naval Architect, New York Shipbuilding Corporation, Camden, N. J.

Another former trial-and-error process of the first importance was that of hull form and the power necessary for a given speed. Thanks to William Froude and his disciples, that phase has yielded to treatment; all the competent naval architect needs nowadays is a reasonable time and cost allowance for model experimentation. Any questions not settled by model tests, to an accuracy of within 2 or 3 per cent, may well be left for experience to determine. With regard to such testing, we do not claim to know it all, but the progress of the last two generations has been great.

H. Gerrish Smith.[10] From the standpoint of a ship operator, this paper presents an informative analysis of the characteristics of present-day merchant ships, particularly as to their types of machinery; the evolution of ship design over a period of years; the fundamentals of design; and the problems of the designer in reconciling the many demands of the various branches of ship operation.

The writer can agree with many of the observations of the author until he reaches the section on "Ship Construction Costs;" even then, there is agreement with some of his statements in that section. However, the writer wholly disagrees with his conclusion that the high cost of ships is due to "the incompetency of the shipyards themselves." Such a conclusion is considered to be unfair and unreasonable.

The author asserts that "our shipyards build good ships" and that "they are the equal of ships built anywhere in the world and the superior of many." The writer would go further and say that the ships we are now building are of more exacting specifications and, therefore, are in many respects superior to those building anywhere abroad for similar service, and are far ahead of those built in this country 10 years or more ago.

Since the previous war, the speed of cargo vessels has been increased on the average from 11 knots to $15^1/_2$ knots. On the basis of earlier designs, such an increase in speed would require more than double the power and, therefore, double the fuel consumption. However, improvements in form, propulsion, and fuel per hp-hr have kept the fuel consumption per knot to practically the same for the $15^1/_2$-knot ship as for the earlier 11-knot ship.

Reduction in the weight of the ship by the use of welding and the use of more efficient machinery have resulted in a greater deadweight carrying capacity within the same over-all dimensions.

These improvements have made it possible for 3 ships of today's design to do the work of 4 ships of the older design—a very important point to be kept in mind in any discussion of this paper.

Other features of the design to meet owner and government requirements or to comply with new acts of Congress to make a more workable and a safer ship are as follows:

1 Improved accommodations for all members of the crew, including locker rooms, washrooms, and recreation spaces.

2 Extension of electricity to the point where virtually everything but the main engines are operated electrically. Expensive but efficient electrical equipment has replaced less expensive and less efficient steam-driven cargo winches, steering gear, anchor gear, capstans, and engine-room auxiliaries. Its use has made possible the development of desirable equipment unknown in the older ships, such as automatic alarm systems, remote controls, fans, and mechanical galley equipment.

3 The simple cowl ventilators for natural ventilation have virtually disappeared from the latest ships and in their place are complex mechanical ventilating systems. Cargo holds, once without ventilation, are now well aired by special air-conditioning equipment in order to minimize the spoilage of perishable cargoes.

4 Ratproofing for the preservation of health of passengers and crew and the protection of cargo.

5 Greatly extended use of fire-resistant materials; passenger ships are divided into zones to localize fire should it break out, requiring the insulation of many bulkheads and decks within these spaces which would not otherwise be needed; noncombustible material instead of wood in stateroom construction.

6 Greater subdivision of ships for safety.

7 Higher standards for lifesaving equipment; automatic watertight doors; greatly increased fresh-water-evaporating capacity.

8 Radio direction finders; electrical sounding devices; gyrocompasses and mechanical steering apparatus to take the place of the compass and the lead.

9 More outside rooms for passengers on passenger vessels.

The additional requirements must be warranted by a resultant increased efficiency and safety or a reduced operating cost, but certainly the increased cost due to their addition cannot be laid at the shipbuilder's door.

The cost of ships, however, does not stop with these added owner and government requirements for the following reasons:

Wages today are higher than at any time in the past, including the war period and 1929. Shorter working hours required by law have increased the time to construct a vessel because many highly skilled operations cannot be carried on by second and third shifts. A longer time of construction increases the overhead expense. Overtime allowances have been increased. Vacation with pay is now quite general. Increased taxes, both local and federal, and social-security taxes, where none existed a few years ago, have added to cost. Increased labor questions following passage of the Wagner Act, the Walsh-Healey Act, and the Wages and Hours Act, and the increased expense of workmen's compensation, by broadening the scope of state laws, have added to cost.

National-defense features in some cases require more power and speed than are necessary for peacetime operation, thereby adding to cost; some defense features are an integral part of the ship's structure and add to cost.

These various elements of increased labor cost are not peculiar to shipbuilding alone, but are experienced likewise by the suppliers of material from whom the shipyard must purchase such items as steel, boilers, turbines, navigating equipment, and innumerable other items. Practically all classes of material cost more now than in the past. There has also been an increased demand for special and higher-grade materials.

Delays occasioned by government inspection and approvals are vastly greater now than a few years ago. At the present time, plans of an ordinary cargo ship are subject to approval by the Maritime Commission, Navy Department, Public Health Service, and the Bureau of Marine Inspection and Navigation under the Department of Commerce. Plans are also subject to approval by a classification society, such as the American Bureau of Shipping, Lloyd's Register of Shipping, or both.

The increase in shipbuilding costs is not limited to the United States. They have gone up abroad as well as here but, as stated, the requirements and specifications for American vessels are much more exacting than for foreign vessels in a similar service.

Coming to the subject of shipbuilding versus the building of automobiles, the author appears to have reached his conclusion that shipyards are inefficient on the assumption "that the technical efficiency which has produced the American automobile" is applicable to the production of an American merchant marine. In his own language, he admits that a ship is a highly specialized structure, as he states: "The tools must fit the job if the job is to be well done. There is no such thing as a ship satisfying the requirements of all routes." He must know that to the

[10] President, National Council of American Shipbuilders, New York, N. Y.; President of The Society of Naval Architects and Marine Engineers, New York, N. Y.

contrary an automobile is a highly mechanized product. Wherein the latter is produced in great numbers, often as high as hundreds of thousands or even a million from the same designs, patterns, jigs, and fixtures, a ship is a custom-built product, of which only a few are ever fabricated from the same design. An entirely new set of plans and new patterns are required for each new type of ship. Furthermore, the use of costly jigs and fixtures for individual parts of a ship is not permissible except to a very limited degree, because of the high cost of production of such jigs and fixtures and the small number of ship parts that could be produced from them.

Limited study of the problems involved in the construction of a made-to-order structure such as a ship, as compared with a mass-production article, such as an automobile, will show clearly to anyone, who cares to investigate the subject, the essential differences in the methods of production employed for each and the effect of mass production on reduction of cost. A specially designed automobile, not standard, would cost many times as much as a standard automobile produced in quantities.

Mr. Ford apparently overlooked the difference between automobile construction and ship construction when he undertook to build 200 Eagle boats for the Navy Department during the previous war (about half of which were completed), on an attempted construction basis similar to that used in building automobiles. If the writer's information is correct, Mr. Ford lost money on that contract and it is noticeable that he discontinued shipbuilding.

There are a few specific statements, in the author's section on the cost of ships, requiring comment as, for example, the following:

"When the United States Maritime Commission sent out its first invitations to bid on commercial tonnage, some startlingly high bids were received. The favorite explanation was that many unusual requirements were specified. The author is reliably informed that the Maritime Commission promptly met this situation by asking what reduction in price would be offered for the revision or elimination of any or all items or restrictions which imposed unnecessary expense. The resulting prices from the shipyards indicated that the effect of naval requirements on the bids had been negligible."

The last sentence in this statement would seem to have no bearing on the subject of the elimination of items, but the records show a very substantial reduction due to eliminations, running as high as 13 per cent.

Reference is also made to the bid of one of the major shipyards on the C-1 cargo vessels. The gist of the statement is that ".... this shipyard had every way filled on July 11, 1939, a little over a year" from the time bids were submitted on the C-2 vessels until "a bid was entered upon a similar ship but 1000 tons smaller and about 2 knots slower. The price submitted was almost identical with the earlier contract price cited, namely, $2,020,000."

In the first place, a reduction of $60,000 from the bid of $2,080,292 on the C-2 vessel is hardly an "almost identical" bid and, in the second place, a careful review of the specifications will show that the C-1 vessel had additional requirements over the C-2 vessel which are estimated to cost not less than $150,000 per ship.

On the occasion of the opening of the bids for the C-1 vessels, one of our shipbuilders was accompanied by a British shipbuilder who remarked that he would like to take a contract for the construction of these vessels at half the bids submitted. He was asked, "To the same specifications?" and he replied, "Oh no." What the Britisher had in mind was a ship built to an entirely different specification.

While foreign ships as built are undoubtedly satisfactory to their owners they would not pass present American specification standards; the fuel economy would not be acceptable to the American owner; ratproofing and fresh-water arrangements would not be satisfactory to our Health Department; accommodations and many other features of the foreign vessels would not meet the standards of our Maritime Commission and of the Bureau of Marine Inspection and Navigation.

At another point in his paper, the author states: "The National Council of American Shipbuilders (in 1928) has said: 'Give us some ships to build and then we will get the cost down.'" He goes on to say: "That has been done and the reverse has happened." This statement is, of course, in error as the actual quotations, within the last 2 years, for ships for the Maritime Commission and private operators, show that, in every case where bids are called on 2 to 8 ships, the bid per ship for more than one has been less than for one ship of a design. The average reduction in bids for 4 ships of the C-2 type is about 13 per cent each less than the cost of 1 ship; the average reduction for 4 ships of the C-3 cargo type about 10 per cent less; the C-3 passenger-and-cargo type, about 11 per cent less; and the C-1 cargo type about 16 per cent less.

An analysis of the bids on the C-1, C-2, and C-3 cargo ships, the C-3 passenger-cargo ships, ships for the Seas Shipping Company, for the Export Line, and for the Mississippi Shipping Company, shows that, for 60 of these ships where bids were submitted for group construction as well as for a single ship, the actual saving on group-construction bids would be in excess of $18,000,000; in other words, a sum sufficient to build 9 additional C-1 ships.

The Maritime Commission has performed a commendable job, through a substantial degree of standardization of ship forms and characteristics, which has made possible the ordering of groups of ships of the same design, and has thereby effected considerable savings, as indicated for each ship of a group, under the cost of a single ship of a given design. By limiting the number of designs it is permitting the program to be carried out with a much smaller technical staff of shipyard employees than would otherwise be the case.

The author is also at a loss in his paper to reconcile certain figures presented by the National Council of American Shipbuilders before the Committee on Merchant Marine and Fisheries in February, 1928, in which statement the National Council presented certain figures as to differentials in shipbuilding costs in the United States and abroad. This statement of 1928 has little to do with the present-day cost of ships. However, to reconcile the figures of the National Council it should be noted that the statement referred to a price of $125 per ton for a 10-knot freighter, built to American design and specification. The author states that at that time "The building price of this class of tonnage in Great Britain varied between $42 and $45 a ton." Taking account of the National Council's figure for cost differential, he cannot reconcile an apparent difference unaccounted for of $25 per ton. The answer to this apparent discrepancy is simply due to the fact that the type of 10-knot freighter referred to by the National Council is a far different type of vessel from the simplest type of freighter on which quotations appear from time to time in the British press.

The shipbuilder offers no apologies on the subject of efficiency. There are numerous shipyards in the United States in different geographical locations, owned by different interests, run by different managements, and each is doing its best to devise ways and means of building ships at less than the cost to the other fellow. Competition alone is a sufficient incentive to each shipyard to do its best to produce at a minimum of cost.

Every conceivable method to increase shipyard efficiency has been studied and those judged to be sound have been adopted. Some yards have built up extensive organizations for producing

plans covering every detail of construction, for arranging schedules for the orderly progress of each part of the work, and with ample supervision to see that each workman knows exactly what he has to do and that he does it at the proper time to dovetail into other work under way. Other yards have tried and are trying the plan of keeping down organizations, issuing only the least possible instructions, and leaving it as much as possible to foremen and workmen to build the ships. Some yards have production departments of considerable extent and a production manager whose sole duty it is to provide for the most efficient possible production.

The shipyard practices of the different shipyards are well known each to the other and there is at least a general knowledge in American yards of the practices in foreign shipyards. It is incredible that those same shipyard managements which have produced efficient designs and "good ships" have not devoted equal energy to the development of efficient methods of production.

As a matter of fact, the going shipyards of the United States have kept their equipment up to date since the last war, many times when there has been promise of but little work ahead for them. They also have given close attention to the development of efficient methods of shipyard operation.

Anyone, of course, might obtain an opinion about the efficiency of shipbuilding by a careful investigation and study of the industry, and that is always invited. It is quite apparent, from the analysis that has been made in the foregoing of some of the statements in the paper in question, that the author has not studied conditions in the shipbuilding industry carefully or he would be more conversant with the facts. There appear to be no facts to justify his conclusion of "shipyard inefficiency." The writer is quite sure that any disinterested investigation of shipbuilding will show that the industry is well abreast of other American industries in its efficiency, and far in advance of many. In relatively few industries has the progressive development of both the product and manufacturing methods been so noted in the last 20 years. It might be concluded that the operation of ships is inefficient, but the writer's opinion would not make it so. The writer's background of experience in ship operation is not sufficient to justify reaching such a conclusion.

The shipbuilding industry is appreciative of the problems confronting the ship operator and has every reason to be sympathetic toward their solution. No shipbuilder profits in the long run by a curtailment of the volume of his business. Every shipbuilder therefore has every reason for reducing the costs of shipbuilding in order that his yard may remain active. But the shipbuilder has to provide what is ordered, not what is least expensive. His bid is controlled by the specifications. He is confronted in his operations by many matters largely beyond his influence. His own best interests are served by a policy of fairness to all elements concerned in the problem of upbuilding the American merchant marine. If there were anything inherently unsound in his methods, he would be the first to desire to correct it.

The shipbuilding industry is proud of its achievements in the design and construction of vessels, and in shipyard operation and believes it has been well at the forefront in the advancements that have been made by industry in the 20-year period since the previous war.

Author's Closure

In this closure I wish to express my appreciation of the considered discussions. Frankly, one of my purposes was to develop argumentation, particularly on the question of American costs of shipbuilding, and at least in this design a success must be admitted. In this closure it is not my purpose to prolong disputation, but merely to explain my point of view. Necessarily, in preparing a paper such as this, to be delivered in a limited time, one should eliminate all material possible. Even with this having been done the paper remains too long.

Doubtless the best refutation is a disclosure of error on the part of the opponent. I was careless in my reference to the *Titanic* and neglected to explain that I used the popular conception of the disaster rather than the technical one. However, Admiral Rock and others have carefully rectified this error, and there is nothing to be gained by a further discussion of it.

Mr. Metten has placed deductions in my paper which I do not think can fairly be found there. The paper was prepared for the consideration of a distinguished gathering of engineers. With men of this caliber it certainly would have been a waste of time to have elaborated my reference to the efficiency of an American automobile by an explanation that the building of a ship and the building of an automobile were not similar in so far as one could make use of quantity production methods. One of the speakers referred to the Eagle boats assembled by Mr. Ford during the war as a shocking example of what a mistake it would be to apply any automobile technique to the building of a ship. The fault with the Eagle boats was not with their assembly, which was remarkably well done. The fault was entirely one of design. I speak from the knowledge of having been the master of an Eagle boat on several extensive voyages.

In the discussion it was stated that a proper and unbiased analysis would show that the differentials in cost between American and foreign flagship operations were not as great as the differentials in cost the American shipbuilder has to face and that, therefore, if my deductions with regard to American shipyard cost are based upon sound reasoning, I as an operator might dispense with any form of government subsidy by applying the same method of efficiency. In my paper I stated that I believed that an operating subsidy for American ships would gradually disappear. On the other hand, I have yet to see this proper and unbiased analysis that in any way justifies the cost of building in American shipyards.

Mr. Smith has kindly agreed with much that I have said, and I in turn agree with practically all that he has said. Certainly American shipyards and operators are burdened with a lot of requirements that add to the cost of the ship. Many of these requirements are of questionable value. The problem of cost of ship construction as developed in my mind, however, accepted all of these many requirements and still found the American cost too high. How could I come to such a conclusion? For several years there was doubt in our minds as to whether or not it would be possible to go along with an American shipbuilding program. During those years we submitted several times to good builders in the United States and to good builders abroad identical specifications. These specifications included all the extraordinary requirements of American-built tonnage. The differences in the bids received at the same time and on the same specifications were startling. They reflected no credit on American shipbuilding costs.

From time to time this question of American costs has been discussed by me, informally to be sure, with the various shipbuilders. They have always assured me that there was complete justification for their costs. If such a justification exists, it seems to me that it ought to be very easy to put it down in a provable analysis. To prove this cost the shipbuilders should not have to rely on mistakes made in my paper with regard to the *Titanic*, nor the date of flooding curves, nor the date of the first double bottom, nor the failure of Mr. Ford to build ships, nor the cost of ratproofing an American ship not required in a foreign ship, nor to the fact that a ten-knot freighter is a far different type of vessel from a fifteen-and-one-half-knot vessel, nor to the self-evident fact that shipbuilding and automobile manufactur[illegible] are different processes. Mr. Smith states that a disinterested

investigation of shipbuilding will show that the industry is well abreast of other American industries in its efficiency, and far in advance of many. If this be true, it strikes me as curious that such a disinterested investigation has not been made, or if it has been made, it is not better known to those of us who ought to know.

Mr. Smith states that the shipbuilding industry is proud of its achievements and believes that it is well in the forefront of advancements that have been made by industry in the twenty-year period since the war. Complacency and self-glorification sometimes obscure the vision needed for self-discipline and correction. The Shipping Act of 1936 unfortunately places a premium upon inefficiency in the shipbuilding industry. The shipbuilder is entitled to ten per cent profit on his cost. Hence, the greater the cost the greater the profit. I made it quite evident in my paper that I was viewing the situation within the shipyards from a layman's point of view and without adequate experience in the yard. To my inexperienced eye there was a great deal of lost motion in every direction. It is possible, even probable, that I am entirely mistaken. In all fairness, however, are we not entitled to some tangible evidence of this? My purpose, frankly, was to arouse discussion in the belief that discussion leads to enlightenment, and enlightenment to improvement. In view of the volume of discussion, it seems, at least to that extent, the paper has been successful.

Problems of the Highway User in the United States

By FREDERICK C. HORNER,[1] NEW YORK, N. Y.

The present-day highway problem is made up of many elements, namely, cost of construction, ability of highway users to pay for highways as they are built or during their life expectancy, the kind of taxes providing revenue to pay for highways, types of roads required, competition between transportation systems, and kindred matters. No single solution exists for all of these. The author analyzes comprehensively each of the elements of this nation-wide problem and suggests practical approaches to their solution. Of all the factors making up this problem that of cost is probably dominant. How the costs are to be met is the crux of the situation as it now stands, with the ever-expanding highway needs pressing for action. It is the author's view that a recent report of the Federal Works Agency, Public Roads Administration on the general question of "Toll Roads and Free Roads" offers the soundest long-range plan for national highway development yet advanced. A comprehensive analysis of this report has been included and appears as an Appendix to the paper.

IN A PAPER presented by the author at the World Engineering Congress in Tokyo on November 4, 1929, the application of motor transport to the movement of freight and passengers was dealt with. In the ten years that have intervened, much progress has been made in this field of transportation, but largely along the lines of design, material, and construction of the vehicles, as compared with new uses to which they have been put—application. For example, ten years ago concrete was being "mixed in transit," not so efficiently or economically perhaps, but being done.

In the process of making these rapid strides in the use of motor vehicles, many problems, some quite serious, have arisen to confront the users of the highway. It is interesting to note that, in spite of this, the desire for individual transportation—the automobile—is so strong and the necessity for the truck and bus transportation services so vital to all of us that the march is ever onward.

An engineer need not always approach every problem of public importance from those technical points of view in which, by his training, he is particularly informed. An engineer is a citizen as well as being a technician; consequently, when broad national problems confront the citizens of a nation, technicians of all types properly are expected to view such problems not alone from their technical aspects but from the economic, social, recreational, educational, and other characteristics which many of our problems now have come to possess.

Cost of highway construction; the ability of highway users to pay for the highways in the main as they are built, but surely during their life expectancy; the kind of taxes from which revenue is to be derived to pay for highways; the varieties of roads to be built; the economic welfare to be subserved by highways; and the maintenance of competition among and between transportation media; constitute a main portion, but surely not the whole, of the nation-wide problem which now confronts our highway users.

It is a recognizable fact that the highway users in the United States cannot single out one phase or aspect of our national highway problem and maintain with assurance that the solution of the particular segment of the problem is the solution for the whole. Different individuals naturally select different phases of the problem as being most important but, for the purpose of the present discussion, it may be stated that the cost factor in the future highway problem of the United States is, if not the most important, at least an extremely dominant one.

None of us could realize twenty to thirty years ago, at which time the modern highway era was first being planned economically, technically, and legislatively, that it would sweep forward with that speed of construction and use which is now evident. Strong words are necessary to describe the 1939 highway situation in the United States; perhaps stronger words are necessary in any attempt to describe the highway era to be further developed during the next two decades. Gigantic costs already have been met; gigantic costs are yet to be met. Spectacular mileages of all types of roads, serving all parts of the nation and all citizens therein, have already been laid down and yet we continue to look forward to many great and necessary improvements in our highway facilities.

Construction and Maintenance Costs

In considering the cost factor relative to highway building, maintenance, and amortization, it is natural to observe that it divides into two parts: first is the continuing and annual expense in building new highways; second, is the constant annual cost of maintenance.

Referring again to the initiation of our highway era not much more than two decades ago, our arithmetic of cost at that time was all centered on the building of new roads. That was natural in what may be called the pioneer era of building highways in the modern manner. We then estimated total costs in the nation as a whole in millions of dollars. We now actually face highway costs which have been elevated into the billion-dollar classification.

Furthermore, we are now realizing that maintenance of highways, the cost of which we are beginning to realize after two decades of use of the highways first constructed, is the increasing feature in our national highway financing. Two or three decades ago the uninitiated thought that highways were practically everlasting and that the initial cost was the only cost, but as the years move along maintenance costs of highways are probably destined to equal or surpass costs of original construction.

Right here a word of advice, of warning, needs to be sounded in regard to the highway costs of the future. We can run

[1] Assistant to Chairman, General Motors Corporation.

Prepared for presentation at the Highway Transportation Session, the Society of Automotive Engineers cooperating, at the canceled Fall Meeting of The American Society of Mechanical Engineers, which was to have been held jointly with The Institution of Mechanical Engineers of Great Britain in New York, N. Y., September 4–8, 1939. Presented at a meeting of the A.S.M.E. Metropolitan Section, October 31, 1939, New York, N. Y.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

riotously into highway costs which will prove to be an extreme burden on the present and future highway users of the country if we build new roads, of whatever type they may be, far beyond present or prospective future traffic needs. Particular point may be made in this connection in regard to the transcontinental super toll roads, which some sources are now advocating be flung across the country, east and west, north and south, quite regardless of original cost, of traffic needs, and of assured methods of payment.

An important service—it may be stated an epochal contribution—to current thinking on this question has been rendered in the recent report of the Federal Works Agency, Public Roads Administration (formerly the United States Department of Agriculture, Bureau of Public Roads) on the general question of "Toll Roads and Free Roads." Little comfort is found in this report by those who, with superenthusiasm, advocate super-transcontinental highways. Indeed the report of the Road Administration recognizes that engineers can build highways of the most elaborate kind and cost, if only some source of revenue will provide the money. But that is not the question. The real question is: Do we need these superhighways? Connected with this question is the correlative one relating to the ability of highway users to pay for such roads.

The high spots of the Road Administration's report are as follows:

Transcontinental superhighways cannot be supported by tolls.

There is no habit of transcontinental travel by highway.

Less than 6 per cent of all trips outside of cities are longer than 50 miles.

Only a small portion of present traffic could be attracted to a toll system.

Motor-vehicle traffic on main roads in 1960 will be virtually double that of today in miles traveled.

There should be a system of direct interregional highways with necessary connections through and around cities.

By-passes will not relieve congestion within and near cities.

Ninety per cent of the traffic on main highways near cities is bound to or from the cities themselves.

Express highways cutting directly into and through the centers of big cities are needed.

An independent Federal Land Authority should be created, empowered to acquire lands needed for public purposes. It should be implemented to acquire, by purchase or condemnation, necessary lands for adequate urban and rural rights of way at reasonable costs, which would be sold or leased to the state or municipality on an amortized basis. It should also be *empowered to acquire and sell excess lands* for the purpose of recoupment.

Such "excess taking" would require changes in federal and state laws.

In addition to the foregoing, this report is of such profound importance not only to all those connected with highway transportation but to every citizen of this country as well, that an appendix is being included with this paper which gives a comprehensive analysis of the Road Administration's findings and recommendations. The author urges that it be read carefully.

No criticism is being directed at multiple-lane highways where they are needed, but it logically may be concluded that our future building of new highways in the nation, and maintaining of our roads, will be a gradual evolutionary process, very much like the building of the present so-called primary highway system has been. It has taken us approximately two decades to get the primary roads built; to get them connected state to state; to get them flung across the country north and south, east and west.

It is in regard to highway costs that the Report of the Road Administration is a monument to that sound economic thinking which we must not surrender, unless we are willing almost wholly to disregard the ability-to-pay principle, as applied to the highway users of the nation.

Here it should be pointed out that one of our most serious problems in the expansion and improvement of our highways is that of securing rights of way. It is no exaggeration to say this is the crux of the problems facing us. Unless and until means are found to secure rights of way within a reasonable time and at reasonable costs, amortized over a period of years, it will not be possible for us to proceed very rapidly in this important undertaking.

Ability-to-Pay Principle of Taxation

Closely akin to the cost factor in highways is that personal and economic factor frequently applied to taxation technique in all its forms, namely, ability to pay by those who are expected to pay taxes. Statistics have been compiled—which need not here be repeated—which show that the average highway user in the United States enjoys only a modest annual income. More than half of all family automobiles are owned by families which have an annual income of $1500 or less. In addition to this, the highway user drives a car the present average value of which is only $197. On this car he is already paying an average annual total tax of $53, more than enough to confiscate the value of his car in 4 years' time. Less than 5 per cent of all cars are owned by families having an annual income of more than $5000. Less than one third are owned by families with an income in excess of $2000. From trends which, fortunately, seem at least partially stopped by the joint activities of many highway-user groups, it has been concluded that the highway users of America could pay any taxes which any administrator or legislator cared to enact and to impose. On the contrary, for example, to the motorcar owner with an income of less than $1500 a year, a toll of one cent per mile would very seriously increase his cost of operation and hence retard the usefulness to him of his motor vehicle.

In former years it was the usual plan, when more money was needed, to increase the gasoline tax, to raise the registration fee, to enact a ton-mile tax, or to penalize the highway user further with constantly increasing charges for driver's permits. These trends, not wholly eliminated but definitely retarded at least, have forced us to recognize that the average driver of the family car, or of the truck, is a person who is making his living from day to day by honest toil and is not blessed with fabulous wealth which can be taken from him by the imposition of various forms of motor imposts.

Not the least occurrence in recent years which has caused the highway user to rise up in rebellion against constantly increasing costs of highway use, is his realization that the money he pays for highway revenues has been used in too large quantities for almost every other imaginable purpose of government. The question of the diversion of highway funds, iniquitous as it is in a highway era, has, however, served the useful purpose of awakening the highway users of the nation to a militant position; first, that revenues from motor imposts must be used for highway purposes; and second, that there is a limit of taxation, already reached, taking the nation as a whole, which limit is the ability-to-pay principle. This is always a safe yardstick to apply to any form of taxation. When this principle is disregarded by lawmakers and administrators, the point of diminishing returns in tax revenues is reached, and public opinion characteristically solves the difficulty by taking into its own hands policy making in regard to taxation, as is now evident in regard to highway taxes and the dedication of highway revenues wholly to road purposes.

To the highway users of the United States this is rapidly be-

coming a serious menace to their interests and, therefore, it seems desirable to explain more fully what is involved. The use of the revenues from the taxation of the motorists for purposes other than highways customarily is termed "diversion." To understand the popular attitude toward diversion, attention must be devoted to the basic economic theory underlying the taxation of the motorists.

Benefit Taxation

Originally, fees for registration of motor vehicles were required as a method of regulation in the use of the highways. In recent years, however, the intent has changed somewhat. The current conviction seems to be that the payments of such fees, in general, should vary according to the weight and the carrying capacity of the vehicle.

Beginning twenty years ago the fee for registration was supplemented by the state tax on gasoline. It is contended that consumption of gasoline is a valid index of the economic benefits derived from use of the highways. If this contention is sound, such a levy taxes the motorist in direct proportion to his use of the roads. The economists commonly refer to it as taxation in accordance with benefit.

Both these taxes, therefore, originally were intended to compensate for use of the highways. Because of the very nature of the tax on gasoline, an exemption from the tax or a refund customarily is granted on all gasoline which is not actually consumed in the propulsion of motor vehicles on the highways. On the same grounds, the proceeds of the tax logically should be devoted entirely to the construction and the maintenance of roads.

Early Recognition

The principle that revenue from the taxation of the motorists should be used only for roads was recognized fully in several states some years ago. In 1920 the electorate in Minnesota approved an amendment to the state constitution establishing a system of trunk highways and creating a sinking fund for the retirement of obligations issued to finance highways. This amendment required all funds from the taxation of motor vehicles to be deposited in the sinking fund. When the gasoline tax was adopted in Minnesota in 1924, the Trunk Highway Fund and the State Road and Bridge Fund were established. All of the revenue from this new levy was required to be deposited in these two funds.

The tax on gasoline first was imposed in Missouri in 1928. At that time, the electorate approved an amendment to the state constitution requiring all of the revenues from the taxation of the motorists to be used exclusively for highways.

When Kansas first levied the tax on gasoline in 1928, a somewhat similar provision was inserted in the constitution of that state.

Some discussion of these constitutional amendments seems appropriate. In this country it is the custom to embody the fundamental principles of government into a single written document. The federal government, of course, possesses only those powers specifically granted it in the federal Constitution. All other powers, therefore, are reserved to the states.

Rigid limitations upon the taxing power of the elective representatives always have been considered legitimate subjects for inclusion in state constitutions. In fact, such limitations are quite common and quite general.

Tendency Toward Diversion

In some states for simplification in accounting, a single general fund has been established and, as the state revenues are collected they are placed in it. The appropriations for the financing of the state government then are made from this same fund. However, in some of these states special safeguards have been erected to guarantee that the taxes collected from the motorists are expended for roads. Statutory provisions require the appropriation from the general fund of a sum equivalent to the yield of the levies upon the motorists.

During the depression, there was a marked decline in the yield of the established sources of revenue for the financing of general governmental functions. The revenues from the taxation of the motorists, on the other hand, showed a relatively stable yield. As a result, there was a strong temptation to divert the funds from the taxation of the motorists to supplant the decline in the revenues from other sources. This tendency naturally was strongest during the depth of the depression, but it still persists. In 1937, the most recent year for which detailed information is available, such diversions amounted to $161,413,000 or 13.7 per cent of the total collections of $1,177,827,000.

Legal Safeguards

Recently there has been definite evidence of a reversion to the original concept that the funds should be used only for highways. As the electorate has become concerned over such diversion, its concern logically has become evident in a movement to amend the state constitution. This was the case in Colorado, for example. Extensive diversions of the highway funds in that state, during the early years of the depression, prompted the initiation of a constitutional amendment. The measure was approved at the election in November, 1934, prohibiting all diversion after July 1, 1935. Similar constitutional amendments were approved in California, New Hampshire, and Michigan at the election in November, 1938.

The Congress of the United States similarly has disapproved diversion. No doubt many of you have some knowledge of England's system of subventions and grant-in-aid made by the central government to the local units. Our system of federal aid to the states for highways is quite similar. It is the author's understanding that the grants in England almost invariably are rigidly circumscribed, and that certain conditions usually must be fulfilled by the local governments before the funds can be obtained. In this country, certain requirements likewise must be met. One of the earliest was that the funds be matched 50–50.

In 1934 the Congress imposed further restrictions upon the granting of federal aid for highways. The language of the Act makes it apply to "Those States that use at least the amounts now provided by law for such purposes in each State *from State motor-vehicle registration fees, licenses, gasoline taxes, and other special taxes on motor-vehicle owners and operators.*" The maximum penalty for failure of compliance was to be the loss of one third of the annual allotment of federal aid. Two states, Massachusetts and New Jersey, thus have been penalized.

The general public, therefore, fully is convinced of the logic of strict adherence to the basic tenet in taxation of the motorists in accordance with benefit. This conviction, in turn, is reflected in the acts of the electorate's duly designated representatives in the state legislatures and in the Congress. The current trend clearly is toward more rigid adherence to the principle of taxation solely for benefit.

Highway Tolls No Solution

But what kind of taxes are we to have in our necessity to maintain all our present and future highways, and to build new roads? This question can be answered negatively and positively. The negative answer, briefly stated, is that the nation is not inclined to turn history backward and to resurrect and reinstate highway tolls. Some say casually that highway users once paid tolls so why not have them again. But such a casual state-

ment—one can hardly dignify it with the use of the word argument—fails to realize that roads, upon which tolls once were assessed and collected, were built in the main by the use of private capital. Roads now are built by the use of public revenues. Highway users will not tolerate the imposition of tolls on highways for one simple reason. The people pay for the roads in motor imposts in the main. They will not pay tools for the use of an instrumentality for the construction and maintenance of which funds have been provided from public taxes. That is the whole answer to the highway-toll proposition. History is not going to repeat itself in regard to toll roads in the United States. Free roads, along with free schools, are two foundations of a representative democracy and our national forefathers, who started us going in the form of government we are now maintaining, made provisions for these two fundamentals of government.

It is in this connection that reference again may be made to the report of the Public Roads Administration, "Toll Roads and Free Roads." This report does not condemn a toll if it is charged for a specific highway purpose, as for instance, a bridge over a navigable stream which, when paid for by tolls, becomes free. The exceptional conditions rendering toll collections feasible include also situations in which there is either an absence of a competitive facility or so great an advantage in the toll facility as to justify, in the minds of users, payment of the toll required. But the nation-wide application of the toll principle to superhighways is condemned.

The report does not state, but one may reliably conclude, that, if tolls should be relied upon to pay for any or all highways, ultimately the tolls failing in this regard, recourse would necessarily need to be taken to increase motor imposts which are already as burdensome as the average highway user can afford to pay.

The positive answer to the form of taxes which highway users are to pay may be found in the statement that the motor imposts, which are now being paid, seem to be the most logical method of highway taxation ever devised, if only in the nation and locally highway users will be on guard to prevent these imposts getting out of all bounds, in so far as the ability of the highway user to pay taxes is concerned.

The gasoline tax is an equitable and rational method of requiring the highway user to pay in proportion to his use of highways. Obviously, all motor vehicles must be registered with some proper governmental authority. But the cost of such registration is a problem which public opinion, concentrated among the highway users, should decide rather than to rest such decision with administrators.

Farm-to-Market Highway

The questions of the taxes paid by highway users and the motor revenues derived therefrom are directly related to the kinds of roads which are to be built in this nation. Reference has already been made to the multiple-lane or the divided highway, where traffic density is known to require such a road. On the other hand, so to speak, of highway types, is the country road or, as it is now named in federal statutes, the farm-to-market highway. Between these two extremes, the country road on the one hand, the multiple-lane highway on the other hand, is comprised the future program of highway building and maintenance. To build one of these classifications of roads without the other would be an unbalanced program. To build them both in compliance with the information contained in the Report of the Public Roads Administration, as well as the highway surveys now rapidly nearing completion in the states, is the part of wisdom.

Again public opinion must not be disregarded in highway matters. Public opinion gives recognition to the farm-to-market highways, although it required two decades to accomplish this. Public opinion recognizes also that congested traffic nearer metropolitan areas is a modern problem which, for purposes of highway safety, as well as factors of economics and pleasure, must be supplied with modern-type multiple-lane roads.

Fifty thousand communities in the United States have no ingress or egress for persons or for products other than by highways. Twenty-five million automobiles, approximately, serve the families of America and the business of the nation every minute of every day. Approximately 4,250,000 trucks roll to markets, factories, and stores with products of all kinds. Here, for instance, are a few: The entire milk supply of 17 cities ranging in size from San Diego to Detroit. Nearly three fourths of all the milk used in New York and Philadelphia. More than 95 per cent of all used in Atlanta, Baltimore, Pittsburgh, and San Francisco. All the milk that is consumed in thousands of smaller cities and towns from coast to coast.

More than half of all fresh fruits and vegetables eaten in the thickly populated northeast section of the country. Ninety-five per cent of all that is hauled 300 miles or less to market. More than 5,000,000 tons of livestock, upward of 27,000,000 animals, from farm to market. Fifty-five thousand tons of butter to Boston, New York, Philadelphia, and Chicago alone. Nearly 4,000,000 cases of eggs—upward of a billion eggs—to the same four cities every year. Buses make their valuable contribution to the transportation services of the nation to an extent which was undreamed of ten years ago; there are 130,000 now in use.

Modern Transportation Methods

It is idle for anyone to state that highway transportation has not taken its place alongside the other methods of transport which the nation enjoys at the present time. Highways, railways, waterways, airways, and pipe lines are the quintuplets of transportation in the United States. In other words, the economic welfare of the nation does not revolve around one transport facility, highways or otherwise.

The railroads are in a competitive era. The people will be served in transport matters. They demand transportation at the lowest possible cost. They advocate also high qualities of service, which cannot be given them by any one method of transportation. Accent again may be given to the thought that public opinion is always a controlling influence in public affairs. The public believes in competition; the public is against monopoly in transportation or otherwise, because it is the public that pays the bill. Any plan, therefore, that would peg or freeze rates or carrying charges, thus killing competition, which in the case of transportation means efforts to render a better service at a lower cost, is not in the public interest and should be fought to the last ditch, and in this country, at least, it is the author's belief that it will be.

Entering the decade of the 1940's, we are at a period during which this question of competition in transportation will be adjusted, if not solved. Such adjustment or solution unquestionably will be such as to benefit the average citizen if he, as a highway user, stands firmly for his own rights. But if, on the other hand, competition in transportation, through regulation and legislation, is made impossible and, if the public should be taught to believe that competition no longer is the life of trade in transportation and otherwise, then, inevitably, the citizen will pay more in the future for transportation than he should pay, or than he is able to pay. He will get a poorer quality of service and will eventually discover that, after having paid to a large extent for every method of transportation we have, he is destined to get no competitive benefits from them.

Unfortunately regulation by government has come to be, in recent years, an answer to almost every public question. Some

years ago, the railroads began to discover that they had competitors in the transportation field and that their half century of monopoly was ending. Immediately, those who spoke for the railroads—and in a most natural way—began to clamor that all other methods of transportation should be regulated to the same degree as the rails have come to be in a half century of development under the Interstate Commerce Commission. In other words, the solution of the railroad problem, as voiced by railroad representatives with their slogan "Equality of Opportunity," is to regulate the competitors of the railroads into that position of incapacity wherein they would be unable to render a cheaper and more flexible transportation service by highway.

Less Regulation of Transportation Methods Required

The people are beginning to realize—or perhaps they definitely do realize—that the solution of the highway problem in the United States is not to overcome, to subdue, and to neutralize competitive factors in transportation by the process of imposing extreme regulations on transport media, but lies rather in the other direction; to relieve the five methods of transportation from much of their regulations so that the people may be served more adequately by the very initiative of free, self-controlled management of free business enterprise engaged in transportation. But in recent years we have seen such extremes of regulation sought to be imposed against highway users as: Ports of entry at state borders; the denial of reciprocal arrangements among states; the diversity of sizes and weights for commercial vehicles; the threat of increased taxation; and encouragement given to diversion of highway funds.

Recently we have seen forty-four state legislatures in session in as many states. Actually thousands of bills have been introduced having to do with highway transportation, many of which have sought to impose more regulations or more taxes on highway users, or both. Too many of these measures were negative in character; they sought to destroy; they were not written and introduced to aid one method of transportation, but primarily to harm a competitor. Few of these negative trends in state legislation were enacted into law, but it has required constant and almost superhuman activity on the part of highway-user organizations to keep the battle line of defense intact, and to prevent ridiculous and extreme regulations being imposed on highways.

Highway use requires only two general categories of regulation. One is to provide for highway safety; the other is to protect the highways themselves by establishing uniform standards in sizes and weights of motor vehicles. When these two regulatory requirements are in effect, any further advance in regulating highway traffic reduces its competitive influences and, to the same degree, denies to all of us those benefits from highway transportation which otherwise we would enjoy.

It is not a sensible argument in a great nation like the United States to state that competition in transportation, the easing up on regulation rather than magnifying it, will ultimately eliminate one or more methods of transport. Some are even so inaccurate as to state that competition in transportation means that the nation would ultimately have only one method of transportation left. Such a conclusion is fallacious in the extreme, even though it is true that more than a hundred years ago one method of transportation, the newly developing railroads, did make obsolete the then existing methods of transportation, the canals, and covered-wagon-type facility.

But now we have 130,000,000 people who are moving from place to place to extents which were undreamed of by our forefathers. We have commodities now, both raw and manufactured, of such tonnage, volume, and variety that one method of transportation could not possibly handle. We have uses for transportation now which formerly were seldom thought of, such as recreation, travel, pleasure, enlightenment, which no one method of transport is wholly qualified to give. As a result of this competitive era in transportation, all citizens will be benefited; highway users will be allowed more economically to enjoy and to profit from the highways of the nation; and the entire economic structure of the country will be strengthened.

All of this question of regulation and legislation, centering in recent months in state capitols, more recently has revolved around Congress on Capitol Hill at Washington, where the effort for ten years has been to put all methods of transportation under the Interstate Commerce Commission. In the earlier years of the present decade, the slogan was "coordination." Later this was changed in words but not in meaning to "equalization of transportation opportunities." Both of these expressions meant, reflected in proposed bills and statutes, that by the methods of regulation competition in transportation either would be reduced to a minimum or wholly eliminated, spelling higher transportation costs.

Consequently the complete program of coordination of transportation media in the Interstate Commerce Commission has not been accomplished except in part. Motor carriers were placed under the Commission in 1935 with some support from certain motor carriers. Now it may be stated with some accuracy that those who represented motor transportation in 1935 and in prior years and who sought federal regulation in the Interstate Commerce Commission alongside its rail regulation, with the experience of several years, are questioning the wisdom of their former position. This questioning attitude is strengthened by a significant statement in the last annual report of the Interstate Commerce Commission, wherein the record is made that, as a result of the Motor Carrier Act of 1935, *highway transportation is more comprehensively regulated than are the railroads.* This statement would appear publicly to give recognition to the startling fact that, in less than one half a decade of federal regulation of motor vehicles, a strait-jacket of regulation has been drawn as tightly, or more tightly, around motor transport than had been accomplished in regard to the railroads in half a century.

Efforts to Regulate All Transportation

In the last session of Congress, the regulation-type solution of the problems of all users of transportation in the United States continued to be the one most relied upon in the consideration of so-called railroad relief bills. The effort was first made to put air transport under the Interstate Commerce Commission—that failed. The effort was made to impose on highway users the commodities clause which for a quarter of a century has been in operation for the railroads and which, if imposed on other methods of transport, would, for instance, deny a baker, a farmer, a carpenter, or any other citizen having his own motor vehicle the right to haul his own products to market. The effort to put the commodities clause on highways, waterways, air lines, and pipe lines was indeed the nth degree of the ambition to cure all troubles by the process of regulation. That effort failed, as it deserved to fail. But the problem of regulation and legislation, both at Washington and in the forty-eight state capitols is a continuing one and largely revolves around the question whether or not competition in transportation is to be continued.

New communities, new enterprises, and new opportunities have everywhere followed the development of new and better means for moving goods and people. But progress in transportation—the reduction of distance in terms of time and cost—is in a larger sense only a symbol of expanded horizons in every field of activity, a symbol of the opportunities that have been created by the capitalization of technological progress, and indicative of the future contribution of science and industrial research.

As an expression of this concept of the economic and social functions of transportation and its impact on industry as a whole in the world of tomorrow, the author wishes to direct your attention to General Motors' New York World's Fair exhibit of the last season, which many of you visited and which was built around the theme, "Highways and Horizons"—broadening highways of transportation, with expanding horizons of industry.

The "Futurama" in effect is a panoramic tour of a cross section of the country as it might appear in 1960. From moving sound chairs the visitor sees, as from an airplane, a dramatic conception of the towns, cities, and farms of twenty years hence. New highways link the cities. Feeder roads tap fertile agricultural areas. Produce of the farm moves swiftly to market. Industrial products are carried more economically to consumers in every community.

The cities themselves are decentralized. With convenient suburbs taking the place of congested areas, with city traffic freed by wide, open thoroughfares leading into and through metropolitan areas, a new type of city community is made possible. Workers are enabled to live at a distance from their employment. Suburban and farm dwellers have new access to town and city conveniences. Everywhere are evidences of quickened economic and social life. Better homes, better schools, more plentiful parks and playgrounds, new industries, more healthful surroundings, have in this fantasy of 1960 expanded horizons of living for all. Truly a marvelous conception of the possibilities for economic and social progress.

A free interpretation of the forecast into the next two decades given us in the Public Roads Administration report, "Toll Roads and Free Roads" would be that highway transportation will move forward in the nation gradually; that highway costs, both for construction and maintenance, will be constantly kept in mind; that no great departure from practices now well established in regard to free highways will be tolerated; that, although it is possible for highway engineers to build any type highway, anywhere, economics and the ability of highway users to pay taxes will be observed in the construction and maintenance of all roads; that the question of rights of way for the future, more than in the past, will be of growing importance; that such rights of way, with the wider highways now needed in certain areas, might cost more than the ability of the highway user to pay will permit, unless proper steps are taken to expedite right-of-way acquisition; and that the highways, being here to stay, must be allowed to be of the greatest possible economic use to the people of the nation.

Appendix

Congress, under the Federal Highway Act of 1938, directed the Bureau of Public Roads to investigate the feasibility and cost of building a system of transcontinental superhighways to be supported by tolls—such a system to be composed of not to exceed three roads east and west and three north and south.

The report in its final form was transmitted to Congress by a special message from the President on April 27, 1939:

"I recommend the report for the consideration of the Congress as a basis for needed action to solve our highway problems."

With this closing sentence, the President placed his stamp of approval upon findings and recommendations of the Bureau.

The following language appears elsewhere in his message:

"It shows that there is need for superhighways, but makes it clear that this need exists only where there is congestion on the existing roads and mainly in metropolitan areas."

The report is properly divided into two main parts, each replete with tables, maps, and plates setting forth statistical information. The bureau has drawn extensively from the traffic counts and other basic data developed during the last two years by the state-wide highway-planning surveys now being conducted in forty-six states.

1—FEASIBILITY OF A SYSTEM OF TRANSCONTINENTAL TOLL ROADS

Important Conclusions

The report asserts that a system of transcontinental superhighways cannot be supported by tolls; that the factual evidence clearly indicates, "direct-toll highways cannot be relied upon as a sound solution of the problem of providing adequate facilities for the vital and necessary transportation of the United States or to solve any considerable part of this problem."

From a purely engineering standpoint, the report shows that such a system might be entirely feasible, physically, and the construction could be completed by 1945, with a capacity sufficient to handle the traffic that would be developed by then and for the period 1945 to 1960.

A toll superhighway must be so constructed as to offer a special attraction to traffic. It must have an adequate number of lanes to accommodate comfortably the peak load. It must offer advantages which loom larger than the tolls charged. The width or number of lanes must depend upon the maximum rather than upon the average use.

The report finds that 400 vehicles per hour, divided equally in both directions, is a maximum which may safely be carried over a two-lane road without inconvenience. It has been found that a peak load of 400 cars per hour for certain hours will approximate a total of 1500 vehicles per day, on the same road. It also finds that three-lane pavements are undesirable; they show no marked increase in the volume of traffic above that which can move comfortably over a two-lane road.

Traffic exceeding 1500 vehicles per day should be carried on divided four-lane highways.

The year 1960 has been selected as being far enough in the future to permit of careful long-time planning. Furthermore, it is estimated that by that year the motor-vehicle-traffic mileage will be double what it is today.

Estimated Cost

Pursuant to the directions of the statute and after a thorough analysis of the wealth of basic data concerning volume, character and range of traffic, the condition of existing highways, and the need for new facilities, the bureau selected approximate locations for six superhighways, the total length of which as projected would be 14,336 miles. The estimated cost of constructing them to desirable standards would be $2,899,800,000 or an average of $202,270 per mile.

The report answers any possible suggestion that proposed toll rates might be increased to provide the required revenue. It emphasizes the fact that the average motorist has an income of only $1500 per year. It also points out that even a superhighway toll charge of 1 cent per mile would actually double the cost of operating a small automobile. The more money people spend for tolls, the less they have left to spend for operation of their vehicles.

Toll rates which would probably produce the most favorable rate for the system as a whole would average 1 cent per mile for each passenger car and 3.5 cents per mile for each motorbus or truck, with the latter rate varying considerably with the weight and capacity of the vehicles. It is assumed that bus and truck traffic constitutes 20 per cent of the total traffic. An approximate average rate would be $1\frac{1}{2}$ cents per mile for each vehicle regardless of type.

Potential Toll-Paying Traffic

The total utilization of these six superhighways in their entirety

would not be expected to exceed 4,544,000,000 vehicle-miles of toll-paying traffic per year. The study indicates that 3,635,000,000 vehicle-miles would be by passenger automobiles and 909,000,000 by motor trucks and buses. This averages 12,450,000 vehicle-miles per day, or an average of 699 passenger vehicles and 175 motor trucks and buses on each mile of superhighway per day.

"The most optimistic estimated average daily toll-paying traffic for the period varies from a maximum of 5998 passenger automobiles and 1500 motor trucks and buses for the section from Jersey City, N. J., to New Haven, Conn., to a minimum of 96 passenger automobiles and 24 motor trucks and buses for the section from Spokane, Wash., to Fargo, N. D."

The cost of construction, maintenance, and operation of these six turnpikes between the years 1945 and 1960 would average $184,054,000 per year. On toll rates of 1 cent per mile per passenger car and 3.5 cents per mile per bus or truck, the revenue for that period would only be $72,140,000 per year. "It is therefore concluded that a direct-toll system on these six superhighways in their entirety would not be feasible as a means of recovering the entire cost of the facilities."

Only a small portion of present traffic could be attracted to a toll system. Long-distance travel constitutes only a small fraction of the total. The majority of trips outside of cities is for less than 10 miles, and less than 4 per cent of all such trips are longer than 50 miles. Only 300 passenger vehicles cross a given line daily in transcontinental travel. There is no habit of transcontinental travel by highway.

Vast portions of rural and interurban travel would never reach the nearest superhighway and could not be considered as even potential traffic for the system. Vehicles traveling shorter distances than the spacing between access points would not use the toll roads.

A major share of the longer-range traffic could not be counted upon when adequate free highways approximately parallel the toll roads. The bulk of traffic would continue to use the main public highways. The remainder of potential patrons who are able and willing to pay the toll "in practically all cases is too small to support the cost of the desired facility except at a rate exceeding the willingness or ability of even these."

Heavy-Traffic Sections

The portion of the proposed system estimated to be most nearly self-supporting is the 172 miles from a point near Philadelphia to a point near New Haven. With the increase in traffic expected by 1960, this portion alone would earn slightly more than its estimated cost for that year. Twenty-five other sections are analyzed upon which the anticipated revenues for 1960 would produce from 91.8 per cent down to 50.5 per cent of the estimated cost for that year. Thus it will be seen that only 4000 miles of the entire 14,000 miles would come within 50 per cent of paying its way.

The report suggests that, if Congress desires to make a test, a section of highway properly located between Washington and Boston would offer the best possibilities of attracting traffic in sufficient volume to approach financing through the toll method.

3—A MASTER PLAN FOR FREE-HIGHWAY DEVELOPMENT

Component Parts of the Plan

The bureau, in addition to making a study of a suggested toll superhighway system, supplemented its report with a proposed "Master Plan for Free-Highway Development" throughout the nation. This calls for appropriate action by federal, state, and local governments. As desirable joint contributions of the federal and state governments, the report lists the following undertakings:

1 The construction of a special, tentatively defined system of direct interregional highways, with all necessary connections through and around cities, designed to meet the requirements of the national defense in time of war and the needs of a growing peace-time traffic of longer range.

2 The modernization of the federal-aid highway system.

3 The elimination of hazards at railroad grade crossings.

4 An improvement of secondary and feeder roads, properly integrated with land-use programs.

5 The creation of a Federal Land Authority empowered to acquire, hold, sell, and lease lands needed for public purposes and to acquire and sell excess lands for the purpose of recoupment.

In addition to these enumerated undertakings, the bureau concludes that:

The federal government should recognize this national problem by advancing the funds essential to the purchase of lands necessary to this capital investment.

These lands should be leased to the states and their subdivisions for a period of years on a basis which will result in amortization of the cost.

Construction of a special system of direct interregional highways, as referred to in item 1, would tentatively include 26,700 miles of roadway. Existing main highways can be modernized to form a large part of that system, but some new highways will be needed to provide directness of travel. Although these roads represent less than 1 per cent of the total mileage of rural roads, the bureau estimates that they would serve, when improved as indicated, at least 12.5 per cent of the total rural-vehicle mileage.

Transcity Connections and Express Highways

One of the striking characteristics common to all highway-traffic maps is a sharp enlargement of the bands representing the volume of traffic on the important highways as they approach the larger cities. Obviously, these enlargements have a local cause. In fact, they are caused by a multiplicity of short movements into and out of the city; and it is not uncommon to find that the traffic on a main route approaching the city is swelled to several times its volume a few miles from the city limits.

Ninety per cent of the traffic on main highways near the entrances to large cities is bound to or from points in the cities themselves and cannot be by-passed around them. A large part of that traffic is destined to or bound from points in the very heart of the city or points conveniently reached by going through the center of the city. Express highways cutting directly into and through the centers of big cities are greatly needed, not only for through traffic, but also for daily in-and-out movement of local traffic between downtown sections and suburbs. This can best be handled on overhead or depressed highways, preferably the latter.

By-passes may not be regarded as means for the relief of congestion of this kind. Even if the entire through traffic on the main highway could be diverted over a by-pass route, the volume of traffic on connecting streets at the center of the city would not be reduced by any appreciable proportion. Only a small percentage of the existing traffic at the city's entrance can be diverted. The bulk of the traffic that is bound to or from the center of the city can best be served by transcity connecting routes and express highways. By-passes are recommended for the smaller towns, while a new type of belt-line distribution road around cities is proposed.

Using the city of Baltimore as an example, it was found that

the great problem is to provide relief for the in-and-out movement of local generation. For instance, there are over 9000 cars per day traveling between Washington and Baltimore but only 1068 of these cars travel between points beyond Washington and points beyond Baltimore.

The report deals with the subject of slow decay in those parts of the city that are adversely affected by existing traffic conditions. Greater space is needed for the unfettered circulation of traffic. Plans must be made to remove the impediments that embarrass the movement of twentieth-century traffic through eighteenth-century streets.

"Excess Taking"

The most spectacular addition to the accepted highway methods of the last three decades is the proposal to empower federal and state governments to embark upon a large program of purchase and condemnation of wide strips of land in both rural and urban areas.

The report points out that the early obsolescence of rural highways previously built is due in a large degree to restrictions imposed upon their design by inadequate rights of way. Major revision is also needed in the present archaic street plans in order to permit the free flow of modern traffic. Farsighted improvements of both are blocked everywhere by the inability of the state and local governments, unaided, to provide required rights of way. There is danger that "expedient measures forced by the irresistible pressure of traffic will result in heavy new investment destined for early obsolescence." Needed new facilities will involve a heavy present investment but it should prove to be a permanent one and should pay large dividends in the avoidance of future expenditures.

A Legislative Problem

Many state and local highway authorities operate under definite statutory restrictions as to the maximum width of right of way that may be acquired. These statutory widths often were adopted many years ago, and it is difficult for the authorities to acquire rights of way in excess thereof, regardless of what traffic conditions to be met may require. The United States Supreme Court has indicated that the use to which the land is to be put is subject to definite limitations in order to avoid infringement of rights guaranteed by the Constitution. Consequently, legislative changes must be made, both state and federal. The Ohio Supreme Court has said: "We cannot sanction an arbitrary and unreasonable taking of excess private property."

The report recommends that the statutes of each state be carefully examined and revised where necessary; that such revisions should eliminate maximum widths which may be acquired and, if any specific limit is prescribed, it should be the minimum not the maximum; that discretionary powers should be conferred upon highway authorities to determine the width desired with specific authority for such right of way to include lands in excess of those actually needed for the physical location of the facility so as to provide for safety, roadside development, recreational, sanitary, and other facilities, and for future expansion of the transportation facility to meet prospective future needs.

"When we consider that the highway widths provided for in existing statutes were adequate for all practical purposes less than twenty-five years ago, it is not difficult to understand why we now find the right-of-way problem one of the most difficult with which we have to deal."

Federal Financing

By supplying capital for investment in adequate rights of way, on a scale sufficient to protect the facilities and provide amply for their expected growth, the federal government can lend practical aid.

"Such rights of way, acquired with federal funds at the request of a state highway department and in accordance with state and federal laws, could remain the property of the federal government subject to lease by the state over a period of 50 years on terms that would in that period amortize the initial cost.

"In view of the predominant national importance of such a system, the federal government could reasonably contribute to its construction in a proportion materially larger than that in which it contributes under the Federal Aid Act."

The creation by Congress of a Federal Land Authority is recommended. It should have a corporate status with authority to issue obligations and power to acquire, hold, sell, and lease lands for stated purposes, such as, adequate width for future rights of way, safety factors, roadside development, recreational areas, sanitary provisions, and removal of unsightly obstructions.

Such an authority would also be an effective means for promoting reasonable coordination with other federal agencies that must purchase land for their own use, such as, public buildings, parks, and slum clearances. The proposed aid of the federal government could not be effectively employed in any state in the absence of constitutional authority.

Extent of Acquisitions

"Acquisitions by such agency should include all areas, the need for which might reasonably be anticipated for the physical construction of the improvement and for necessary roadside development, including probable future expansions." Authority should also be given to solve the remnant problem, i.e., small parcels that are separated by the road improvement from the main body of land to which they were originally attached and the value of which is impaired to the owner by the separation. It is far cheaper to buy such lands outright in many cases than to pay the actual or proved damages.

Detailed investigations should be made leading to the designation of a system of reasonably direct interregional highways with appropriate connections through and around cities and limited in total extent to not more than 1 per cent of the total mileage of the rural highways in the United States.

The report of the bureau includes in its appendixes a copy of the "Restriction of Ribbon Development Act, 1935" of Great Britain. This provides for the acquisition of any land within 220 yards from the middle of any road, which is declared necessary for purposes of construction or improvement or for preventing the erection of buildings detrimental to the view. This provides a strip 1320 feet in width.

Other Recommendations

The Master Plan, according to the report, is a 20-year program, and any delay at this time means increased congestion by 1960. Outside of city limits, there is need of modernizing the main highways to ease curvature, reduce grades, and extend sight distance. Near the cities, there must be a steadily increasing mileage of four-lane divided highways.

Such improvements are required on most of the federal-aid and state highway systems, especially those parts built before the comparatively recent increase in travel speed of motor vehicles. For the most part, the report shows these improvements involve only local changes in existing roads.

The suggested improvement of secondary and feeder roads would include a careful selection of mileage from among the 2,650,000 miles of roads outside of the state and federal-aid systems. This 78 per cent of the country's total road and street mileage at present serves only about 10 per cent of the total

vehicle mileage of traffic; but located on them are the homes and working places of about 75 per cent of the rural population. The choice of these secondary roads to be improved is important, therefore, in the promotion of beneficial land use. The states should select not to exceed 10 per cent of the rural mileage for such improvement. These thoughts are incorporated in the following recommendations:

By continuance of cooperation with the states in the improvement of the federal-aid highway system and the elimination of hazards at railroad grade crossings, with annual authorizations commensurate with those previously provided.

By continuance of the program of secondary- and feeder-road construction, with appropriations equal to, or larger than those authorized for the fiscal years 1940 and 1941, to be expended in such a way as to give effect to the principles enunciated in this report.

Comments

There can be no doubt that the proposal of excess taking is the crux of the Master Plan. It should be noted that the President's message strongly emphasized the principle as a means of preventing excessive purchase and condemnation payments, and of self-financing through the resale and rental of excess parcels along the right of way. In fact, the President would apparently carry out the idea much farther than the report seems to recommend. The Executive message reads in part:

"Under the exercise of the principle of 'excess taking' of land, the government, which puts up the cost of the highway, buys a wide strip on each side of the highway itself, uses it for the rental of concessions, and sells it off over a period of years to home builders and others who wish to live near a main artery of travel. Thus, the government gets the unearned increment and reimburses itself in large part for the building of the road"—rather than providing a profit "to a mere handful of lucky citizens and which is denied to the vast majority."

This theory of excess taking and recoupment was espoused by the President a year ago when he made his first pronouncement in discussing a toll superhighway system.

The report sets forth the fact that "attempted takings by condemnation in excess of that actually necessary for the physical location and construction of definitely contemplated improvements have been held unconstitutional by the courts." With that fact in mind, the question naturally arises as to whether the situation can be remedied through new legislation, either federal or state. It may require constitutional amendments in many jurisdictions, and that is something which cannot be hurried.

Possible Legislation

It is understood that bills are being drafted for the creation of an independent agency to be called the Federal Land Authority composed (probably) of the Secretary of Agriculture, Secretary of War, and the Administrator of the United States Housing Authority with the Chief of the Bureau of Public Roads as executive director. This authority would have corporate powers with a capital stock of $100,000,000 pledging the full credit of the United States. It would be empowered to issue bonds and securities not exceeding $500,000,000 outstanding at any one time.

Such bills will, no doubt, include the right of eminent domain and of condemnation for the purchase of lands to be used for highways and the power to purchase adjacent lands. Purchase or condemnation will probably require prior approval of the state highway departments and the Bureau of Public Roads. The authority will doubtless be authorized to sell lands adjacent to condemned or purchased rights of way and to enter into contracts with municipalities before condemnation or purchase of urban extensions; the municipality to repay the authority the purchase price, plus interest, over a period of forty years. It is understood that at least one such bill would clothe the authority with power to collect tolls.

The idea of "taking" lands in excess of those absolutely necessary for use in developing the facility will have to be worked out with the greatest care. The political implications must be thoroughly analyzed in order that they may be avoided. It will not be sufficient, in the minds of many, to authorize broad powers of condemnation simply for the purpose of transferring the profits of the unearned increment from the individual property owner to the government.

New Landmarks

In "excess takings," including excess condemnations, a new term has been added to the highway lexicon. It is a term that denotes a new idea in highway technique and one that deserves careful and intensive study.

The report indicates a definite alteration in engineering thought relative to by-passing cities. By-passes have been urged and recommended by engineers for two decades, to permit through travel to avoid downtown traffic. Now it is the local traffic, to and from the downtown area, itself, that must be relieved. The data developed by the state-wide highway-planning surveys are responsible to a large degree for this changed thinking.

Roads, once thought of as being rural, are coming to possess more and more urban characteristics. City streets, instead of being considered incidentally as urban extensions of main rural highways, are now advanced to a more dominant position in the road program.

Among other questions raised with reference to the report, and its recommendations, are the following:

Are there adequate grounds for the assumption that highway traffic will be doubled by 1960? There are those who predict a lessening of highway travel due to improved home conditions, such as air conditioning and television. Any appreciable increase in cost of travel would also act as a deterrent.

A question is raised as to the amount of existing highway mileage that will be suitable for incorporation into the twenty-year interregional-highway plan. This is particularly questioned with reference to radial highways, belt-lines, by-passes, overheads, and depressed highways.

The report contains no estimation of probable costs of the recommended Master Plan. There is, of course, the assumption that a major portion of land-acquisition costs to be borne by the federal government may be recouped through the sale of excess parcels, the government profiting by the unearned increment. The fact remains, however, that there will have to be vast sums appropriated by the federal government for the proposed Federal Land Authority and that the federal government's immediate share will probably reach 75 per cent of the initial total cost. There is apprehension on the part of some that this might result in increased federal gasoline taxes.

A Contribution of Great Value

Practically all observers believe that the Master Plan seeks to solve the future problems of highway construction with a forthright and constructive program. There is no gainsaying the fact that the problem is of vital interest to the entire nation. In an editorial comment,[2] it is noted as being "one of the most important guide documents of public policy in developing modern road transport since the federal-aid laws of 1921." Further commenting on the report, the editorial states: "Its great con-

[2] *Engineering News-Record*, May 11, 1939.

tribution is bringing measured fact to bear on the problem and relegating to well-deserved limbo the fantastic schemes for transcontinental superhighway grids that often find voice in Congress."

The report* has been prepared by the most expert minds now dealing with the problem. Common business judgment demands that it receive most careful and serious consideration by automobile owners, truck and bus operators, business representatives, and legislators of both state and federal governments.

There is an annual diversion of special motor taxes to other than highway purposes that should go far toward financing this plan almost in its entirety. If the program is to be adopted, the antidiversion campaign should become an integral part of the whole idea.

Discussion

THOMAS H. MACDONALD.[3] Engineers as a class have been too content to let other elements of our social structure carry the flag where public policies are concerned. It is highly desirable for engineers to assume a leading role in economic discussions involving the facts which are, after all, based upon data with which the engineer works continually and knows how to evaluate, perhaps to a greater degree than any other element of our social structure.

In this field of highways and highway transportation, engineers have a particularly fertile field for the exercise of leadership, based on sound facts. Fortunately, accurate information is becoming more widely available through the efforts of city and state planning bodies, as well as other organizations which are coordinating the information from various sources, as a basis for establishing sound policies in the future.

The problem of developing freeways, i.e., free-flowing highways throughout the cities and in the metropolitan areas, in my opinion, is the major problem in which to become most profitably interested in the future. The matter of securing rights of way, adequate for that development, will be a serious one financially. So far as may be foreseen, this problem can be met only by the use of all the credit facilities available, both nationally and by states and municipalities.

It is particularly serious when the number of cities which have reached their maximum debt limit is realized. Changes in their constitutions are necessary to provide authority to borrow when saddled with debts of that character. So we must turn to the state and federal governments if we are to supply the credits essential to securing and amortizing these rights of way over a long period of time. Viewed from that angle, it appears to be a tremendous undertaking, which it actually is. However, looking at it from the angle of what will happen otherwise, it is much more serious.

There is no doubt of the authenticity of this freeway conception of passing through metropolitan areas, as a solution of the problem of rehabilitating such areas. It is the only solution for the serious migration of values taking place in our metropolises.

The principal question of the moment is: What will be the future of the cities? If that question could be answered, many of the problems of planning and laying out road systems in metropolitan areas to provide for future demands could be solved. Will the city be a compact area with population highly concentrated, or will it be more loosely knit with the inhabitants spread out over greater territory and with metropolitan highways acting as connecting links between principal centers within the metropolitan area? The discussion on the present paper will unquestionably develop some thoughts on this phase of the problem.

There is one detail in connection with the use of present-day highways upon which the writer would comment, namely, the overemphasis placed on criticism of the truck and slow-moving vehicle in traffic. In our own driving, we are conscious of such vehicles and have the feeling that, if they were removed from the highways, we might enjoy pleasanter and more expeditious trips.

That is true to a limited extent. However, the question generally arises where highways have sufficient traffic that the slow-moving vehicle is an obstacle to the free flow of passenger-car traffic. For example, a two-lane highway when overloaded would be no better off if all the truck traffic were removed.

For 3 years, we have been conducting studies of the utilization of two-lane highways by automobiles and trucks. Instruments have been developed which automatically record the speed, position, and other characteristics of the behavior of vehicles or drivers in given areas on different types of roads. From the records obtained, we are establishing factual data on highway conditions as the first essential step toward rectifying such conditions as offer traffic hazards.

While the writer is more concerned about the economics of the situation than planning or specifying the type of highways to build, there is some question of the effect of buses and trucks on the life of highways. Deterioration of highways from this cause usually may be accounted for by poor foundations rather than poor surface construction. Structurally, the problem of providing durability in highways has largely been solved by soil stabilization. Formerly much of the destruction was caused by solid-tired trucks and heavy vehicles. With soil stabilization and the use of pneumatic, particularly balloon, tires combined with better construction and inspection, the structural problem of providing durability in a highway is no longer serious.

Turning to the matter of imposing tolls as a general tax upon those who use the highways, in general, this would seem to be an unsound proposal. Certain cases may be justified on the basis of the highway functioning as a time-saving facility. It appears that the American public will pay for time-saving as they will pay for no other commodity within their reach. The question of metropolitan highway development, which at present confronts us in an acute manner, must be settled independently for each city to meet the particular needs of the community. The city highway-traffic problem is urgent and will require the best thought that we can muster for its solution.

The matter of development of adequate roads in the rural districts will be solved largely by planning and by better engineering. Soil stabilization is one of the two answers to that problem. In time, the farmers can be served, if the roads are properly planned so as to limit the mileage to the least possible.

HAROLD M. LEWIS.[4] The author states that highway use requires two general types of regulation, one to provide safety along the highway, and another to protect highway surfaces by regulation of sizes and weights of vehicles. These types of regulation are both for vehicles. The writer would suggest supplementing these by an additional type of regulation which would apply to the right of way, rather than to the vehicles, i.e., restrictions to protect the carrying capacity of the highway, (*a*) by regulating the roadside uses along the highway, and

* NOTE: Copies of the full text of the report, together with all maps and plates, may be obtained.

[3] Commissioner of Public Roads, Federal Works Agency, Public Roads Administration, Washington, D. C. Mr. MacDonald acted as chairman of the meeting at which Mr. Horner's paper was presented.

[4] Chief Engineer and Secretary, Regional Plan Association, New York, N. Y.

(*b*) by regulating access from such uses to the actual roadway of the highway.

Cases are familiar in which highways, constructed as important major routes and hailed upon their opening as providing express movement between municipalities, have, within 10 or 15 years, become so clogged, due to the fact that business and other uses have been built up along their borders, that it has become necessary to consider replacing them entirely by parallel routes.

One of the best examples of this condition is Route 25 in New Jersey, between Newark and Trenton. The State Highway Commission now admits that it will be necessary to provide an entirely new route in order to carry traffic without interruptions and at speeds which prevailed along the present state highway at the time when it was opened.

The most complete solution to this problem is what has become known as the freeway, or limited access highway. So far, legislation authorizing highway departments to construct this new type of highway has been adopted in only four states. Those are the states of Rhode Island, New York, California, and Connecticut. Other states have considered this legislation, but so far as the writer knows, none has adopted it.

What is meant by a freeway, or limited access highway? It has been generally defined as a strip of public land, devoted to movement, over which the abutting owner has no right of light, air, or access. In other words, it is exactly the same as a parkway with the distinction that the parkway is a strip of park property, devoted essentially, in theory, to recreation. Although parkways as we know have also been devoted to movement, they are limited to passenger vehicles, while the freeway supposedly would be open to all types of traffic.

Such freeways would accomplish two definite financial savings over a long-time highway program:

1 By constructing roads in this way, it would not be necessary to pave local lanes either in the form of extra width for local traffic, or in the form of service roads paralleling an express highway, because the roadway would be dedicated to the use of comparatively long-distance or through traffic.

2 It would avoid the necessity of duplicating roads which may later become clogged by roadside uses, and thus constitute an important means of saving funds in construction costs of new highways.

The Bureau of Public Roads Report, parts of which appear in the Appendix of the paper, refers to the possibility of excess condemnation and resale along these highways. It would seem to be almost essential that any such program should be coupled with some such regulation of roadside uses as the writer has outlined. Otherwise, the process of condemnation and resale would encourage intensive development along such rights of way and, if access were not properly controlled, would lead to a rapid decrease in the efficiency of those highways.

All main highways in a state highway system need not be constructed in the form of freeways. The writer believes that a considerable mileage of existing main highways can be made permanently useful and efficient by adequate zoning along those routes, combined with the establishment of substantial setback lines for any building development which may take place along them. Thus, in rural areas the state system may largely utilize existing roadways.

A freeway is particularly needed in suburban areas on the edges of metropolitan districts, or as main access highways either to or through large urban areas. The writer visualizes a main-highway pattern in a metropolitan area as including a series of radial parkways and freeways outside the central business district. As these come closer in and perhaps approach some major waterway crossing, a parkway and a freeway might well be merged into a single route, that is, the parkway might join the freeway and the parkway traffic travel over the latter for some distance before arriving at a main waterway crossing.

Where parallel freeways and parkways will not be justified in the suburban areas because there is insufficient traffic, it might be possible to develop a type of route which would combine these two by functioning as a freeway during week days, and as a passenger-traffic parkway exclusively during week ends and holidays. While there is no record of this scheme having been tried, it is being seriously considered by a county in a section of the New York metropolitan district.

The importance should be stressed of making the most use of existing facilities. The writer believes the best means for attaining this end is to have not only a master plan for federal highways, but one for municipal, state, and county units as well, which may be dovetailed with the master plan for federal agencies.

A word of caution should be given against making estimates of too great growth of motor-vehicle traffic. Population in this country is becoming stable, as is also the curve of number of persons per motor vehicle. By this it is not meant that traffic will not increase. It will increase because, in the writer's opinion, the use of the individual car, as measured by mileage per year, will continue to increase as improved facilities are provided. We shall use our cars more, although the registration will tend to stabilize as the population also stabilizes.

The following is an example of the dangerous tendency continually to propose the addition of new facilities. Ten years ago, the New York Regional Plan was published, which presented a picture of main highway routes existing and proposed for the New York metropolitan district. Within the time, approximately 50 per cent of the mileage of major routes shown on that plan have been rebuilt or built in new rights of way, so that that system is fairly definitely fixed. We find that, as this tremendous rate of highway construction has taken place in the New York region, regional-plan proposals for additional new routes, which were considered radical and extreme by many persons ten years ago, are now considered as being relatively conservative. Many other proposals have been advanced which, in multiplicity of routes and extravagance of construction, would far exceed what was proposed by the regional plan.

CHESTER H. GRAY.[5] Highway transportation is a part of the general transition in transportation which is taking place rapidly in the United States. During such a transition period, new developments occur or older methods assume new forms. Mention might be made of a few of the new aspects of the transportation problem, not particularly as they would impress the farmer, but as they would appear to all citizens.

It appears that we are in a period of maintenance which in dollars and cents, reflected in taxes assessed and to be collected from the highway user, is quite likely in the future to amount to more annually than the money spent in construction. This fact is not generally realized.

For two decades we have been building highways in the modern manner; at first, under the slogan that they would be permanent. It was soon realized that there is no such thing as a permanent highway. Now we are entering into the period of intense maintenance cost of these older highways. The maintenance cost of existing highways will continue, but added to it will be the upkeep cost on highways yet to be built. Most of the latter will cost more per mile than the ones thus far constructed.

Therefore, a new aspect of highway financing and of highway taxation, namely, the measure of ability to meet maintenance costs for ourselves and future generations, must be considered

[5] Director, National Highway Users Conference, Washington, D. C.

when we evaluate and plan the highways of the future. Maintenance sometimes begins the year after construction and undoubtedly within 5 years after construction, no matter how well-built the highway may be. Once it commences, maintenance continues perpetually, until the road is worn out or must, for one reason or another, be displaced with newer construction in its entirety. Thus, two factors must be carefully considered, maintenance cost of all highways old and new, and amortization of new construction.

In the future, two types of highways will take precedence, i.e., the multiple-lane or express highway through country areas or metropolitan districts and the farm-to-market highway. Where the necessity exists for such highways because of density of traffic for persons and products, and ability to pay for such construction over a reasonable length of time is evident these roads must be built.

In the main, payment will be made by highway users, principally in special imposts, the most prolific revenue-producing source so far developed being the gasoline tax.

In the case of the farm-to-market highway, which entails lower construction costs, public opinion will demand that they be built in increasing numbers.

Accompanying increased construction of these two types of highways will be a continuation of road construction as it has been known in the last two decades.

Another consideration, which is assuming some importance, is that of tolls. For certain causes and for certain limited projects, tolls may be permissible as, for example, the payment in a reasonable number of years of a tunnel under a river or through a mountain. In the case of bridges over navigable streams, the toll principle had assumed the proportions of a political racket; so much so that farm organizations among others in recent years have opposed it to the point where such construction has practically ceased. The ability-to-pay principle within reasonable time limits should be the measure of necessity for practically all projects, be they tunnel, bridge, highway, or some other. If funds which users of the highways already provide were applied to highway purposes and not diverted to other uses, the problems of construction and maintenance would be greatly reduced. In other words, emphasis should be given to the warning that we must not go too far and too fast in approaching the toll principle which some people now are advocating as the cure-all for financing highways.

A word of caution is necessary, in connection with acquiring rights of way for new highways, that the cost of this land does not too greatly exceed the actual cost of construction. With the liberal attitude toward public funds that has existed in Washington in recent years, the tendency of holders of land, required for rights of way to widen old roads or build new ones, has been to demand handsome payment from the government. There are many instances where such costs have been 50 or 75 per cent of the total cost of a highway. Twenty years and more ago, landowners were generous in this matter and held it as a matter of pride to donate land for this purpose. Legislation is needed to correct this tendency, so that funds provided for highways will largely go toward construction and maintenance and not into purchase of rights of way. Such legislation should be formulated in Congress, so that in January, 1941, when the legislatures of practically all states will again be in session, bills on this matter may be formulated and enacted.

This is a period of highway planning during which roads should be built of the proper materials and type to meet the traffic and other conditions to be imposed. In the future roads should be built so that subsequently they will not require straightening, leveling, or grading; they will proceed around or through cities as the need exists, and as funds and public demand make possible. They will be built in the country and, above all, a scheme must be developed by which a considerable proportion of the cost may be paid as they are laid, and the balance amortized over a reasonable period. Mr. Horner has done well to bring these important road matters to public attention.

L. W. Horning.[6] The author states that the two big problems confronting highway users are the continuing expense of building new highways and the annual cost of maintenance. There is also a third problem, that of rebuilding the roads which have been destroyed.

The ability of highway users to pay for them in the main as they are built, but surely during their life expectancy, has been referred to. It is a fact that in many cases highways are torn up and destroyed long before the bonds which financed them have been retired. The writer recently discovered a series of bonds which will not be retired until 1947, while the road which they financed was rebuilt last year.

There are two classes of highway users, i.e., private-car owners, mostly having modest incomes, about 25,000,000 in number, including the farmer and the merchant with their small trucks, and another group of bus and truck operators who use the highway as a place of business for private gain. Certainly there is no community of interest between the private motorists and these others. The writer does not believe that the average motorist has occasioned the rebuilding of 22 per cent of our highway systems at a cost, reported by the American Association of State Highways in a hearing before Congress in 1938, of $1,607,609,000.

The current conviction seems to be that the payment of motor-vehicle fees, referring to gasoline taxes and license fees in general, should vary according to the weight and carrying capacity of the vehicle. With that principle, the writer largely agrees.

However, he disagrees with the statement that gasoline taxes, federal, at least, were originally intended to compensate for the use of the highways. In a recent discussion before Congress, Senator Barkley said, discussing the gasoline tax, "Just for the record, I think it ought to be stated that, when the tax on gasoline was enacted, it had no direct connection with building roads." It was not enacted specifically for the purpose of using it to build highways. This excise tax, therefore, represents a contribution for the support of general government.

We do heartily agree that where a tax is levied upon gasoline or upon motor vehicles for the express purpose of constructing, maintaining, or repairing highways, that every red cent of that money should be used for that purpose. But we also maintain that there is nothing so sacred about a gallon of gasoline or a motor truck that taxes should not be levied against them for the support of general government. All this talk about diversion may backfire one of these days and the ordinary homeowner and taxpayer may demand that his taxes be not diverted either. Where would our highway users be, if you please, if those millions of people who are not highway users should demand that we spend on highways only the income from motor-vehicle levies?

With Senator Barkley's conception of the purposes to which gasoline taxes may be put, the writer is in full agreement.

At another point the statement is made that the motor imposts now being levied seem to be the most logical form of highway taxation yet devised. The writer believes that, generally, the principle is correct in so far as the private-car-owner class is concerned, but certainly it is not a fair measure of highway use nor a fair and equable tax for the business user, unless, for ex-

[6] Regional Director, Competitive Transportation Research, American Association of Railroads, New York, N. Y.

ample, the gasoline tax provided for a high rate when it was to be used in a 10-ton or a 5-ton truck as the case might be. A ton-mile tax might be a fairer measure of highway use by such vehicles.

Speaking of farm-to-market roads, it is a fact that the railroads are keenly interested, since about 14 per cent of railway taxes are used for that purpose. Such roads act as feeders for the railroads. In a recent statement of policy, highway users announced that farm-to-market roads should be paid for by taxes on land, not by levies on the users. The author referred to thousands of communities located on such roads served only by motor transportation. It is these communities which are largely located on the secondary or farm-to-market roads and still the highway users would have this class of road maintained by "taxes on land" and not on the users.

The author states that highways, railways, waterways, airways, and pipe lines are the quintuplets of transportation in the United States. In other words, the economic welfare of the nation does not revolve around one transport facility, highways or otherwise. With that the writer heartily agrees. Every one of these has a definite place in the transportation scheme of things.

Then he refers to our cry for equality of opportunity. What is wrong with that? Isn't every American business, isn't every American, no matter what business he is in, entitled to equality of opportunity? Certainly, one railroad is entitled to equality of opportunity with its competitors and, certainly, the railroads are entitled to equality of opportunity with their competitors who operate on the public highways, upon the waterways, and elsewhere. Today, that is all the railroads contend for.

One vitally important method of regulating highway users, not mentioned by the author, is that of regulating rates and services. The writer believes that most of the common carriers, engaged in transporting freight upon the public highways, would welcome regulation of the functions which other highway carriers perform as contract carriers. In fact, many of them demand the enactment of legislation to that end. So it has not always been railroad-inspired legislation that would have imposed regulations on the carriers upon the highways. These carriers themselves, have demanded and are still demanding such legislation and here and there are highway carriers "for hire" who have suggested that the private carriers should be regulated too.

In 1933, representatives of the highway users and the railroads in conference agreed upon certain fundamental principles which were applicable to highway transportation, among which was the matter of regulation. The conference was unable to agree upon the uniformity of weights, sizes, and rates.

The railroads contended, and still do, that there can be no uniformity in the size of motor vehicles until there is uniformity in the highways, uniformity in the ability of the people to pay for the highways, and uniformity of traffic. As regards reciprocity, the highway users agreed that trucks from one state traveling into another should pay something for the use of the public highways. They said that reciprocal agreements should be entered into at "equitable rates." Now they contend, not for equitable rates, but for free reciprocity.

Much has been said about the regulation applied to common carriers as highway users. A recent statement of the Interstate Commerce Commission is quoted to the effect that highway transportation is more comprehensively regulated than are the railroads. It is not quoted exactly. The statement was: "These

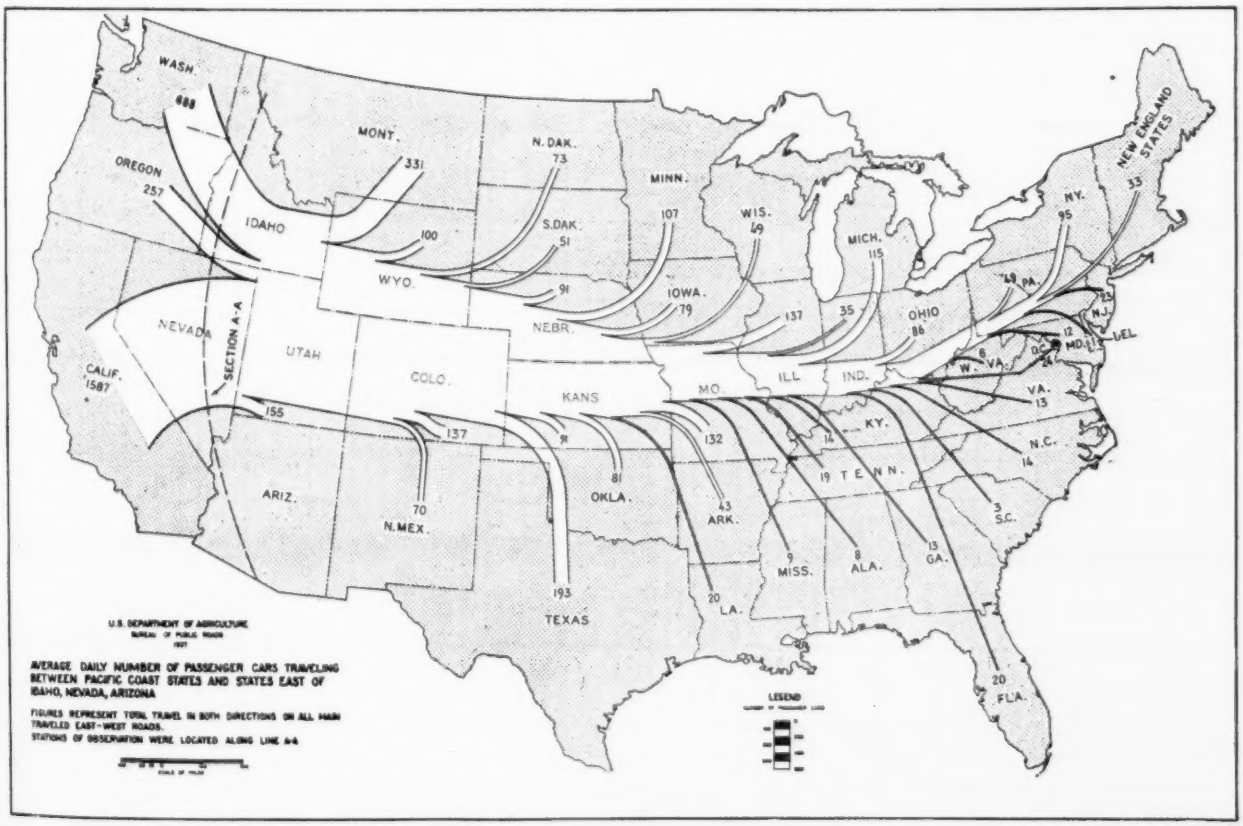

FIG. 1 DIAGRAM SHOWING THE STATES OF ORIGIN AND DESTINATION OF TRAFFIC ON ALL MAIN EAST-WEST ROUTES TRAVERSING THE STATES OF IDAHO, NEVADA, AND ARIZONA
(Traffic local to the named States omitted.)

two acts (the Motor Carrier Act of 1935 and the Civil Aeronautics Act of 1938) provide for the motor carriers and the air carriers, respectively, a system of regulation which is, if anything, more comprehensive than that which has been provided for the railroads." Possibly that is true. The writer believes such carriers should be, because they are operating on public highways, while the railroads operate on private rights of way.

H. S. Fairbank.[7] The report of the Public Roads Administration to which reference has been made in Mr. Horner's paper was in response to a definite question directed to the Administration by Congress. The report therefore took its character from that question. The question was whether or not it is feasible to build a system of three transcontinental roads running east and west, and three running north and south, from the Canadian border to the lower extremity of the United States, and whether or not it would be feasible to support such a system of six through or transcontinental roads by means of tolls. That was a definite question and the report first addressed itself to that question.

The conclusion at which it arrived, namely, that the building of transcontinental toll roads is not feasible, was the first answer that we attempted to give to that question and it was in the negative. In giving that answer, we did not mean to imply that there is no room, in the financing of highway facilities, for the use of a toll method. In fact, we specifically referred to the feasibility and possibility of using the toll method for financing certain portions of a highway, and especially for the financing of bridges and tunnels and other relatively short sections of highways, particularly in metropolitan areas where a toll facility is feasible because it offers a service greatly superior to that afforded by the competing free-highway facilities.

Having given the negative answer to the question of the feasibility of a toll system, the report proceeded to attempt to indicate what might be a positive answer in dealing with the general problem of providing adequate highway facilities for the United States. That answer was made along the following major lines:

[7] Chief, Division of Information, Public Roads Administration, Federal Works Agency, Washington, D. C.

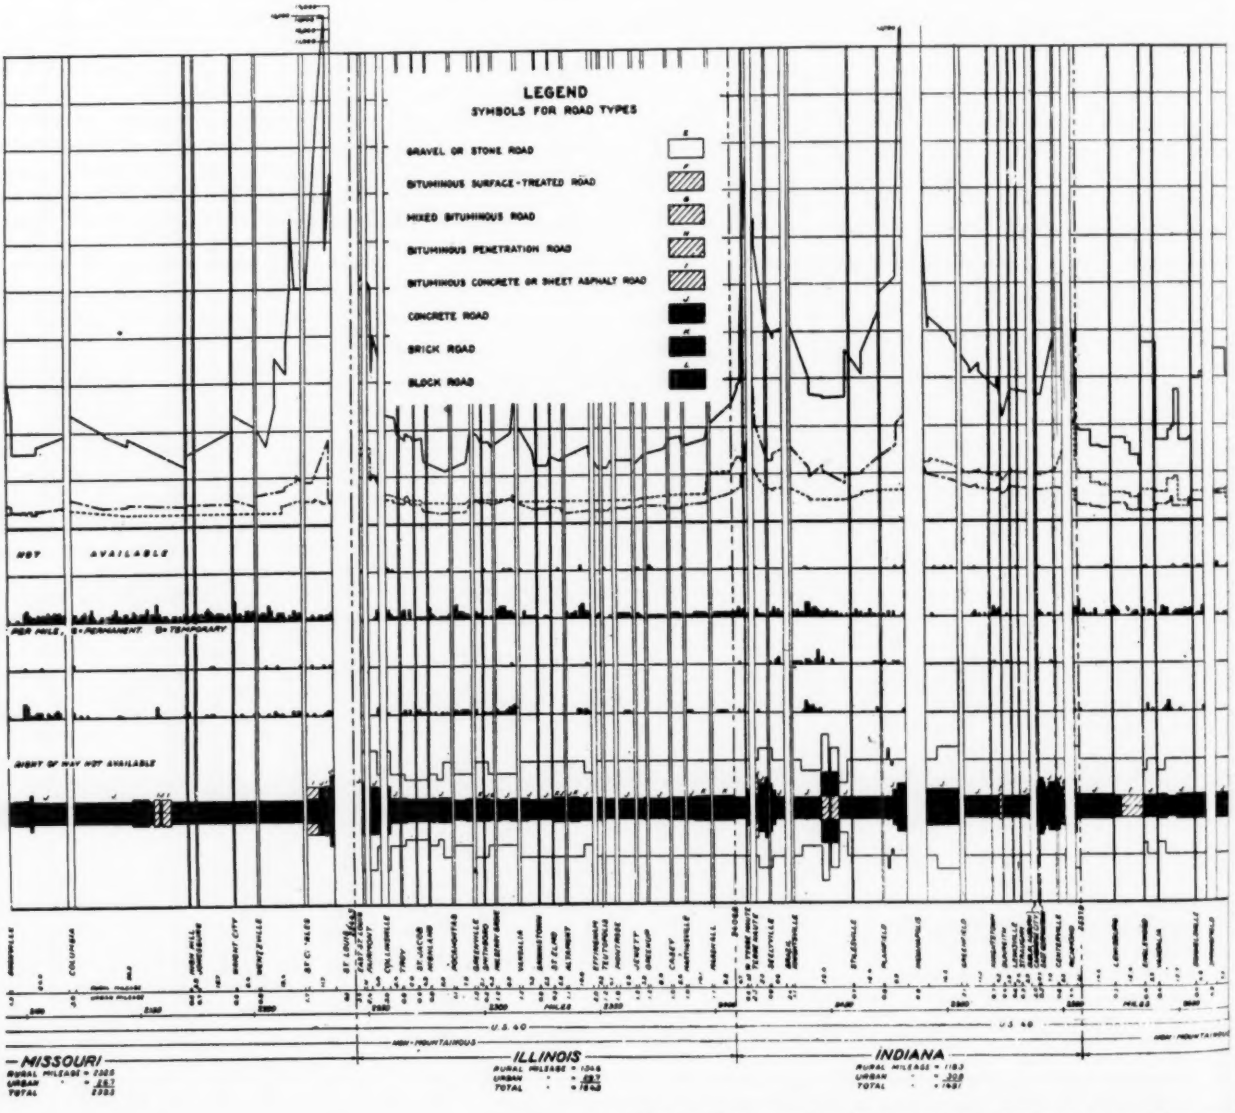

Fig. 2 Straight-Line Diagram of a Portion of the Principal Existing Conditions, as Revealed by the

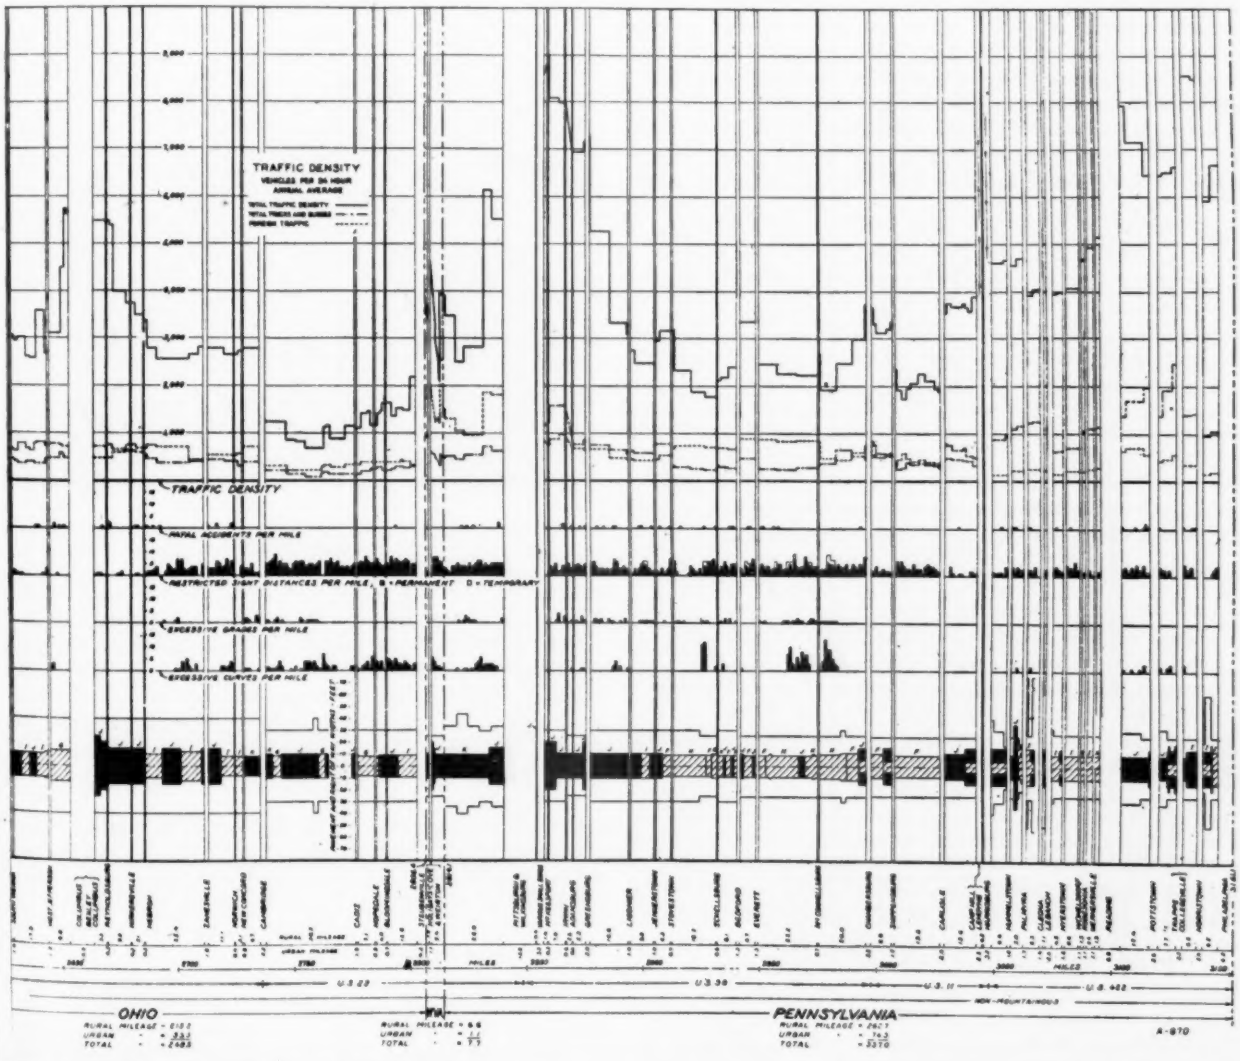
First, the report pointed out that the most serious problem has developed on our highways in the vicinity of the metropolitan areas, and in the cities. It also pointed to the necessity for a modernization of the main highways of the customary type, which were built largely in the previous decade, in order to fit them for safe use by vehicles now operating at speeds very much higher than were foreseen when the roads were built. This the report treated as the first element of a proposed master plan.



Next it was indicated that the principal location of such modernization of the main highways would be necessary along lines which might be extended into the formation of an interregional highway system of fairly limited extent, suggested as the second element of the plan. The report fixed the probable extent of that system as about 30,000 miles.

The third element referred to the secondary and "feeder" roads, local roads which are the feeders not only of the main highways, but also of the railroads. The three elements then were coordinated to form, in our estimation, a well-rounded plan of highway development which would meet all of the requirements of modern transportation, as they might develop. This plan was submitted as an alternative to the one-sided proposal which contemplated the construction of six main transcontinental highways. The building of such highways would only superficially touch the real problems that have developed through the growing use of our highways.[8]

Unquestionably, there has been built up in the popular mind an impression that the volume of transcontinental traffic to be served is large. To determine the actual dimensions of transcontinental traffic, a study was made of all main east-west highways, traversing the width of the country from the Canadian line to the Mexican border. Traffic counts were conducted in the states of Idaho, Nevada, and Arizona.

The result of questioning all but local traffic indicated that, on an average day, there passed along all of these highways, a total volume of about 2532 vehicles. Of these 2532 vehicles,

[8] At this point in the discussion Mr. Fairbank, by means of slides from the Public Roads Administration Report, illustrated major points developed by the author in his summary of this report. Copies of the report are available on request from the Administration.

Route Between Philadelphia and San Francisco Showing State-Wide Highway-Planning Surveys

1587 were bound to or from points in California; 257 were bound to or from points in Oregon; and 688 to or from points in Washington. The volume of traffic having its origin or destination on the East Coast amounted to but 300 per day. Thus transcontinental traffic is a rather thin trickle of our total traffic on the highways. (See Fig. 1 on page 87 of this paper.)

Conversely, the bulk of traffic on our highways is of a highly local range of movement. For example, based upon traffic observations, vehicles crossing into New York or out of New York, over the Hudson River by all the means of crossing from the Battery to Tarrytown, total on the average 82,000 daily. Beyond the metropolitan area of New York and New Jersey, nearly 5000 a day go to or come from points in New York State. Nearly 5000 a day go to points in Pennsylvania, or come from those points. Nearly 3000 come from or go to other points in New Jersey. Of the total of 82,000 crossing into or out of New York City, only 3100 remain as that portion of the large volume of traffic which either comes from or is destined to points more distant from New York City than the local counties and states. It is generally true that only about 6 per cent of total traffic throughout the country has a range greater than 50 miles per trip length. In sparsely populated areas, where distances are long and towns are far apart relatively light traffic flows on the main roads.

The areas of greatest traffic density are in the eastern and in the north central states, where distances are short and where there is a great concentration of short-distance movements.

Reference has been made to the fact that our present highways were built during a period when the speed of vehicles was less than it is now and, because of this fact, there is considerable

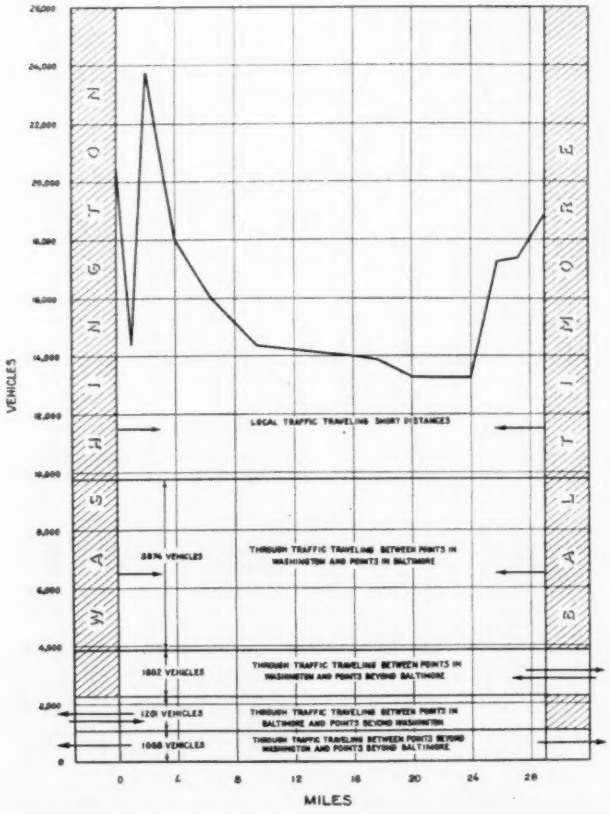


FIG. 3 DIAGRAM SHOWING THE ORIGINS AND DESTINATIONS OF TRAFFIC ON THE BALTIMORE-WASHINGTON ROAD, AND INDICATING THE SMALL PERCENTAGE THAT COULD BE BY-PASSED AROUND EITHER CITY

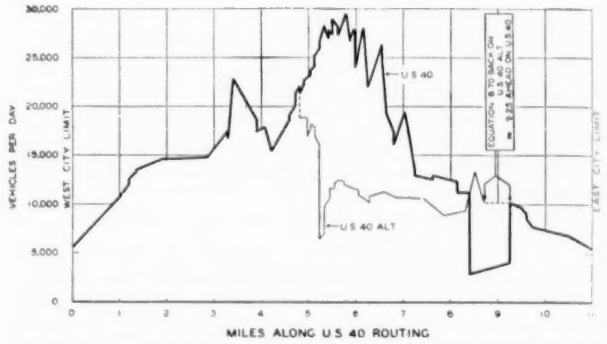

FIG. 4 TRAFFIC PROFILE ON THE ALTERNATE SECTIONS OF U. S. ROUTE 40 THROUGH COLUMBUS, OHIO, INDICATING THE LARGE EXTENT TO WHICH THE PEAK OF TRAFFIC ON THE ROUTE AT THE CENTER OF THE CITY IS DUE TO LOCAL CITY TRAFFIC

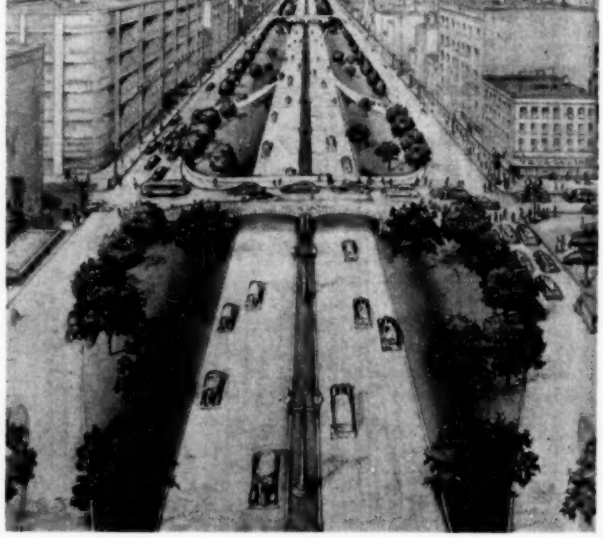

FIG. 5 SUGGESTED FORM OF A DEPRESSED EXPRESS ROUTE THROUGH A LARGE CITY

obsolescence of roads that were built during that earlier period. This is unquestionably a fair general statement of conditions.

One of the purposes of the so-called state-wide highway-planning surveys, which have been undertaken in most of the states, has been to determine just what that condition of obsolescence is, just what our problem of rebuilding may be, where that problem is located, and to what extent it is influenced by the density of traffic and the character of the provision that has been made previously (Fig. 2).

One of the facts developed by the surveys is that the greater percentage of traffic approaching a city is destined to, or emanates from, the city itself. Any proposal to by-pass that traffic would fail as a solution of congestion in the city, because the traffic cannot be by-passed, since most of it is generated by the city or induced by the city (Fig. 3).

A certain proportion of traffic might be by-passed around a city, but actually the greatest percentage of the movement has its origin or destination in the city. For example Columbus, Ohio, is traversed by two transcity extensions of U. S. Route 50. One of these is the main highway and the other an alternate route. The main highway carries about 5000 vehicles at the borders

of the city, while inward, traffic builds up to nearly 30,000 vehicles a day. If all the border traffic were to be by-passed, only a small percentage would be removed from the city. Therefore, by-passing as a remedy for traffic congestion within the city confines would be of but little account (Fig. 4). Actually the congestion is caused by the increasing volume toward the heart of the city being forced into streets diminishing in width. This is a condition generally experienced in older cities which have developed around narrow streets.

Where new and broader highways have been built, traffic will follow the line of least resistance, but when it must be diverted into the older and narrower streets of a business section, congestion occurs.

One solution to the problem of congestion within cities is the use of the depressed highway for bringing the major arteries into them (Fig. 5). There is no fixed preference for the depressed highway, but, in general, we believe that the depressed form of artery, rather than the elevated, is more consistent with the requirements of the modern motorcar. It would seem to make possible the extension or the wider distribution of settlement and does not necessitate the crowding or the concentration which might be indicated by the use of the elevated type of artery.

As we enter a city along such routes as those described, before long we penetrate a band or a zone within the city which represents the old residential sections. As the motor vehicle has made possible an outward movement of residential areas, we have left behind, in the band adjacent to the downtown sections, properties which were once good residences. These descend from one class of property owner to a lower class and finally become the slums of the city.

That condition exists in most cities and represents one of the tremendous tasks that must be dealt with in considering their future. As the necessity of providing through arteries is considered, the existence of decadent areas of old residential property seems to offer some hope that it might be possible to acquire rights of way for superior types of arteries, without involving too great expense, since the values of the old properties are declining steadily.

Beyond the cities, interregional roads have become a necessity. While such a system would comprehensively cover the country, it is not to be regarded as a transcontinental system. It becomes transcontinental only by the connection of local sections.

WILLIAM G. GROVE.[9] Mr. Horner's paper has emphasized many of the points brought out in the report "Toll Roads and Free Roads" prepared by the Federal Bureau of Public Roads, and the writer wishes to compliment Mr. MacDonald and the Bureau of Public Roads upon the thoroughness of that report. It is a masterpiece, and its careful perusal by anyone whose duties are connected with highway traffic is sincerely recommended.

For the last few months the writer's activities have been connected with the organization of the toll station on the Merritt Parkway and hence this discussion will reveal something of Connecticut's experience in the collection of highway tolls.

In June, 1938, the first section of the Merritt Parkway was opened to the traveling public. This parkway is a continuation of the Westchester County parkway in New York and, when completed, will extend from the New York state line to the Housatonic River, a distance of approximately 35 miles. The parkway is a dual type of highway; each traffic section is 27 ft wide and the dividing central island is 21 ft wide.

The Merritt Parkway will cost about $20,000,000, of which $15,000,000 is covered by a bond issue, now being refunded at the rate of $1,500,000 annually from the highway funds. The $5,000,000 remainder will also come from highway funds. The Merritt Parkway will be completed to the Housatonic River by July 1, 1940, and at the same time the bridge over the Housatonic River is scheduled for completion. This $1,000,000 structure is on the Wilbur Cross Parkway and is being financed through a P.W.A. grant covering 45 per cent of the amount; the remainder is to be taken from the regular highway funds.

The Wilbur Cross Parkway will eventually extend from the Housatonic River to the Massachusetts state line. The portion from Hartford south to Berlin is now under construction and will be paid for from the regular highway funds. Certain sections between Hartford and the Massachusetts state line have been built and other sections are now under construction.

The section from the east bank of the Housatonic River to Berlin, a distance of about 35 miles, could be completed in four years if funds were available. This stretch will cost approximately $20,000,000, and will require 20 years to complete on the basis of appropriating $1,000,000 a year from the regular highway funds for that purpose.

This, then, was the situation confronting the Highway Department at the first of the year, 1939. In order to complete the Wilbur Cross Parkway to Berlin by 1944, instead of 1960, three courses of procedure were considered: First to take $5,000,000 a year from the regular highway fund; second, to increase the state gasoline tax from 3 cents to 4 cents per gallon; and third, to float a bond issue in order to provide for the necessary amount of money and to amortize these bonds over a period of 20 years with money obtained by placing tolls on the Merritt Parkway and also on the Wilbur Cross Parkway as the latter parkway is completed.

Connecticut has a motor-vehicle registration of about 450,000 vehicles of all types. On the assumption that these vehicles average 10,000 miles a year and consume gasoline at the rate of 15 miles to the gallon, the approximate gasoline consumption at the present time is 300,000,000 gallons per year. The present state tax of 3 cents per gallon yields about $9,000,000; registration fees on 450,000 vehicles yield an additional $6,000,000, and these, with some miscellaneous revenues, provide an annual fund for the highway department of about $17,000,000 to $18,000,000 a year.

If the cost of the Wilbur Cross Parkway from the Housatonic River to Berlin were financed at the rate of $5,000,000 a year from the highway fund, the regular road program for both maintenance and new construction would be seriously crippled. Furthermore, a state tax of an additional 1 cent a gallon on gasoline consumption would provide only $3,000,000 a year.

The third plan that suggested itself was to raise the necessary funds by means of tolls. The 1939 session of the state legislature passed a bill, which was signed by the governor, authorizing tolls on the Merritt Parkway and, as commercial vehicles are not permitted on this parkway, a flat rate of 10 cents per car was specified in the bill. In order not to work unnecessary hardship on motorists who use the parkway regularly, a commutation rate of $10 was specified for any car licensed in Connecticut, which would entitle that car to unlimited passage through one toll station on the Parkway for a period of 1 year. The bill provides that one toll station shall be located in the Town of Greenwich and a second toll station located in the Town of Milford, and that there shall be such additional toll stations as the highway commissioner may deem necessary.

A study of the traffic over the Merritt Parkway near the New York state line indicated that approximately 5,000,000 cars would pass the Greenwich toll station annually, thus yielding $500,000. When the toll station at Milford could be placed in operation, after the completion of the new bridge over the

[9] Associate Highway Engineer, State Highway Department, Hartford, Conn.

Housatonic River in June, 1940, it was estimated that 3,000,000 cars would pass through that toll station annually, yielding an additional income of $300,000 a year.

The act further provides that 5 per cent of the highway funds shall be used for the Wilbur Cross Parkway and also authorizes the flotation of a bond issue, not to exceed $4,000,000. During the two-year period until the next session of the legislature in 1941, there should be available for the Wilbur Cross Parkway $850,000 a year from the regular highway funds of $1,700,000, $4,000,000 from the sale of bonds, and approximately $1,300,000 from tolls making a total of $7,000,000, or more than one third of the total amount required, which will be sufficient to purchase the right of way and to have under contract the construction of a considerable portion of the parkway from the Housatonic River to Berlin.

The 1941 session of the legislature will then be in a position to authorize the flotation of additional bonds, which, when added to $1,700,000 from the highway funds and $1,800,000 from tolls, will cover the total additional cost necessary to complete the Wilbur Cross Parkway to Berlin by 1944.

The act further provides that all monies collected from tolls shall be earmarked and placed in a separate fund known as the Wilbur Cross Parkway Fund, which fund shall be used, after deducting the cost of collecting the tolls, exclusively for paying the current bond interest and amortizing the bonds. After the Wilbur Cross Parkway has been completed to Berlin and paid for, and all the bonds have been amortized, the legislative act provides that no further tolls shall be collected.

The parkway toll bill was passed by the legislature on June 6, and signed by the governor on June 16. On June 21, at 8 a.m., the collection of tolls started at the Greenwich toll station and up to the present date (Oct. 31, 1939), approximately 2,350,000 vehicles have passed the station, which at 10 cents per vehicle amounts to $235,000 in 133 days, an average of almost $1800 per day.

During the summer the average traffic was 130,000 vehicles a week. After Labor Day, this weekly average dropped to 110,000 during September and October. The approximate monthly traffic was 590,000 for July, 570,000 for August, and 550,000 for September. The October traffic will be about 470,000 cars.

Sunday traffic averaged 30,000 cars for July, August, September, and October, with Saturday traffic averaging from 20,000 to 25,000 cars for the same four months. The greatest daily peak occurred on Labor Day when 39,855 vehicles passed the toll station. Based on present figures and allowing for decreased seasonal traffic during November and December, the three-million-vehicle mark should be reached about Jan. 1, 1940.

While the report prepared by the Bureau of Public Roads condemns the general use of toll roads throughout the United States, the report does state that in certain sections of the country toll roads would be self-liquidating and these sections are listed in the order in which the most profit is indicated. The number-one section on this list is from Jersey City, N. J., to New Haven, Conn. It is fortunate in that the beautiful Merritt Parkway is located on this number-one section. Traffic over the parkway is at the rate of 5,000,000 vehicles a year past the toll station when an alternate free route (the Post Road, U. S. No. 1) which parallels the parkway, is only 5 miles away. This is the answer to critics, that the public is willing to pay for superservice, which provides, first, safety, and second, a saving of time through the absence of red lights over a distance of 35 miles.

V. P. Ahearn.[10] Mr. Horner has surveyed the entire range of the question of sound public policy in the development of our highway systems. However, there are some points which, while not new, deserve special emphasis.

One of these is the tremendous threat to national unity which is presented in the multitude of state-highway regulatory laws, like the Port of Entry Law, the Milk and Food Inspection Law, and the like. Anyone who has read Dr. Buell's article[11] on this subject will have an uncomfortable realization that laws of this character, each prompted by the desires of special interests to monopolize local markets, will eventually reproduce in the United States some of the sore spots which are at the bottom of European controversies.

It seems to the writer of this discussion that there is real need for a dispassionate evaluation of our methods of land acquisition. Obviously, present public authority is admittedly inadequate even for the building of multiple-lane highways in some areas.

If regulation is inevitable, and if hopeless confusion is to be avoided, it would appear that uniformity of regulation is necessary. We should consider the question: "Is uniformity desirable?" If it is desirable, federal regulation would seem to be the only alternative. If that is true then it would be unwise to oppose such legislation solely on the ground that the powers of the federal government would be increased.

W. L. Waters.[12] The diversion of highway taxes has been much criticized. But we do not ask that cigarette taxes be used to provide smoking rooms or beer taxes to build saloons. So we cannot insist that motor-vehicle taxes be used exclusively for highways. The government taxes where it can, and gasoline like beer is ideal for the purpose.

As to highway construction, civil engineers are now working on soil mechanics and stabilization, and it is likely they will soon be able to develop a technique of building economically almost anywhere highway foundations equal to those of the Roman roads of 2000 years ago. So ten years hence highways may consist of a stabilized earth foundation covered with a thin flexible mat to protect it from wear, and the costly concrete type of highway will be obsolete.

It is also possible we are emphasizing too much the need for heavy expenditures on alignment and grades. Probably not one man in a hundred is physically and temperamentally fitted to drive at 50 mph in traffic; and long straight stretches of low-gradient highway are a temptation for the lunatic driver to speed at 70 or 80 mph.

As to highway routes in outlying suburban and rural districts, this problem is not difficult. It is merely a question of planning and spending money. But in the cities it seems hopeless. Some years ago I saw quite a disturbance in a village on the border of Burma and China which resulted from two caravans meeting in a street so narrow that the laden donkeys could not pass one another. So evidently traffic congestion is nothing new, and the history of large cities from time immemorial has probably been that transportation difficulties choked them so that they decayed, were abandoned, and replaced by new cities elsewhere which again went through the same cycle. And as our facilities which were sufficient in the horse-and-buggy days are now obsolete because of the demands of motor-vehicle transport, the same threat of decay hangs over our own large cities. Conditions can be somewhat bettered by substituting organized public-utility transport for much of the city traffic, by handling at night all trucking except household deliveries, by garaging automobiles in the suburbs, by severely restricting parking, by closing many street crossings, and by similar improvements. It is a question

[11] "Death by Tariff," by R. L. Buell, *Fortune*, August, 1938, pp. 32–35.

[12] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

for each city to decide whether it will submit to such restrictions or be gradually choked to death by traffic congestion.

The paper is most valuable, and it is to be hoped that it will result in a really common-sense national economic discussion of the highway problem. If it does, and if we can eliminate politics and introduce into our program some of the intensely commercial spirit which has been responsible for the phenomenal success of the motor-vehicle manufacturers, we shall, except in the cities, probably be able to develop most of the facilities required without greatly increasing taxation.

W. D. Ennis.[13] Not merely are roads expensive—major highways now cost as much per mile as railroads. In 1937, road expenditure absorbed about 3 per cent of our national income.

We argue about diversion, comparing total motor-vehicle revenues with highway expenditures therefrom. We began by postulating the application of all such revenues to major highway construction and maintenance. It was a new kind of postulate. Revenues from real estate, by contrast, were never wholly applied for the benefit of real estate. We are still collecting taxes from real estate to be spent on streets and roads. Diversion is not a one-way phenomenon.

Much confusion arises from the term "highway." Sometimes it means a major interurban thoroughfare. If we talk more broadly of "roads," public ways, including county and township roads and city streets, there is a lot of road cost which motor vehicles never pay.

The statement that a (uniform per-gallon) gasoline tax is an equitable and rational method of distributing highway cost in proportion to highway use is one that may be questioned. Such a tax might be fair if the vehicles all required the same character of road. But a large proportion of total road cost is due solely to a limited number of heavy vehicles. Lighter vehicles, including all private passenger cars, should pay no part of that excess cost. In New Jersey, in 1933, less than 5 per cent of all vehicles weighed over 7000 lb, yet it is for such vehicles that roads are planned. Fairer taxes on heavy trucks would open the way toward reduced taxes on vehicles of normal weight.

"Excess taking," the acquisition and sale by government of excess lands in connection with rights of way, is not really a new term or new idea, even in the highway lexicon. It has been discussed in road engineering for years, and experience is that it may require changes not merely in federal and state laws, but also in their constitutions. (Benefit assessments, as distinguished from local assessments of "cost," apparently not mentioned in the paper, are a related device to which there are similar obstructions.) It may be assumed that a moderate program of excess taking will be found most acceptable constitutionally. The Bureau of Public Roads program is moderate, if loose. It contemplates liberal provision for safety, roadside development, recreation, sanitation and other facilities, and future expansion (additional lanes).

The British strip width of 1320 ft (maximum) goes to the other extreme. Constitutional limitations, in our sense, do not exist in Great Britain. Even more extreme is the President's broad advocacy of seizing the unearned increment (equivalent to the benefit-assessment idea) and government speculation in land. If these policies are sound, their application should be broader than in the single field of highway construction.

Wear of Diesel-Engine Cylinders and Rings

By PAUL S. LANE,[1] BALTIMORE, MD.

This paper considers wear mainly from the viewpoint of cylinder and ring materials, rather than from the design or operating angle. The types of iron used, though important factors, have received only limited attention in published data. Existing wear rates in medium- and heavy-duty Diesel and gas engines in various fields of service are reviewed, followed by several examples of cylinder wear as affected by the hardness and structure of the iron alloy. By means of laboratory wear tests, correlated with service experience, the nature and characteristics of the materials used in cylinders and rings are surveyed and discussed in detail, covering the effects of section size, hardness, analysis, and structure. Initial engine wear, as influenced by bore finishes and wear-resistant or chemical surface treatments, is considered, together with the action of bimetallic or composite rings, in retarding scuffing and over-all wear rates.

THE WEAR of Diesel-engine cylinders, liners, and rings is a subject of mutual interest to engine designers, builders, and operators as well as to piston and ring manufacturers. Everyone even remotely connected with Diesel engines and their maintenance realizes that this subject deserves attention and study, particularly in view of the higher operating pressures, speeds, and temperatures which make lubrication problems more difficult. Even though improvements are being made in Diesel lubricating oils, the bearing and wearing characteristics of the rubbing parts will continue to have an influence on wear rates.

A review of published data on Diesel-engine cylinder wear gives considerable information as to the effects of lubricating and fuel oils, air and oil cleaners, design features, etc. However, only a few scattered references are made to cylinder and ring materials, and their influence upon over-all wear conditions.

In this paper it is proposed mainly to discuss and review present-day practice in regard to cylinder and ring materials, considering their wear performance not from the standpoint of any particular type of engine or service, but solely from the metal-structure viewpoint. An attempt is also made to illustrate the scuffing and scoring tendencies of various irons, and the possible effects of hardness, surface finish, and chemical treatments. Brief mention will be made of service results obtained through the use of piston rings of the Gold Seal or "insert" type, in reducing wear problems in various Diesel applications.

Rates of Wear

Before considering the possible influence of the foregoing factors, it seems advisable to offer the present interpretation of normal and abnormal cylinder wear in various engines.

Although it is agreed that the usual wear rate is greater than desired, yet this is difficult of measurement in service due to the gradual nature of the change. For example, it has been stated by Shidle[2] that, when a 5-ton truck finally wears out, it has actually lost in weight something in the neighborhood of 5 lb.

In the case of cylinder wear in medium- and slow-speed engines, the figure of 0.001 in. wear (diameter increase at top-ring travel) per 1000 hr is often considered normal. This means a wear per hour of 0.000001 in., which requires considerable amplification before it is possible of measurement with ordinary micrometers.

Table 1 shows wear figures submitted by Lee Schneitter,[3] which logically take into consideration a life expectancy of 6 years for liners, based on 8000 hr operation per year. Such figures must of course represent an average condition; the values appear to conform with general experience.

TABLE 1 LINER WEAR OF SLOW-SPEED ENGINES, BASED ON LIFE OF SIX YEARS

Cylinder diam, in.	Wear (maximum), before liner replacement, in.	Wear per year, 8000 hr running, in.	Normal wear, per 1000 hr in.
25	0.180	0.030	0.004
20	0.150	0.025	0.003
15	0.100	0.017	0.002
10	0.060	0.010	0.0013

Table 2 shows additional actual wear figures from a group of large stationary Diesel engines operating in pipe-line service in Oklahoma. These figures have been kindly contributed by J. B. Harshman.[4]

TABLE 2 LINER WEAR OF DIESEL ENGINES OPERATING IN PIPE-LINE SERVICE

	Four-cycle engines	Two-cycle engines
Number of engines	44	33
Number of cylinders	180	120
Size range, bore diameter, in.	16¼–22	15–20¾
Speed range, rpm	164–225	180–257
Usual load, per cent of rating	80–95	80–95
Average hours running per 0.001 in. wear	869	992
Average wear per 1000 hr, in.	0.0011	0.001

Two leading engine makes included in the two-cycle group of Table 2, have a service record of 250 to 500 operating hours per 0.001 in. wear (or 0.002 to 0.004 in. per 1000 hr). One engine, also included, gives 2000 to 3000 hr operation per 0.001 in. wear (or 0.0005 to 0.00033 in. wear per 1000 hr).

A recent service experience, involving a 925-hp, four-cycle Diesel engine, further illustrates the fact that very low wear rates are sometimes encountered. This engine, in ferryboat service, operates 24 hr per day every day in the year, except for two 2-week periods in dry dock for scraping and bottom painting. This engine is of the solid-injection type, 18 in. diameter × 24 in. stroke, running at 200 rpm.

New rings were installed in October, 1936, at which time the cylinders showed an average wear of 0.003 in. When recently examined in February, 1939, the maximum wear was found to be 0.009 in. or 0.006 in. increase in approximately 18,000 hr running; this is equivalent to a rate of 0.00033 in. per 1000 hr. Lubricating-oil consumption is reported to have been less than 5 gal per day or approximately 4400 hp-hr per gal.

In automotive engines, a cylinder wear of 0.001 in. to 0.003 in. diameter increase per 10,000 miles seems the normal experience with American engines. Piston-ring wear generally averages 0.003 in. to 0.005 in. per 10,000 miles.

[4] Master Mechanic, Stanolind Pipe Line Company, Tulsa, Okla.

Aircraft engines, even with very hard nitrided cylinders, frequently give a barrel wear of 0.0025 in. per 1000 hr. In this case, however, the time is roughly equivalent to 150,000 miles. Rings are of course always renewed at the overhaul period of 400 to 600 hr.

While all of the foregoing wear figures are offered as average values, undoubtedly there will be disagreement as to their being typical, since they may not be in accord with individual experience. It is this element of doubt which justifies employing some form of laboratory wear-test apparatus in an effort to eliminate the many variables experienced in actual service, and to rate the wearability in arbitrary values.

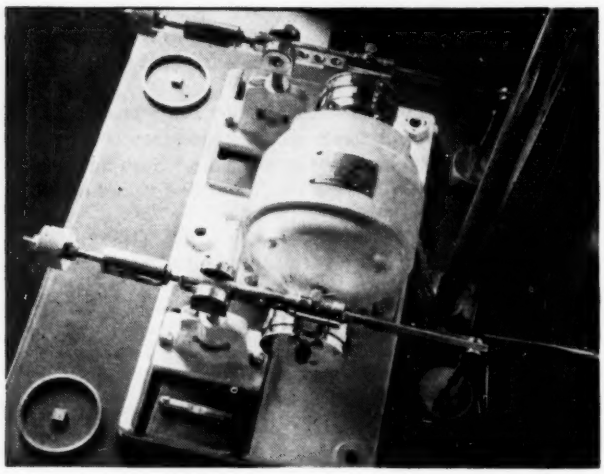

FIG. 1 TOP VIEW OF WEAR-TESTING UNIT USED FOR LUBRICATED TESTS UNDER HIGH PRESSURES AND LOADS

LABORATORY WEAR TESTING

During recent years, as a result of work done by various investigators relative to the effect of metal structure on wear resistance, it is now quite generally accepted that structure, rather than hardness, mainly determines wear resistance.

In spite of a wider knowledge of wear-resisting materials and alloys, the nature of wear itself yet remains an elusive quality, since it appears that each individual type of installation (having apparently its own particular set of conditions) reacts differently in relation to its wearing parts.

These conditions are further complicated by the fact that there is no universal or accepted method for testing or measuring wear resistance. In fact, it has been stated that a standardized wear-test machine is highly undesirable, as such an apparatus cannot possibly simulate conditions of all classes of service, on much the same basis that no standardized corrosion test has been found entirely reliable.

Due to this fact, many different types of machines have been used with varying degrees of success. All of these machines have failed, in one respect or another, to duplicate exact operating conditions. Nevertheless, it is believed that each of these attempts at measuring wear has added a bit more toward the total knowledge of wear characteristics in metals.

In a previous paper,[5] the author described certain wear results obtained with a machine of the brake-shoe type, wherein a flat specimen is held against a revolving drum, using a fixed load, no lubricant being supplied to the surfaces. A feature of this procedure is that, at the start of the test, the unit pressure is extremely high (momentarily at infinity), as the specimen makes only line contact with the drum. As wear takes place, unit pressures are lowered, depending upon the rate of wear of each specimen.

Fig. 1 shows the wear-testing apparatus, additional details of operating procedure may be found by reference to the paper.[5] Table 3 gives arbitrary wear values used to rate piston-ring-iron specimens.

TABLE 3 WEAR VALUES FOR RATING IRONS

Rating	Weight loss in 1 hr, mg
Excellent	18 and under
Good	20–24
Fair	26–30
Poor	over 30

Fig. 2 shows a schematic view of results on an extended wear test, comparing "time to seat-in" for a "good-" and for a "poor-" wearing iron. This illustrates the possible range encountered in the method of testing under consideration.

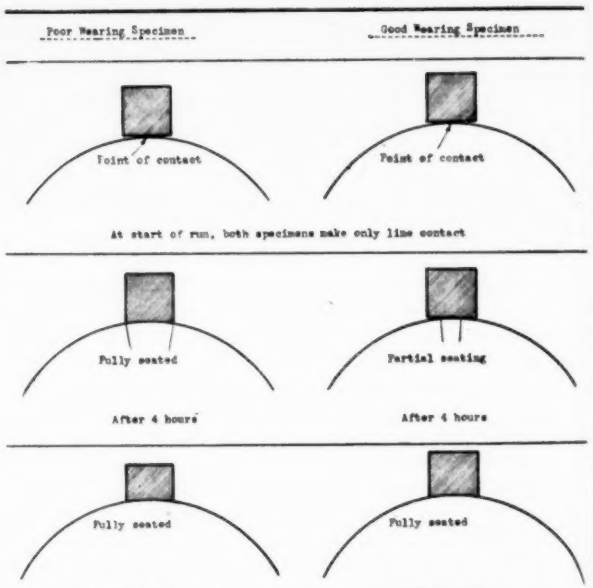

FIG. 2 DIFFERENCE OF SEATING-IN TIME FOR GOOD- AND POOR-WEARING IRONS

Gray cast iron is markedly affected by the speed of cooling. This in turn, is largely determined by the section thickness of the casting. This action is illustrated in Table 4, which shows the effect of section on the same ladle of iron poured in different size test bars, the combined carbon and hardness increasing as the section size decreases.

TABLE 4 EFFECT OF SECTION SIZE ON GRAY IRON CASTING

Cross section, in.	2	1½	¾	⅝	½
Graphitic carbon, per cent	2.95	2.90	2.80	2.65	2.40
Combined carbon, per cent	0.45	0.50	0.60	0.75	1.00
Brinell hardness	160	180	210	260	320

The change in hardness also means a change in other properties such as graphite size, strength, and wear, or abrasion resistance. This latter action is mentioned for the reason that it will frequently be referred to throughout the remainder of this paper.

DIESEL-ENGINE CYLINDER CASTINGS

One of the early investigations, in which the author partic-

[5] "Some Experiences With Wear Testing," by Paul S. Lane, Transactions, American Foundrymen's Association, vol. 45, 1937, pp. 157–199.

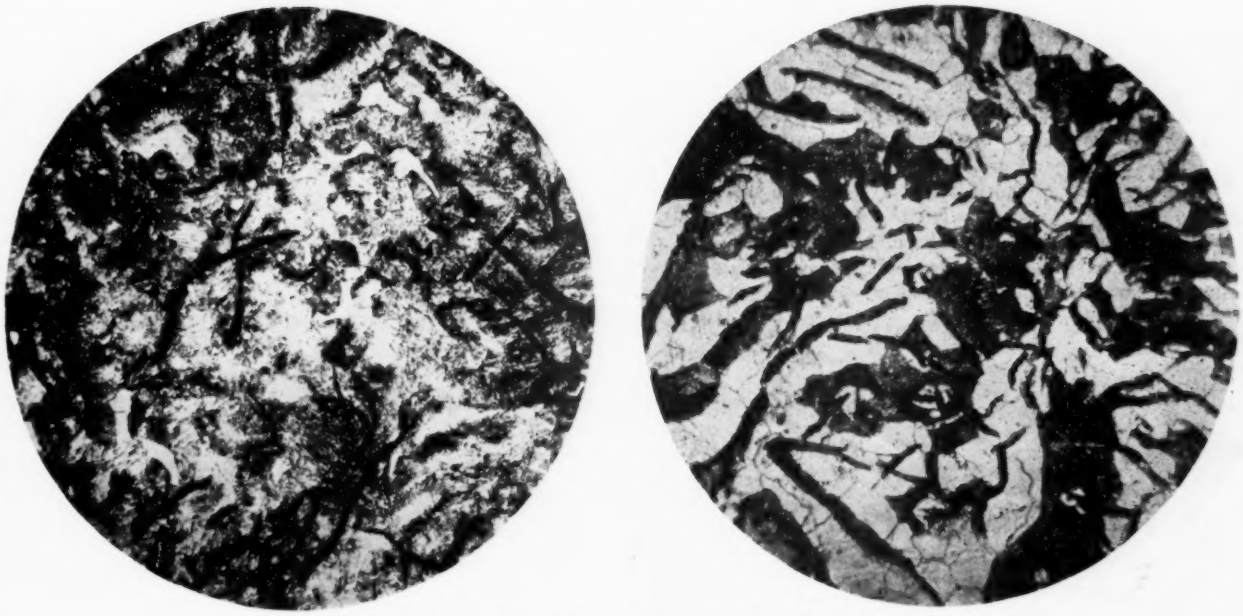

FIG. 3 DIESEL-ENGINE BORE STRUCTURES, ETCHED, ×200

pated, had to do with small Diesel-engine cylinder castings. Two sizes of engines were involved, one having a bore of about 3 1/2 in., the other a bore of 4 1/2 in. The section thickness of the bore proper was 3/16 to 3/8 in. for the smaller engine, and approximately 1/4 in. for the larger. The smaller engine showed normal wear in service, while the larger bore was giving high wear and scuffing troubles. Data on these castings are given in Table 5 and their microstructure in Fig. 3.

TABLE 5 WEAR DATA ON DIESEL CYLINDER CASTINGS

	Bore, 3 1/2 in.	Bore, 4 1/2 in.
Silicon, per cent	2.10	1.92
Sulphur, per cent	0.061	0.097
Phosphorus, per cent	0.19	0.14
Manganese, per cent	0.68	0.69
Total carbon, per cent	3.11	3.28
Graphitic carbon, per cent	2.55	2.86
Combined carbon, per cent	0.56	0.42
Nickel, per cent	0.57	...
Chromium, per cent	0.08	0.10
Molybdenum, per cent	0.06	0.31
Average Brinell hardness	185	158
Rockwell range	87–91B	80–85B
Wear value, mg	15.8	18.6

The wear value on the larger-bore engine is satisfactory from a weight-loss angle and may be viewed as not correlating with service results. On the other hand, it shows that the normal ferrite-graphite structure, if accompanied by large graphite flakes, resists wear (due to its toughness) in so far as weight-loss values are concerned. However, this very toughness accounts mainly for the scarring and scuffing tendencies of such structures. While this is not always clearly defined, it was noticed that marked roughening of the contact surfaces occurred with this specimen. A similar matrix, if accompanied by fine eutectic graphite, which more completely breaks up the continuity of the structure, would show a much higher wear rate.

As to the cause for such undesirable structures, this is due to incorrect analysis for the section thickness. Thick or heavy sections cool slowly, which may allow time for the structure to reach the so-called "stable" and undesirable ferrite-graphite composition (as shown at the right in Fig. 3), instead of one of the normal pearlitic forms. The same iron, only with lowered silicon content to adjust for cooling rate, would result in a structure similar to that in the 3 1/2-in. bore.

In connection with these results, it seems appropriate to mention that such conditions are apt to occur where castings of varying types and cooling rates are made under a broad chemical specification. When this is true, the foundryman should not be held entirely responsible. Rather, the fault lies with the management which may sometimes fail to appreciate the importance of mass effect and demand that all castings fall within a specified composition. This illustrates the need for close cooperation between the engineering and foundry departments, which is being urged more and more by the various technical societies.

VARIATION IN STRUCTURE AT PORT AREAS

Another example of the complications resulting from section thickness and design is the case of a cast-iron port section from a two-cycle Diesel engine having a bore of about 10 in. The ribs which separate or form the port openings have a relatively thin section, which is further exaggerated if the ports enter the cylinder tangentially rather than radially. The tangential design gives a thin tapered section immediately at the bore surface.

Under test and in service, these engines showed normal wear at the areas above and below the ports, where the metal thickness was approximately 3/4 in. Excessive wear was experienced along the port ribs, where the metal thickness varied from 1/16 to 3/8 in. Aside from any consideration of the metal structure, for many reasons it is true that more wear would naturally be expected around the port areas. The possibility of maintaining an oil film at this point is greatly lessened, and unit loading is higher. However, the wear on the ribs was so pronounced that metal-

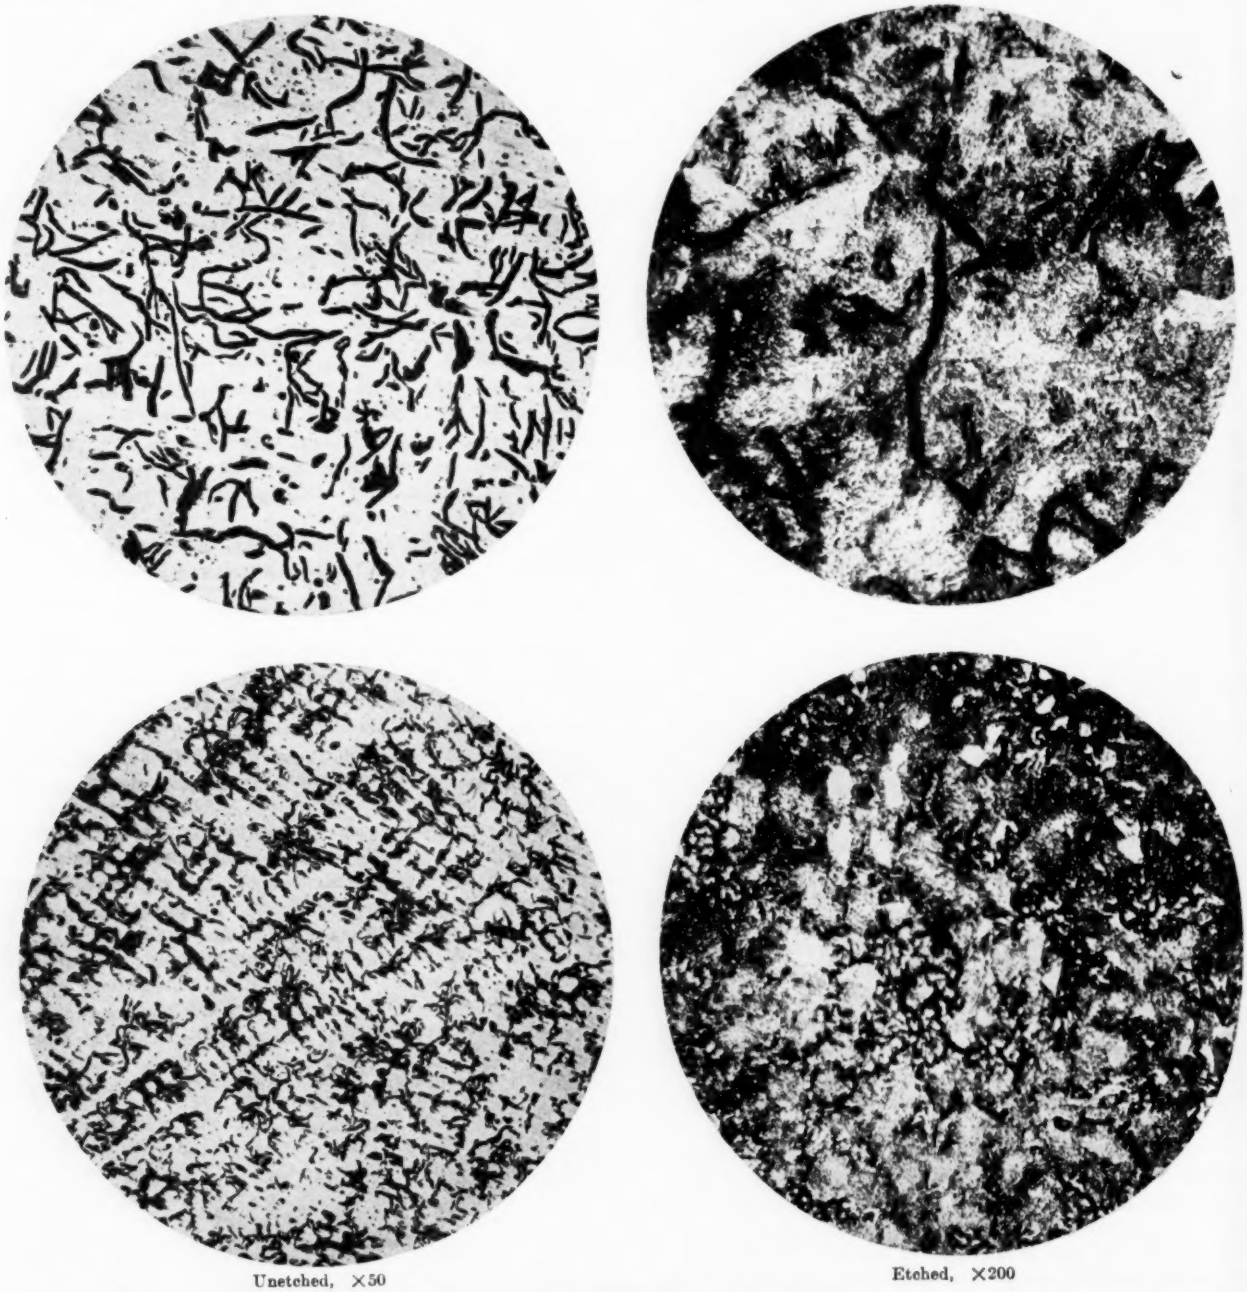
Rib-port section	D	3/8	23.5	89.5	183
Full section	E	1/8 to 3/4	15.3	88.0	175

structure and wear tests were studied. The results are shown in Table 6, together with the chemical analysis and hardness.



From the results shown in this table, it is seen that a 2 to 1 ratio in wear rate is indicated with only a small hardness variation. Fig. 4 illustrates the structure existing at the full sections and rib sections. The heavy section (top) has a normal eutectoid structure, rather coarse graphite (slowly cooled) and good indicated wear. The rib areas (bottom) have the fine dendritic graphite along with numerous ferrite spots; an abnormal structure with lowered abrasion resistance.

These tests have not as yet been brought to a conclusion, so it cannot be stated definitely just how important a part the metal structure will play in the solution of this problem. However, more recent wear tests, conducted on sections poured under different foundry conditions, are shown in Table 7; note the lowered wear rate in some of the rib areas.

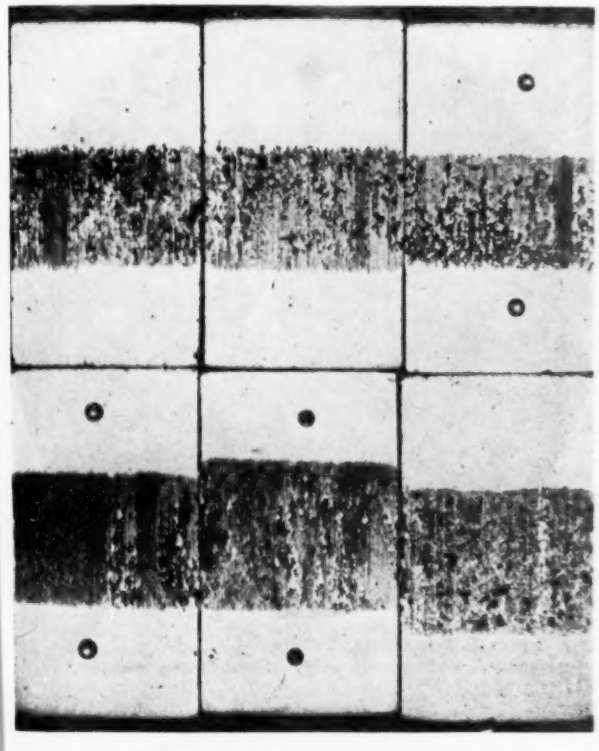

FIG. 5 APPEARANCE OF WORN SURFACE OF CYLINDER IRON; LOW WEIGHT LOSS BUT HIGH SUSCEPTIBILITY TO SCUFFING

variations within a single bore, are less prone to occur in liner or sleeve castings where the section thickness is more regular. However, it appears that present-day liners cover a rather wide range of hardness and chemical composition, as shown in Table 8 along with the section thickness.

NATURE OF LINER STRUCTURES

For the most part, liner irons for larger-bore engines are typical of the usual gray-iron casting used for various purposes. The matrix is mostly pearlitic. Generally, though not always, the liners are devoid of sizable amounts of free ferrite or cementite. Most American and foreign investigators are in agreement that a fully pearlitic structure gives relatively lower wear than other machinable types of structure. Another characteristic of such irons is that they usually have relatively coarse graphite, so they may be classified as of the "coarse-grained" variety.

Such structures, under friction conditions, generally show relatively low weight loss but with decided glazing or scuffing tendencies. This statement is based on a testing experience covering hundreds of various structures during the last few years. Fig. 5 shows the appearance of the worn surfaces of six cylinder-iron specimens. The light areas are dragged or "worked" metal similar to those encountered when metal-to-metal contact is present in rubbing surfaces. Early in wear-test work, the author observed this feature. Subsequent testing has developed a somewhat better understanding of this action, although films and surface effects are far from being entirely understood.

It is believed that the added ductility and toughness of coarsely pearlitic structures largely account for this worked surface. Irons of this type have certain bearing-like characteristics in that, under frictional forces, intimate contact with the mating surface is seldom obtained but rather, high and low points exist similar to the duplex structure in a babbitt. This means that the high points carry the load, while the low points hold the lubricant. It also means that areas of high local stress exist at the "tops" or "peaks" and, when conditions become sufficiently critical, scuffing or seizure occurs.

Pearlite, the dominating microconstituent in cylinder irons, is made up of alternate layers of ferrite (which is soft and ductile with Brinell around 100) and cementite, or iron carbide, having a Brinell of 600, with good strength, but of a brittle nature. Under conditions of boundary lubrication or dry rubbing, there is sufficient flow of the ferritic material to initiate scuffing or incipient galling. This action may tend to strengthen and support the surrounding crystals of cementite. A similar action is also believed to take place in the case of the hard phosphorus or steadite constituent when this is present in the microstructure. In order to explain this action, it appears that the pulling away of the particles of ferrite from the matrix also allows them to roll against and pack around the harder constituents, thus reinforcing the base of these compounds and actually strengthening them.

The ferrite movement between the laminations of cementite may also tend to lower unit pressures on the latter. It is believed that this surface is constantly changing upon itself. It is this quality which leads to the belief that the coarse pearlitic irons tend to "bruise easily and heal quickly," providing the point of critical loading is not exceeded. This theory appears to tie in satisfactorily with the low weight losses commonly experienced in the case of the relatively soft and weak irons. Another observation which should be mentioned is the greater abuse to the contact surface which obtains when testing irons of the cylinder type. This appears to be due, in part at least, to a tendency to load with wear products. In this instance, the nature of the structure is such that the tendency toward "imbeddability" of abrasive particles may be readily understood (Figs. 6 to 9).

Thus, on the basis of the foregoing reasoning, the viewpoint may be taken that cylinder or liner irons, at least those with which the author is familiar, generally have the following characteristics:

1 Coarse graphite and laminated pearlite matrix, generally near eutectoid composition.

2 Low dry-wear values based on the weight-loss method, but with proneness to scuffing.

3 Surface toughness or "flowability" indicated by character of friction surface. Wear products tend to adhere rather than slough away.

4 A "bruise readily and heal quickly" quality, probably a desirable feature if unit loading does not become too high.

5 Imbeddability, which may account for high abuse or lapping action to mating surfaces.

In actual service most Diesel cylinders show an excellent polished or glazed condition in those areas where lubrication is normal and resultant pressures lower. Near the tops of the cylinders, however, higher wear oftentimes accompanied by scuffing is sometimes encountered. Aside from the other causes to which this is frequently attributed, some of the characteristics mentioned may also bear on this phenomenon.

Nature of Piston-Ring Irons

Although piston rings, as well as liners, are of gray cast iron they are very different structurally from the cylinders just discussed. First the graphitic carbon is present in a finely divided form which breaks up the continuity of the metal. Second, though they are for the most part pearlitic, this constituent is of an extremely refined form approaching a granular rather than a laminated make-up. Figs. 10 and 11 illustrate the usual ring-iron structure. A comparison with the cylinder irons, shown in Figs. 6 to 9, brings out clearly the marked differences. Fig. 12 shows the usual appearance of ring-iron wear-test specimens.

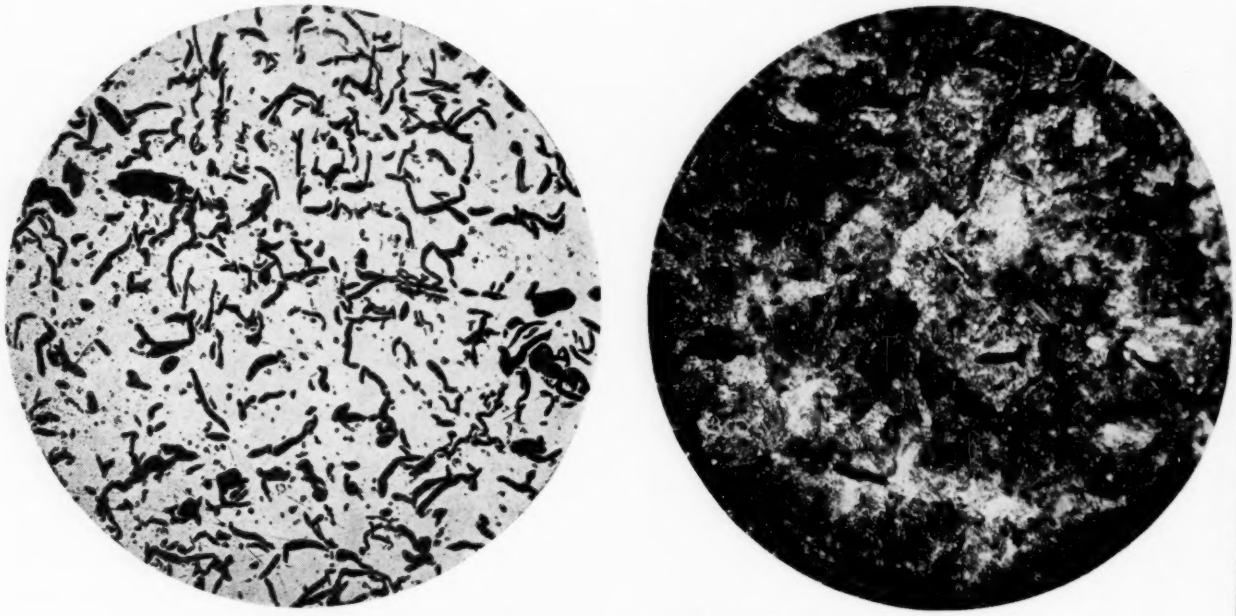

Fig. 6 Microstructure of Cylinder Liner of Engine F, 8-In. Bore; 220 Brinell
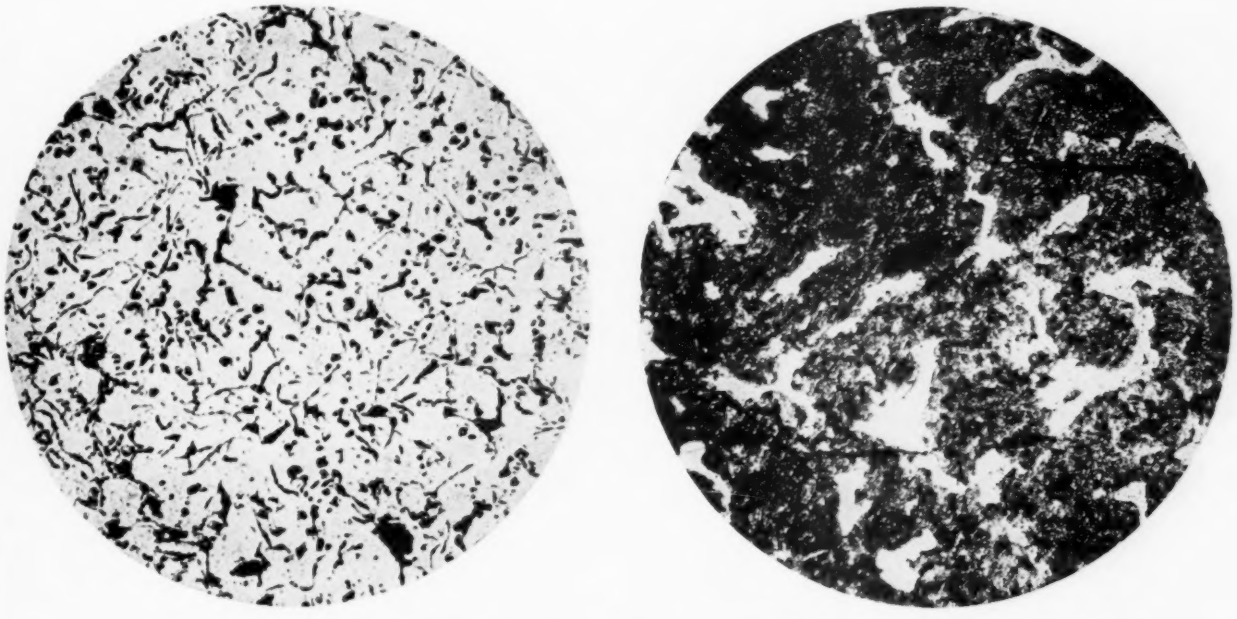
(Wear value, 15 mg; drum wear, 90 mg; total wear, 105 mg. Medium graphite, low phosphorus, pearlitic, slight scuffing tendency.)

Fig. 7 Microstructure of Cylinder Liner of Engine G, 10-In. Bore; 175 Brinell
(Wear value, 10 mg; drum wear, 115 mg; total wear, 125 mg. Very coarse "chunky" graphite low phosphorus, coarsely pearlitic, decided scuffing and welding properties.)

Irons of this group show relatively high wear as tested under the same conditions as cylinder compositions. This is due to the fact that they are "finer grained" and "less crystalline," both of which expressions are erroneous in metallurgical terminology but are used in the hope that they will convey the meaning. These ring irons, however, have two very distinctive and desirable qualities: First, they are exceptionally free from scuffing inclinations, and second, they are sacrificed to maintain the integrity of the cylinder.

The freedom from scuffing inclinations is due primarily to the form of graphite, which results in a ready sloughing away of wear products, permitting the material continually to present a smooth unblemished face to the mating surface. Particles of the surface, cut or abraded by wear forces, do not build or "ball up," but rather are prone to powder away in a fine dust. To illustrate: soft steel, due to its toughness and ductility, is infamous for its scuffing proclivities. Under dry rubbing, the wear products weld to the surface eventually resulting in galling and seizure; this being the converse of ring-iron characteristics.

Tests also have shown that, when wearing against a wide range



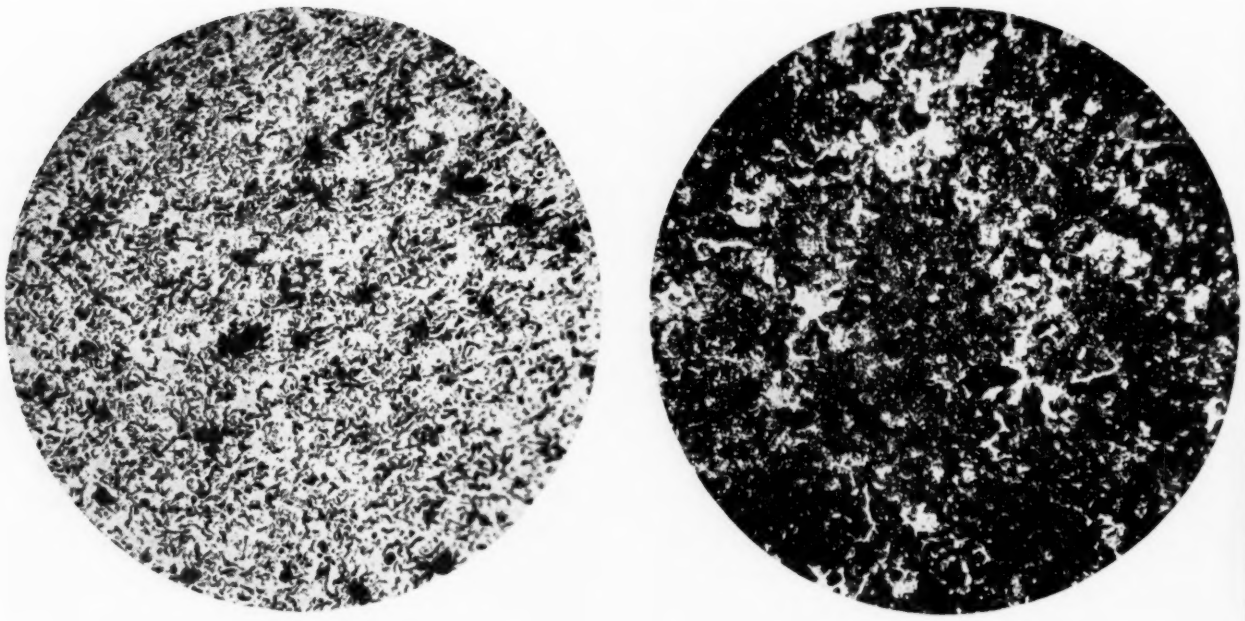


FIG. 8 MICROSTRUCTURE OF CYLINDER LINER OF ENGINE D, 5-IN. BORE; 215 BRINELL

Unetched, ×50 Etched, ×200

FIG. 11 MICROSTRUCTURE 14-IN. DIESEL-PISTON-RING IRON
(Wear value, 27 mg; drum wear, 47 mg; total wear, 74 mg.)

of mating materials and finishes, ring irons do not load or abrade. Instead, they are themselves worn, taking the major part of frictional abuse.

Piston-ring irons, on the basis of the foregoing, may be said to possess the following characteristics:

1 Very fine graphite and sorbitic-pearlite matrix of eutectoid composition.

2 High dry-wear values, based on weight loss only, but with good freedom from scuffing proclivities.

3 A granular surface tending to free itself of wear products, thus presenting a smooth unblemished contact face even under adverse loading.

4 Tendency toward glazing is less than in coarser-type irons, such as are often used for cylinders and liners.

5 Slight proneness to imbedding of abrasive matter so that lapping action is not present on the ring face.

In present-day practice, coarse-grained irons are utilized for cylinders and liners, and fine-grained irons for rings. In both

instances, this is likely a result of foundry practice rather than of choice. Fig. 13 shows the difference in grain or cell size of a Diesel-engine liner and a ring. It is apparent that structurally these irons are very different, this difference being one of cooling rate rather than of hardness and analysis. Fig. 14 further illustrates this condition showing the difference in graphite size between a ring and a cylinder.

The apparent theory is that coarse-grained irons are best for cylinders since they will glaze and polish, due to their natural surface toughness. This results in low wear if lubrication is always present. When oil supply is erratic for one reason or another, metal-to-metal contact occurs. When this happens, normally the piston ring will take the abuse and protect the cylinder. If the dry condition becomes too severe, however, scuffing starts. It is believed that this is usually initiated on the cylinder surface and is then transferred to the rings, with the result that, unless conditions change or relief in the form of oil supply takes place, serious galling or seizure ensues.

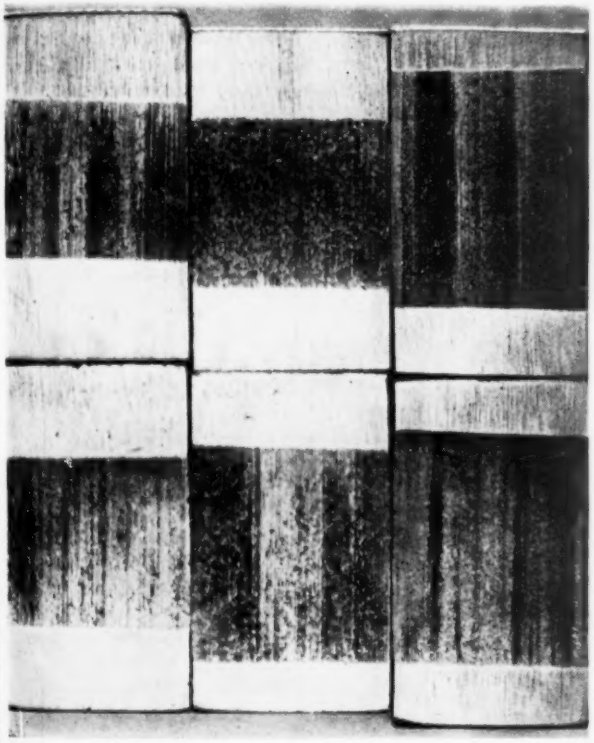

FIG. 12 APPEARANCE OF WORN AREAS OF PISTON-RING-IRON SPECIMENS

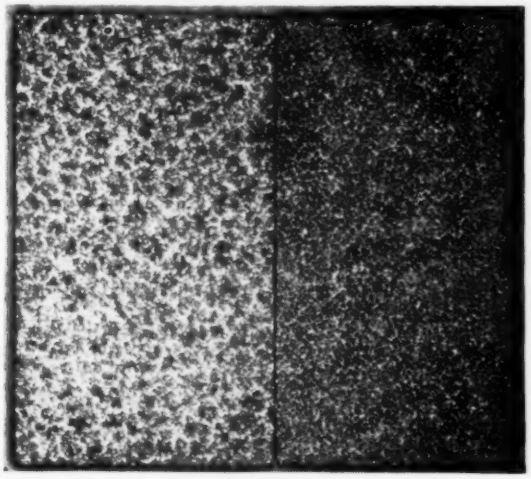
(Relatively high weight loss, but with ability to slough off wear products without surface mutilation.)

TABLE 9 DIESEL CYLINDERS—WEAR VALUES



Engine	Cylinder bore (approx), in.	Cycle	Brinell	Wear, mg			Surface
				Cylinder	Ring	Total	
A	3½	4	185	15.8	59.0	74.8	Smooth
B	3½	4	350+	5.5	140.0	145.5	Scuffed
C	4¾	4	235	11.2	68.8	80.0	Scored
D	5	2	215	8.0	116.4	124.4	Scored
E	5½	4	210	13.2	75.6	88.8	Smooth
F	8	4	215	15.0	90.0	105.0	Slightly scuffed
G	10¾	4	175	10.1	115.0	125.1	Scuffed
H	10¾	4	145	11.2	143.0	154.2	Scuffed
I	14	4	150	17.4	62.0	79.4	Smooth
J	14	2	175	15.0	73.6	88.6	Smooth
K	14	2	165	17.5	60.5	77.5	Smooth
L	16	4	185	12.6	75.1	87.7	Scuffed

NOTE: Ring irons run against cylinder irons average 30 and 45 mg and give total wear of 75 mg without surface scarring.

Table 9 gives wear-test results of cylinder and liner irons operating against surfaces representing average piston-ring structures. Although weight-loss values are relatively low, it is seen that there is considerable abuse to the mating surface (ring wear) accompanied in most cases by scuffing or scoring of the cylinder specimen.

SUGGESTED STRUCTURAL CHARACTERISTICS FOR CYLINDERS

As mentioned early in the paper, this research work has been in the nature of a survey or review of existing practices. It would be presumptuous (if not outright dangerous) for the author to recommend a specific analysis, hardness, and structure for cylinders and liners. This will be obvious when the many factors involved are considered, e.g., castability, machinability, strength,

Etched, ×5

FIG. 13 DIFFERENCE IN GRAIN SIZES OF CYLINDER AND RING STRUCTURES

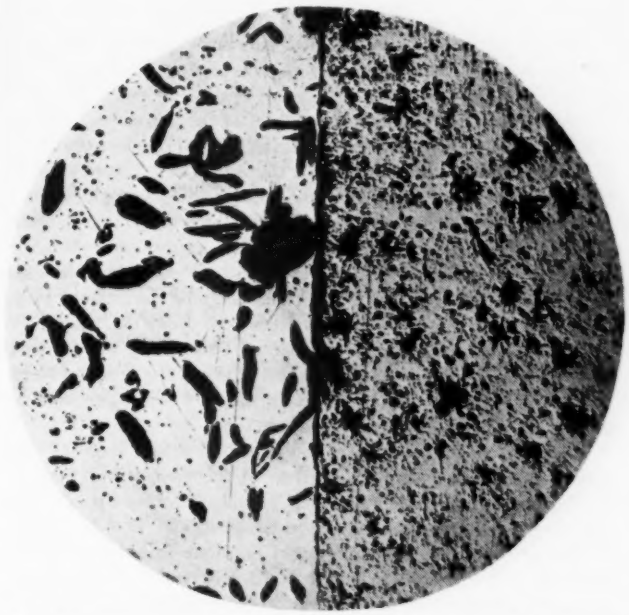


FIG. 14 COMPARISON OF GRAPHITE SIZES IN CYLINDER IRON (LEFT) AND RING IRON

and suitability for a given design, variations in finishing, loads, field of service, lubrication, etc. All of these must of necessity be fitted into the proper balance for any one engine casting.

However, the photomicrographs, Figs. 6 to 9, were selected as being typical (at least from the limited studies made) of the characteristics described. The author feels that, since this phase of the subject has received only limited attention, the trends and characteristics indicated may act as a starting point for further investigations in conjunction with service experience.

Ring and Cylinder Hardness

A matter which is frequently discussed is the relative hardness of rings and cylinders. Often the viewpoint is taken that similar

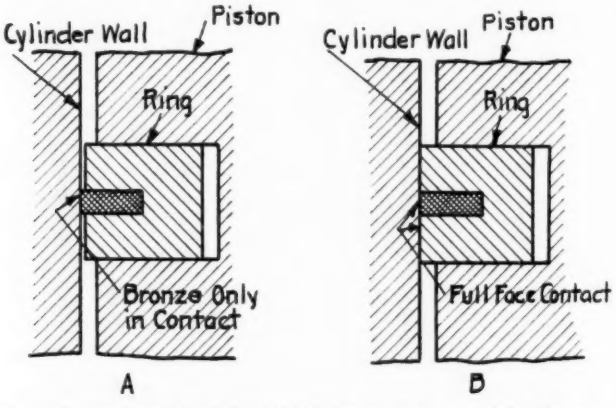

Fig. 15 Insert-Type 8-In. × 1/4-In. Piston Ring—28 Lb Tension (*A*, During run-in, unit pressure is high, 43 lb per sq in.; giving quick sealing and seating, and conditioning cylinder surface. Oil may accumulate between contact face, aiding in sealing action and furnishing lubrication. The bronze can carry high loads without scuffing. *B*, After complete seating, unit pressure drops to 14 lb per sq in. ring and cylinder surfaces are now mated. Filming action of bronze continues, and wear is retarded on both surfaces.)

hardness should in no case be used, this belief probably being derived from the early experiences of running like metals together in many instances with poor results, as compared with over-all wear when dissimilar metals are rubbed together. Then again the belief exists that ring hardness should be less than that of the cylinder or liner to protect the latter and throw wear on the rings. A third thought is that, ring surfaces being so small in relation to the cylinder area over which they travel, rings should be of greater hardness to get the proper wear balance. There is also a feeling that rings should be harder than the liner because of the imbeddability of cylinders, and their tendency to pick up foreign material, such as silica from dusty air, thus forming a lap which would wear the rings. This theory was held before the advent of air cleaners and oil filters in the automobile industry. It also holds under certain unusual conditions such as in oil-field service, hot oil pumps, etc.

Experience and the data here submitted would indicate that more consideration should be given to the compatibility of the mating materials, based on their structural make-up, allowing hardness to come as a secondary consideration. It is reasonable to conceive that an attempt might be made to reduce cylinder wear by utilizing softer rings, based solely on a hardness measurement. Depending upon the type of structure used, the exact reverse of what is desired might result.

Composite and Bimetallic Construction

Even though gray cast iron is a series of alloys with widely different wear properties, for one reason or another it is often difficult to make it satisfy all the requirements demanded by present-day usage. For example, modern high-speed engines, particularly automotive engines, are composed of a variety of metals substituted in the various wearing areas. For many years, engine bearings have been lined with bronze or babbitt, as these allow ready replacement, together with lowered wear rates. Valve-stem guides are now for the most part inserted with a material better suited for the particular heat-and-wear problem in the valve chamber. The same is true for valve seats and cylinder sleeves. Thus, in many cases, the original block casting acts mainly as a rigid frame, upon which are located various alloys, each to handle a specific type of abuse.

Another illustration of this trend is the modern aircraft-engine valve itself, which performs satisfactorily for several thousand hours under extremely adverse temperature conditions. Yet the steel from which this valve is made, though the best known for the purpose, fails to satisfy all the types of abuse encountered.

The wearing properties of the stem are not just right, so the surface is nitrided; the tip, subject to impact, is a special inserted alloy, while the valve face itself is stellite coated. Thus, even this relatively small but important engine part is of composite construction.

In the case of piston rings, the so-called insert or Gold Seal

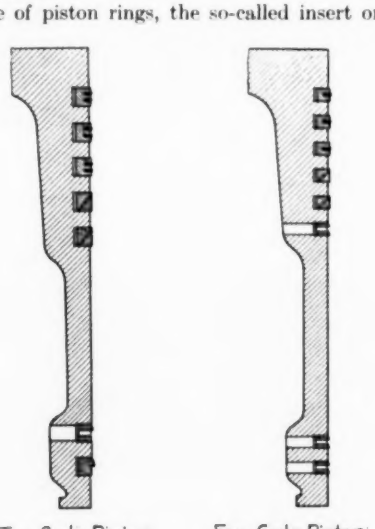

Fig. 16 Typical Insert-Ring Installation

type is quite widely known. This design consists of a cast-iron ring section, having one or two grooves machined in the cylinder-contact surface, into which is pressed a phosphor-bronze bearing strip. This band is permitted to project a few thousandths of an inch so that, during the seating-in period, only the bronze contacts the cylinder, but with relatively high unit pressure. This gives a rapid and complete sealing during the critical seating period and yet the initial scoring and scuffing, so frequently experienced during the run-in operation, is eliminated. This design is illustrated in Fig. 15, which shows the insert ring before and after complete seating. For larger rings with a wide contact face, the two bronze strips form an oil seal and also aid lubrication of the top rings. Furthermore, a bronze film is deposited on the cylinder surface, which promotes friction reduction and retards scuffing action. Such a design seems admirably suited for operation against surfaces which, as indicated in previous data, have scuffing tendencies. Fig. 16 shows typical insert rings for a 2- and a 4-cycle engine.

Fig. 17 shows in graph form the results of laboratory ring- and cylinder-wear tests using plain iron and "insert-ring" specimens. It is seen that besides the marked reduction in ring wear, cylinder wear is both considerably lower and more uniform.

Table 10 indicates results obtained on a $12^1/_2 \times 13^1/_4$-in., auxiliary, marine Diesel engine after the first 1450 hr operation. New liners, with a turned finish were installed, which gives a rather adverse condition from an initial-wear standpoint. The marked reduction in cylinder wear with insert rings is nevertheless significant.

Though ring-wear figures are not available from this test, it was reported that, at the time of inspection, the iron portion of the insert rings was just starting to make contact with the cylinder. Referring to special iron 20C, this was an alloy composition with

20C Special iron rings	−0.0045	11.2	77.3

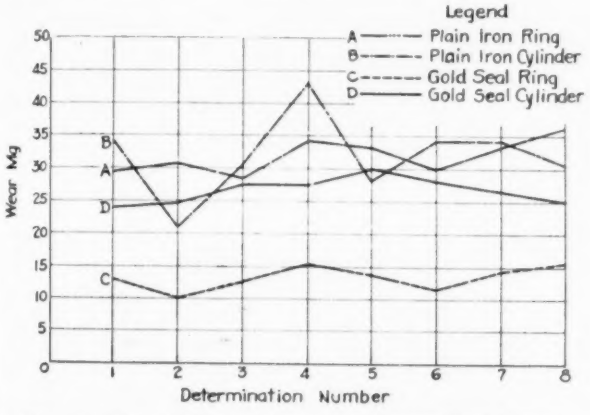

FIG. 17 WEAR TESTS OF PLAIN AND INSERT-TYPE RINGS

a coarse grain structure and Brinell hardness of 170. It is seen that under test and in service, cylinder wear is high, while indicated ring wear is very low. Prior to the above test installation, liner wear for approximately 22,000 hr running was reported as being 0.08 in. or 0.0037 in. per 1000 hr.

A recent service confirmation of the reduction in cylinder and ring wear through the use of insert rings is the experience with a two-cycle submarine engine which showed a maximum cylinder wear of 0.003 in. after approximately 10,000 hr running. Normally in such service a wear of three times this amount is considered satisfactory.

RUBBING-SURFACE FINISHES

During the last few years, remarkable improvements in finishing rubbing surfaces have been witnessed. This has been brought about through a better understanding of friction conditions, action of lubricants, and methods for evaluating or measuring surface roughness. The profilometer, developed by Dr. E. J. Abbott,[6] has already broadened the knowledge on this subject and provided a far better realization of the vital importance of the degree of surface irregularity. This instrument measures, in millionths of an inch, a running average of the height of the irregularities which constitute the roughness of the surface.

Present-day practice, particularly in the smaller-bore engines, tends more and more to honing of cylinder surfaces. There is already evidence that, through these improved surfaces, initial wear is greatly lessened. In larger-bore engines, however, a great number of cylinder finishes is still used, ranging from a so-called "fine-turned," to varying degrees of finish-grinding, with some few manufacturers using or considering honing as the final treatment.

Unfortunately, cylinder finishing is generally done so that the cutting or grinding is normal to ring and piston movement, resulting in a marked "file effect," with consequent high wear. The author recently examined several ground Diesel liners after approximately 6000 hr running, most of the grinding marks, except at the top-ring belt area, were still in evidence. Incidentally, excessive cylinder wear was a problem on this engine. It is likely that considerable improvement might be obtained through better cylinder finishing.

Aside from the rapid wear experienced with poorly finished bores, there is also the matter of the action of lubricating films on various surfaces. A honed finish characterized by a dull appearance seems to give good adherence or adsorption of oil films. Though much remains to be learned of this action, it is believed that surfaces glazed by grinding, chromium-plated surfaces and nitrided surfaces do not "wet" readily, whereas honed or matte finishes, and etched surfaces show good "blotter-like" or wetting action.

As an illustration of improved surfaces, Fig. 18 shows photomicrographs at 100 diameters of piston-ring surfaces. View (*a*) is the conventional side-face finish from a rotary grinder; this surface having a pleasing appearance and luster. However, the surface roughness is between 20 and 30 microinches (expressed 0.000030 in.). View (*b*) is a lapped side-face finish of 2 to 3 microinches. This finish is so smooth that some structural details are plainly visible. A similar type of finish is shown in (*c*), this being the lower contact edge of a tapered aircraft-engine ring which has been lapped to line contact prior to shipment to the engine builder. The cylinder-contact face of a worn piston ring after 4 yr service is shown in (*d*). The similarity between this photomicrograph and those of (*b*) and (*c*) is interesting. This ring had an excellent surface condition free from scoring or scuffing, the surface of the ring having been merely washed with naphtha and alcohol to remove grease and stains prior to photographing.

The improved face finishes on aircraft rings are reported to retard ring sticking and groove wear, reflect favorably on oil consumption, and also provide a ring of better flatness.[7] Piston grooves should, however, also come in for attention when using these improved finishes.

CHEMICAL SURFACE TREATMENTS

The foregoing discussion of metal surfaces would naturally be incomplete without some mention of the wider application of chemical treatment to friction surfaces. C. G. A. Rosen presented a paper[8] on this subject in 1937. Incidentally, his company pioneered in the application of chemically treated surfaces. Mr. Rosen mentions that "piston rings which normally required about 100 hr to obtain full ring-face conditioning, and 100 per cent bearing face, can be run into comparable surface contacts in 3 hr." The basic purpose of all treatments is the more rapid seating and better sealing during the run-in period. Numerous surface treatments are now available so there is a wide range of theory, color and composition at hand, from which the most suitable may be selected to fit a particular case.

Four general classifications might be mentioned: (*a*) metallic

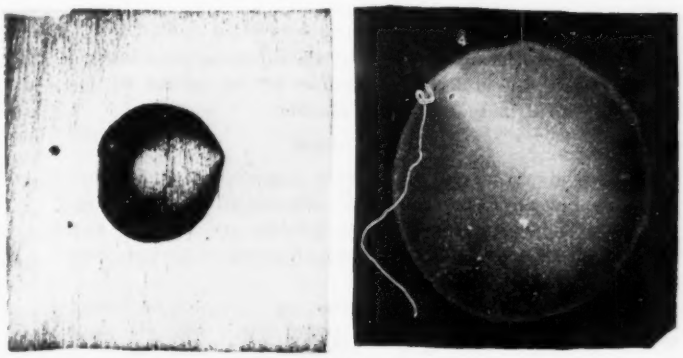
plating, (*b*) oxide coating, (*c*) phosphate coating, (*d*) chemical sulphidizing. It should be mentioned that all of these are short-lived, being designed primarily for the run-in period. The treatment penetration or thickness is usually about 0.0005 in. or less. However, there is no doubt but that they can and often do enhance run-in operations. This of course can affect subsequent wear rates to an appreciable extent.

The metallic platings reduce friction and correct for slight errors in ring and cylinder fitting, this being common also to the other types. If low-melting-point metals are used, there is some question as to their stability, particularly in gas engines operating above the melting point of the coating. Their wetting action is satisfactory and it has been reported that a definite weight increase is obtained when rings so treated are immersed in hot oil. The basic theory for their use is the better friction properties as long as they might endure.

The oxide coatings have the disadvantage that they are generally obtained by high-temperature treatments (around 1000 F) so that distortion may be encountered, particularly since this treatment must be obtained after final finishing. Their wetting

action is good, and they have been widely used in automotive work on rings and valve tappets. In general, this treatment is deeper than the others; the underlying theory being to supply a fine abrasive oxide which acts as a lap and polishes the mating surfaces.

The phosphate coatings were originally developed for rustproofing and paint-adherence purposes. This is really an etching treatment and gives a matte finish with good oil filming. It is quite inexpensive and has received rather wide application since many plants had previously used it for the preparation of painted surfaces and merely applied it to various rubbing parts. A further attempt has been made to enhance its action through the application of colloidal graphite to the surfaces. Tests to date indicate that good success has accompanied this improvement. It has the advantage that temperatures under 200 F are required for treating most ferrous materials.



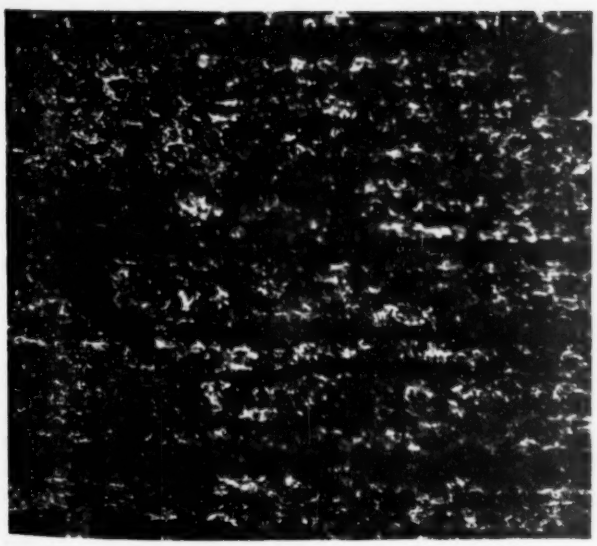


FIG. 20 DIFFERENCE IN OIL-WETTING CHARACTERISTICS OF PLAIN AND TREATED SURFACES

(a)

(b)

FIG. 19 APPEARANCE OF CYLINDER-CONTACT FACE OF RING BEFORE AND AFTER SULPHIDIZING

[(a) Automotive piston ring, untreated; turned finish, ×100. (b) Same ring after applying surface treatment, ×100.]

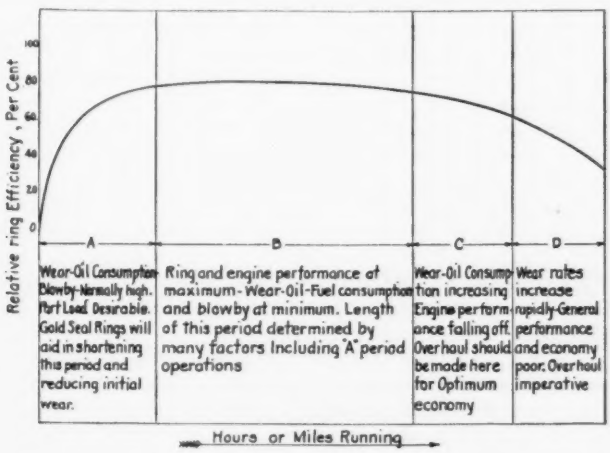

FIG. 21 RING EFFICIENCY CURVE

Chemical sulphidizing is a process developed by engineers of the Standard Oil Company of California. This treatment has found broader application in the Diesel field than any of the others, one leading manufacturer of high-speed, Diesel-tractor equipment having used it for rings and liners for more than a year.

Fig. 19 shows a smooth-turned surface before and after sulphidizing. Besides the removal of certain microconstituents, undesirable from a wear standpoint, the treatment also removes loose metal fragments which induce scratching and scoring. This is strikingly illustrated in Fig. 19.

Fig. 20 shows the difference in the "wetting-with-oil" action. These are two specimens of the same material, the one at the left being untreated. These specimens are $1/2$ in. square and magnified approximately $3\,1/2$ times. An equivalent drop of light engine oil was placed in the center of each specimen, the photograph being taken after 7 min had elapsed. It is apparent that the treated surface permits better spreading of an oil film. After 15 min, the treated-specimen face was completely covered with the oil film, whereas very little change occurred with the plain surface.

Though this treatment has been used mainly for rings, even further improvement results when the cylinder is also treated. The sulphidized surface has extreme pressure characteristics, so that scuffing of areas under high unit pressure is retarded. The adherence of oil films to this surface promotes good sealing against blowby between ring and cylinder and also of the side faces in the groove.

The wetting action and extreme pressure characteristics of the treated surface are largely results of the chemical action during

treatment, since similar properties are also imparted to compounded oil through chemical effects.

Though, as mentioned previously, the foregoing practices are relatively new, the underlying principles are logical and on this basis warrant further study and application.

Ring Efficiency

Fig. 21 shows a theoretical curve of ring efficiency. This refers to sealing, oil distribution and consumption, fuel consumption, and wear. For top efficiency, blowby and wear are at a minimum for a given set of conditions, other related factors being in proper balance.

As seen from the curve, relatively high wear exists during period A or run-in. To a certain extent this is desirable, since it is in this manner that final mating of the friction surfaces is obtained. If there were no wear or surface adjustment whatsoever, top efficiency would not be attained.

Anything done to facilitate this action by shortening the time required to reach the beginning of period B seems worth while. Better ring and cylinder materials and contours, improved finishes and surface treatments—all tend toward reduction of time required, and give better final mating. Unfortunately, even though it is recognized that A is a critical period, it is often given secondary consideration due to apparent need for such things as "immediate application of full load."

The length of period B is definitely influenced by what happened during the A interval. The longer the B period the better; at best it will be too short-lived. During B both ring and cylinder wear will be at a minimum, other factors as noted. This assumes, of course, reasonable care and attention by the operator.

As the C period is approached, indicated by a falling off in performance, and an increase in fuel and lubricating-oil consumption, wear rates again increase. Consideration should be given to overhaul and replacement rather than permitting conditions to reach the D period. This graph while possibly theoretical, seems nevertheless to represent a logical sequence to be followed.

Conclusion

No broad summary nor specific recommendations will be attempted as a result of the data reported herein. It is the author's opinion which seems to be substantiated by the work reported in this paper, that in some cases a possible reduction in wear rates of 2 to 1 may be expected through proper balance of ring and cylinder structures. There is further evidence that with existing conditions, a reduction in cylinder wear of roughly 2 to 1 may be obtained through the use of bimetallic and/or chemically treated rings. Thus, theoretically at least, there appear to be possibilities for an over-all decrease in wear rates in the order of 4 to 1; that is, wear seems possible of reduction to one fourth of existing averages. This seems worthy of consideration, even though the attack on such a problem may probably be somewhat different for each individual case. The author reiterates, that the primary purpose of this paper has been to review and consider the possible effects of metal structures on the over-all wear problem.

Appreciation is expressed to the various engine builders and operators, whose kindness and cooperation in supplying samples and data accounts in a large degree for whatever value may be found in this work, and to the author's associate, Richard Taber, for his care in performing tests and preparing photographic illustrations.

Discussion

Ralph Miller.[9] After studying Mr. Lane's paper, the writer is tempted to conclude that the problem of piston-ring and liner wear might be solved by giving surfaces a high degree of finish before assembling in the engine; for if this can be done, the structure or the kind of material lose their significance.

The oil film under the top piston ring is, of course, very thin and, if the rough projections on the surface are higher than the thickness of the oil film, naturally, scoring will result.

Now, attempts are apparently being made to select materials that can be run in or smoothed down without causing damage to the surfaces. To this end, wear- and corrosion-resistant qualities are being sacrificed.

H. A. Gehres.[10] Referring to the case of the 25-in. cylinder worn 0.004 in. as against the small one worn 0.0013 in., as given in Table 1, it would seem to the writer that the cases should be reversed because the small engine should be the higher-speed engine. Logically the wear should be in proportion to the number of trips the ring makes across the surface. Also it has been the writer's experience that the higher-speed engine runs with higher peak pressure, which would again indicate that it should show somewhat greater wear.

To corroborate and amplify Mr. Miller's statements on corrosion in liners, we have one installation which showed excessive cylinder wear, while other installations with exactly the same type engine have even shown subnormal liner wear. We have been forced to the conclusion that some corrosive substance in the air adjacent the steel plant where this engine is in operation caused the excessive wear, since the liner will wear as much as 0.014 in. while the ring will wear scarcely at all. Apparently deterioration is taking place on the surface of the cylinder which can be scraped off easily by the rings. This material cannot be very abrasive, otherwise it would cause the rings to wear.

About the time we had reached this conclusion, Mr. Van Der Horst of Holland discussed with us his method of chrome plating liners to reduce cylinder wear. He verified the opinion that 80 to 90 per cent of cylinder wear was due to corrosion and that, while the chrome-plated surface was extremely hard, the main benefit derived was not from the hardness but rather from the corrosion-resistance quality.

E. T. Vincent.[11] Cylinder-liner corrosion has been studied rather completely by the Institution of Automobile Engineers of Great Britain, which organization published test results three or four years ago. These results confirm the remarks made by Mr. Gehres. It is entirely feasible for corrosion to be concentrated along the path of the rings, because this surface is being continuously wiped clean by the rings, whereas other portions of the liner become coated with a protective layer of carbon. Therefore, when corrosion does not occur on parts other than the ring travel, it does not necessarily prove that corrosion does not exist.

In this paper a ring setup for four- and two-cycle engines was shown in which the latter were fitted with rings 50 per cent wider than the former. Is this change a definite recommendation, or is it accidental? The writer sees no reason, based on actual experience, why ring width should be changed for either type of engine.

E. A. Haskins.[12] Fortunately, we have experienced no serious difficulty from piston, cylinder, or liner wear. Corrosion has been no problem except in the case of a few experimental applications in which an effort was made to use the harder types of liners. There has been more difficulty with these than with our standard liner, which has a hardness of 200 to 215 Brinell. Possibly it is

our use of aluminum-alloy pistons with their better heat conductivity which keeps ring temperature down.

J. B. JACKSON.[13] The writer has observed cylinder wear which might be attributed to the thermal conductivity of the material, thereby creating higher surface temperatures on the liner and then contributing to the destruction of the oil film. Some of the liner wear which was reported in the case of the older engines may be attributed to a high thermal conductivity of the iron because it is not alloyed.

Another thing that influences ring wear is the surface temperature of the liner, as indicated by the appearance of liners and rings in supercharged engines. The writer has examined pistons removed from engines that were supercharged to 100 per cent above their original power. The pistons and rings appeared to be in far better condition than when they were removed, after operation at standard rating without supercharging. It is the writer's belief that excess air has a tendency to cool the liner surface and give better lubrication conditions.

The question arises as to how thin rings may be made before they become wavy and cause blow-by? The writer advocates thin rings, because of the weight of the ring riding in a relatively soft material. We are successfully using $^1/_8$-in. rings on pistons as large as 8 in. diam and $^3/_{16}$-in. rings on pistons nearly 13 in. diam. No definite evidence of increased cylinder wear is apparent with narrow rings.

A. W. MORTON.[14] Mr. Jackson stated that he would like to see narrower rings come into still greater use. There is a limit to which we can go in this direction. If the ring is made too narrow, it dishes as it is put into the cylinder. Obviously, extremely narrow rings will dish or buckle when compressed and, in the groove, contact occurs only at the edges of the rings. If the face of the ring is reduced, the wall thickness will also have to be reduced somewhat, in order to obtain intimate contact with the land of the piston when the ring is compressed and placed in the cylinder.

With the aid of machine-tool builders, we have been able to produce rings with a flatter surface than heretofore, which enables the ring to lie flat against the land of the piston, when made even narrower than formerly. The oil film between the land and the ring, however, is thicker than that between the ring and the cylinder. Therefore, the insulation value of the oil film is the limiting factor which controls the conduction of heat from piston land to the ring; the less the insulation, the greater the conductivity between the piston and the ring.

There is one point which has not been mentioned and that is cleanliness. When an engine is assembled, the condition of roughness of the edges of the rings, the cylinders, the pistons, and every other metallic part has a bearing upon the initial seating in and upon consequent scuffing or wear. Too much care cannot be taken in cleaning all parts of an engine assembly.

E. J. ABBOTT.[15] When speaking of unit pressures, one ordinarily thinks of the entire face or land of the ring as the working area. On second thought, such obviously is not the case. The surface profile shows many fine irregularities, and the peaks carry the load. Hence, unit stresses of primary interest are those occurring at the peaks of the surface serrations. The roughness of the surface has a tremendous effect upon these local unit stresses; therefore, roughness has an important relation to lubrication, wear, corrosion, and load-carrying capacity. These facts have been thoroughly demonstrated in the last few years.

[13] Aluminum Company of America, Cleveland, Ohio.

[14] American Hammered Piston Ring Division, Koppers Company, Baltimore, Md. Mem. A.S.M.E.

[15] Physicists Research Company, Ann Arbor, Mich.

The widths of the serrations on typical ring and cylinder surfaces are usually a few thousandths of an inch, and their total heights usually between 10 and 400 microin (3 to 100 microin rms; 1 microin = 0.000001 in.). Measurements show that surprisingly large differences exist in production, and that these differences are important.

Measurements of the actual dimensions of surface profiles show that the proportions of the surface are more favorable on smooth surfaces than on rougher surfaces. It is popularly conceived that smoother surfaces simply have smaller and more closely spaced peaks. Measurement shows that the spacing is not much closer on smoother surfaces, but the heights are often very much smaller. This makes the smoother surfaces duller as well as lower, and this is a decided advantage from the standpoint of load-carrying capacity.

Until recently, the measurement of surface roughness was either impossible, or a slow and costly laboratory job. However, the profilometer mentioned by Mr. Lane is a practical shop instrument which allows roughness measurements to be made rapidly and accurately on almost any specimen without damage to it. It is no longer necessary to guess the relative roughness of two or more surfaces. Experience thus far has thrown much light on the relation of surface roughness to the factors under discussion.

P. H. SCHWEITZER.[16] Mr. Morton mentioned the importance of cleanliness. It is a general procedure when we service engines to take a piston out and scrape it, including the lands. There is always a film of accumulated carbon. Some experts discourage cleaning or scraping the lands, claiming that the carbon formation is in consequence of an excess clearance put there by mistake or from figuring that operating conditions would be more severe than those the engine actually encountered. In the space available, hard carbon builds up. Allow it to remain and there is less blow-by. It is as if that much more metal were present.

AUTHOR'S CLOSURE

Mr. Miller asked whether or not wear might be reduced by using smoother surface finishes? That is not only true, but it is also the trend. The author believes the usual present-day practice in finishing Diesel-engine cylinders can be improved, particularly in the larger-bore engines. Unfortunately, due to the fact that the cylinder material range is very different, the same finish cannot always be obtained. Many do not realize this. Given two grades of cast iron, it is almost impossible to put the same finish on both of them.

There is much to be said about smoother finishes from the standpoint of distribution of pressure. We know that in the case of a threaded finish with a given loading, the unit pressure on the edge of the thread or at the tip can be enormous. When the thread is worn off, the pressure drops and we come to what is called a seat. One feature of such a seat is, of course, that the pressure is distributed. If we start with a smoother surface, we will immediately start with better load distribution, without the areas of high load concentration.

However, this matter must be approached rather cautiously. We know that it is possible to get the finish too smooth. It might be desirable to have surfaces smooth from standpoints of wear and corrosion but, having once attained such a high finish, it might be difficult to control the lubrication.

There cannot be much doubt that, as we improve the surface condition, we automatically improve corrosion resistance. In the case of worked material, we find, once it is glazed, that it reacts very differently to acid and to corrosion. If we could ob-

[16] Professor of Engineering Research, The Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

tain such a surface originally, it would probably help to resist corrosion.

When we lap in a ring against the cylinder, we automatically smooth both surfaces. However, it is important to realize, at the same time, that we are changing the direction of the surface roughness. When a ring is lapped, the unit pressure is distributed, the surfaces are polished, and the directional properties of the surface are changed.

In reply to Mr. Gehres, the values, shown in Table 1, for the wear of the engines mentioned, were based on relatively slow-speed engines. Also, there is possibly some difference in material between the small-bore engines and the large-bore engines.

Regarding corrosion, Mr. Gehres' theory was very prevalent in England some two or three years ago, but now it is not quite so popular as heretofore. Unfortunately, our experience has been that the materials which have good corrosion-resisting qualities often fail to have good wearing qualities. It is believed that the oil film between the rubbing parts is of the boundary type so that the wearing qualities of the materials are important. The austenitic alloys are reported to have given good success in high-speed engines in England. They are quite corrosion-resistant, and yet in this country, we cannot seem to get the same results.

Another point that might be mentioned is that corrosion-resistant materials often lack what might be termed emergency-run qualities. Cast iron does have that. It incorporates graphite which represents roughly 10 per cent by volume, and when the dry periods come on, cast iron has enough soapiness or greasy quality to carry over the lean period. This feature is quite desirable.

In reply to Professor Vincent's query concerning the heavier rings on pistons of the two-cycle engines in Fig. 16; they are illustrated for two reasons: One is to show that, as the rings get larger, we insert two bands; and second, because in general the two-cycle engines do carry somewhat heavier rings to enable them to pass over the ports with less danger of port clipping than with narrow rings.

On the matter of heat conductivity, some thought and investigation might be given to improvement in ring side faces; that is, lapping does a great many things which many of us probably did not realize it would do.

In operating a ring with a ground side-face finish, very often high and low points of contact develop around the ring face, showing that it touched the groove only here and there, as compared with a lapped face ring, which makes a much more uniform contact with the piston groove. This means that heat conductivity may be aided through the use of rings which do fit into the grooves more closely. Of course, when rings of this type are used some consideration must be given to the improvement of the ring grooves themselves.

Another thing that the improved side face offers is a freer breathing ring, that is, a ring less prone to sticking, because, with greater smoothness of the surface, carbon deposits are not so likely to build up. It has been reported that in aircraft engines, a decided improvement in oil consumption has been realized mainly through the improvement in the ring-side faces. With flatter ring surfaces and a better fit, there is an improvement in the maintenance of an oil seal between the ring and the piston groove.

Where Does Interpretation Begin?—Analysis of the Oil-Engine Power Cost Report

By P. H. SCHWEITZER,[1] STATE COLLEGE, PA.

This paper is an analysis of fuel-oil and lubricating-oil economy based on the 1937 A.S.M.E. Oil-Engine Power Cost Report. Both analyses are divided into two sections, the factual and the interpretative parts. The nature of the factual analysis does not permit drawing any conclusion beyond the one that, in making more judicious use of graphical representations, the usefulness of the Cost Report can be greatly increased. Conclusions from the interpretative analysis are as follows:

1 Engine load has a great effect on both fuel- and lubricating-oil economy.

2 Engine type has a great effect on lubricating-oil economy and a small effect on fuel-oil economy.

3 Year of manufacture has a great effect on both fuel- and lubricating-oil economy.

4 In both cases the improvement is wholly due to advance in design and construction.

5 Engine size has practically no effect on either fuel- or lubricating-oil economy.

6 Engine speed has practically no effect on either fuel- or lubricating-oil economy.

7 Fuel gravity has practically no effect on fuel economy.

8 Other factors may have some small effect on fuel- and lubricating-oil economy but they have not been sufficiently investigated.

FOR THIS PAPER to be intelligible, familiarity with the Oil-Engine Power Cost Reports is a prerequisite. The graphs and comments are based on the latest report, covering the year 1937. No data given in that report have been arbitrarily omitted from the plots or tables, no matter how improbable they may appear to be.

The Oil-Engine Power Cost Report now enters its tenth year. More than ever it is a carefully assembled and competently edited report. The comprehensive data included are of great value to the cost analyst. At the same time, it must be admitted that the average reader will derive but a limited amount of information from the 52,000 figures and three charts it contains.

A most legitimate object of the Power Cost Report is to enable a prospective purchaser of a Diesel power plant to estimate his probable operating costs. This is admittedly impossible for the reader who has but a limited time to study the report. Since at least 95 per cent of the readers fall in this category the resultant loss is obvious.

It has been repeatedly discussed how the usefulness of the Power Cost Report might be increased. Generally the conclusion has been that it is only possible by an interpretation of the data. Since, however, no interpretation is completely free from bias, the A.S.M.E. Oil-Engine Power Cost Committee does not wish to lend its authority to any interpretation. However, the committee does not discourage other groups or individuals from an interpretation of the "tabulated data if they have the engineering and statistical background for such a study."

Nobody can disagree with this stand, unless to the word "interpretation" too broad a meaning is given. In a sense, every graphical presentation is an interpretation because, although the points shown may be factual, the abscissa is selected at the pleasure or judgment of the analyst. The data of the Cost Report are tabulated in no less than thirty numerical columns. Any of these can be plotted against any other. When the analyst presents a plot of one quantity against another, as in Fig. 1 of the Cost Report, he already uses judgment by assuming that the plant-running capacity factor has a bearing on lubricating-oil economy. Yet no one considers that as an interpretation in the practical sense. A most important question to decide is where factual presentation ends and interpretation begins.

The report states: "Certain of the data are plotted in chart form for illustrative purposes, but for that reason only. Such median and boundary lines as are shown are included to assist the eye in subdividing the plotted data but should not be assumed to indicate trends." That is a very conservative stand but the author believes the users of the Power Cost Report would be the gainers if interpretation which must be excluded were less broadly defined.

If listed data are plotted and a trend is apparent, it would seem to be entirely reasonable to draw a curve. If the data plotted are not listed directly but can be computed without any technical or economic assumptions, that is still factual presentation, rather than interpretation. If in plotting a chart an assumption is used or trend curves derived from other charts are utilized, but the assumption used or the trend established is obvious and not of a controversial nature, then the presentation should still be termed factual rather than interpretative. For example, most business charts are corrected for seasonal trend. If they were not, a wrong impression would be created in comparing the textile production in March with that of February. The correction factors are empirical. They have been derived from plotted data. Yet such a presentation is never understood as an individual interpretation of the statistics. Only if controversial assumptions are used in charting the data, then interpretation really begins. Examples of both types of presentation in reference to the Power Cost Report will be given in this paper. The work has been limited to fuel-oil and lubricating-oil economy. Other cost items should receive similar treatment.

Factual Analysis of Lubricating-Oil Economy

The result of lubricating-oil analysis is shown in Fig. 1. Rated kilowatthours (the horsepower rating of the engine × number of hours operated × 0.746 × 0.9) per gallon of lubricating oil are plotted against year of installation of the engine. The plot shows a shotgun pattern but trends become distinct if the chart is broken up according to engine types. This is done in Fig. 2. The straight lines are median lines showing the trend in lubricating-oil economy of new and older engines.

In Figs. 1 and 2, three factors are recognized, i.e., engine load, engine type, and year of manufacture. The index for engine load is the running-engine capacity factor which is defined as

[1] Professor of Engineering Research, The Pennsylvania State College. Mem. A.S.M.E.

Presented at the Twelfth National Meeting Ann Arbor, Mich., June 19–22, 1939, of the Oil and Gas Power Division of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

$$\frac{\text{Engine output in gross kwhr} \times 100}{\text{kw rating} \times \text{number of hours operated}}$$

Thus the running-engine capacity factor is the average load which the engine carried, while it was in operation, in per cent of its rating.

It is a common observation that the total lubricating-oil consumption per hour is the same at part load as at full load. Both the A.S.M.E. Cost Report and the British Diesel Engine Users Association recognize this by listing the lubricating-oil economy in terms of rated kilowatthours per gallon rather than actual kilowatthours per gallon. The former is the kilowatt rating of

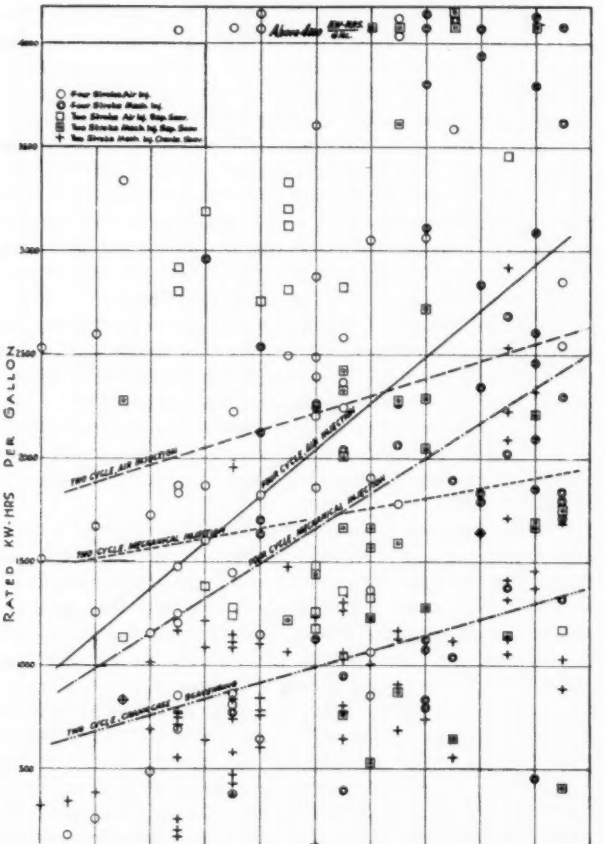

FIG. 1 LUBRICATING-OIL ECONOMY OF 226 DIESEL ENGINES

an engine generator set multiplied by the number of hours operated, or the kilowatthours output had the engine carried full load all the time it was running. The assumption which is implied by listing rated kilowatthours per gallon of lubricating oil is explicitly expressed in Fig. 1 of the Report (see Appendix) by the straight lines going through the zero point.

As to engine type, the Cost Report uses five classifications: (1) Four-stroke, air-injection; (2) four-stroke, mechanical-injection; (3) two-stroke, air-injection; (4) two-stroke, mechanical-injection, separate-scavenging; (5) two-stroke, mechanical-injection, crankcase-scavenging, which has been followed. In Fig. 2 the lubricating-oil performance of the five types of engines is separately plotted and medians drawn. By plotting rated kilowatthours per gallon, the load factor or running-engine capacity factor may be ignored and the abscissa becomes free for another relevant factor, e.g., the year of manufacture (or installation). The economy values plotted in this way in Fig. 2 show an unmistakable trend. With every type of engine, the lubricating-oil economy shows improvement in recent years. The lines indicate that the improvement is still in progress.

While the straight-line medians in Figs. 1 and 2 represent the probable lubricating-oil consumption of various-type engines, the lubricating-oil figures actually observed deviate considerably from the medians. The average deviations have been calculated as follows:

Four-stroke, air-injection, per cent	57
Two-stroke, air-injection, per cent	40
Four-stroke, mechanical-injection, per cent	75
Two-stroke, mechanical-injection, per cent	65
Two-stroke, mechanical-injection, crankcase-scavenging, per cent	33

The most important cause of these great deviations is, no doubt, the personal factor which has a considerable effect on lubricating-oil economy.

Figs. 1 and 2 constitute a limit in factual presentation, but even so they represent a step ahead from Fig. 1 of the Report. The differences are as follows:

1 Engines are plotted rather than power plants. If power plants are plotted, a small plant of one engine and a large plant with ten engines are both represented by one point, which gives undue weight to the engines used in small plants. True, almost half of the engines in the Report had to be ignored because no separate lubricating-oil figures were given. Even so, the fidelity of the plot is improved.

2 The engines are plotted according to their year of manufacture, which enables the reader more correctly to estimate the lubricating-oil performance of a contemplated engine. The idea gained from the Report in this respect is misleading. From the Report, it will be concluded that the probable lubricating-oil economy will be 1560 kwhr per gal at 100 per cent load. According to Fig. 1 of this paper, the probable lubricating-oil economy will be 2410 kwhr in case of a newly installed four-stroke, mechanical-injection engine and with other types more or less, accordingly.

3 In the Report gross kilowatthours are plotted; in Fig. 1 the rated kilowatthours. The two are equivalent if the straight-line relationship indicated in Fig. 1 of the Report is accepted. It is easy to obtain the gross kilowatthours from the rated kilowatthours by multiplying the figure by the load factor or running-engine capacity factor.

4 In Fig. 1 of this paper, instead of a median line for all the engines, separate median lines are shown for every engine type. Fig. 2 shows the separate plots for each engine type.

INTERPRETATIVE ANALYSIS OF LUBRICATING-OIL ECONOMY

The lubricating-oil consumption depends upon many factors, i.e., engine type, size, make, year of manufacture, workmanship, speed, load, hours of operation, condition of the engine, kind of lubricating oil used, its treatment, quality of attendance and management, and others. Any prediction based on a limited number of factors is liable to differ considerably from the figures actually observed. But without undesirable complications, only a small number of these factors can be considered. An important factor, namely, the human element, does not lend itself to plotting. Nevertheless, if the prediction is based upon a few carefully selected factors, the hitting average can be made much better than it is now. How to find the most pertinent factors? A reasonable guess may be made but, whenever possible, statistics should be used.

It is a safe guess that the engine uses no oil while it is standing still, therefore the lubricating-oil consumption per hour is inde-

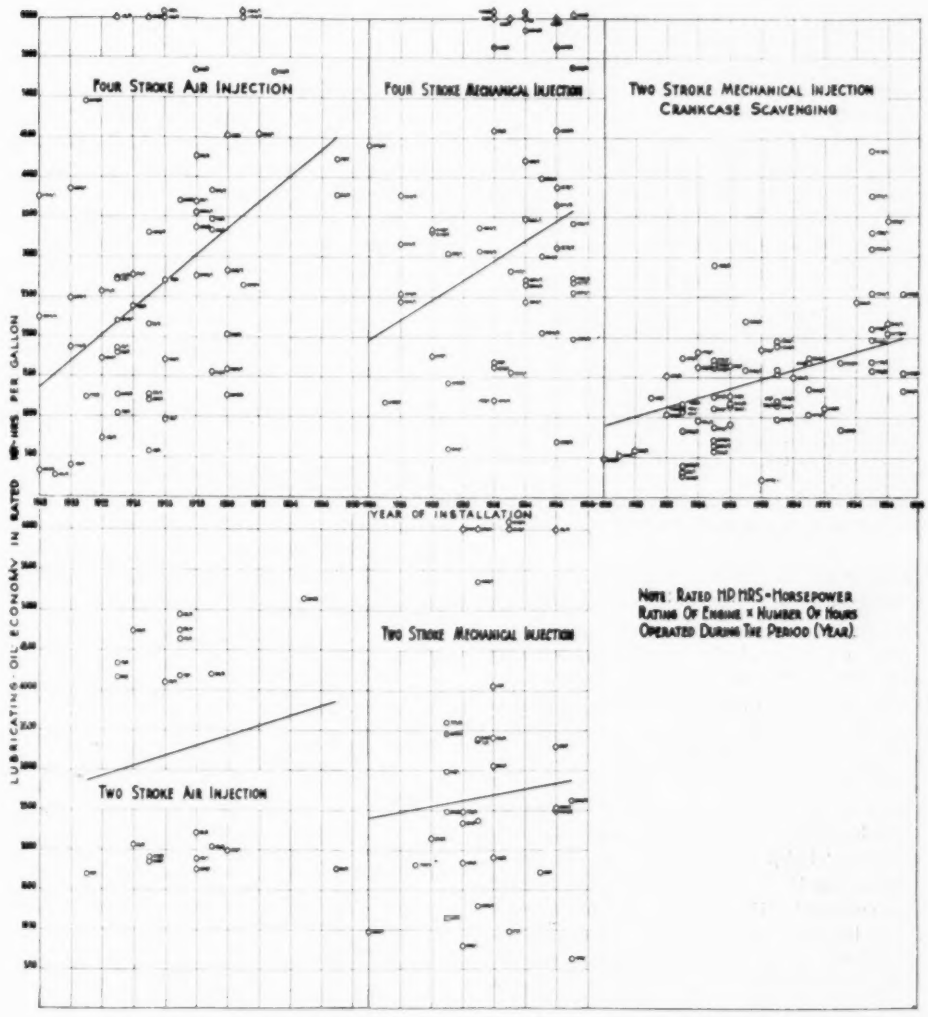

FIG. 2 LUBRICATING-OIL ECONOMY, DATA SEPARATED ACCORDING TO TYPES

pendent of the hours of operation. The evidence also indicates that the load has no effect on the lubricating-oil economy if the latter is expressed in rated kilowatthours per gallon. The engine type and year of installation were found to have a distinct effect as shown in Figs. 1 and 2. Now it is in order to investigate the other factors.

Effect of Engine Age. Fig. 2 shows the remarkable improvement in lubricating-oil economy in every type of engine. Taking a 15-yr period from 1922 to 1937, the increases are as follows:

Four-stroke, air-injection	from 1350 to 3050 rated kwhr	125 per cent
Four-stroke, mechanical-injection	from 1150 to 2400 rated kwhr	108 per cent
Two-stroke, air-injection	from 1970 to 2600 rated kwhr	32 per cent
Two-stroke, mechanical-injection, separate-scavenging	from 1560 to 1900 rated kwhr	22 per cent
Two-stroke, mechanical-injection, crankcase-scavenging	from 750 to 1340 rated kwhr	78 per cent

This improvement is significant. The question arises: Is the improvement due to the better mechanical condition of the new engines or to improvement in design and construction? The answer is that better design and construction are almost entirely responsible. M. J. Reed has investigated the lubricating-oil economy of 74 identical engines over a period of 6 years and obtained Fig. 3, which shows an insignificant variation in lubricating-oil economy as the engine gets older. Of course it must not

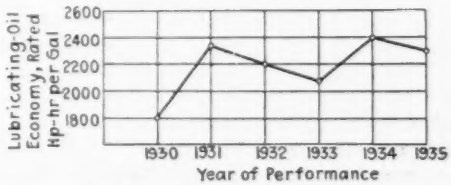

FIG. 3 LUBRICATION PERFORMANCE OF THE SAME 74 DIESEL ENGINES IN THE YEARS 1930–1935 (REED)

be understood that the lubricating-oil economy of an engine once installed remains constant. It usually varies in cycles. In the second year the lubricating-oil economy is, as a rule, better than in the first year because the engine has run in. Then for 4 or 5 years, the economy slightly deteriorates because of cylinder and ring wear. After 5 or 6 years, there is a general overhaul, involving replacement of piston rings, and sometimes, liners. After that the lubricating-oil economy is about equal to that of the new engine and the cycle repeats. Therefore the engine age as such can be ignored as a factor in lubricating-oil economy.

Effect of Engine Size. It is generally believed that large engines are more economical on lubricating oil than small engines. Against this, the Report discloses such glaring cases as a 320-hp engine No. 1167/2 with 45,702 rated hp-hr per gal,

a 300-hp engine No. 1128/3 with 7219, an 80-hp engine No. 1273/3 with 7008 rated hp-hr per gal, on one hand, and a 1200-hp engine No. 1083 with 1283, a 3750-hp engine No. 43/7 with 1875 and another 3750-hp engine No. 43/9 with 1900 rated hp-hr per gal. Of course some of these may be erroneously reported and some others overlubricated.

To obtain information on the effect of engine size, the engines of each type have been divided into three groups, 0 to 500-, 500 to 1000-, and over 1000-hp sizes and the average lubricating-oil economy in each group calculated. The result is shown in Table 1.

TABLE 1 EFFECT OF ENGINE SIZE ON LUBRICATING-OIL ECONOMY

Engine type	Average lubricating-oil economy, rated hp-hr per gal 0–500	500–1000	Over 1000
4-stroke, air-injection	2200 (30)	3027 (30)	4435 (10)
2-stroke, air-injection	(0)	3489 (5)	3110 (15)
4-stroke, mechanical-injection	4605 (27)	3830 (19)	3819 (4)
2-stroke, mechanical-injection	3775 (4)	2971 (15)	4140 (12)
2-stroke, mechanical-injection, crankcase-scavenging	1456 (82)	(0)	(0)

Note: The number of engines in each group is indicated in parentheses.

According to this table the lubricating-oil economy of four-stroke, air-injection engines improves with size; of two-stroke, air-injection and four-stroke, mechanical-injection engines decreases with size; and with two-stroke, mechanical-injection engines the trend is uncertain. These results, of course, should not be taken at their face value. First, because the number of engines on which the statistics are based is too small. Second, because certain factors, which also exert an influence on the lubricating-oil economy, have been ignored. For example, in the case of four-stroke, air-injection engines, the small engines are much older than the large ones. The average year of installation is 1918.3 for the 0 to 500-hp group, 1926.5 for the 500 to 1000-hp group, and 1929.7 for the horsepower group above 1000. This in itself explains sufficiently the 100 per cent increase between the smallest and largest engines without the engine size having any effect. With the other types, the trend is the other way or uncertain. The conclusion is that engine size has no pronounced effect on lubricating-oil economy.

The same conclusion has been reached from a graphical analysis. For each type, the rated horsepower-hours per gallon of lubricating oil, corrected for obsolescence, were plotted against the horsepower rating of the engine. No positive trend could be discerned. The respective graphs have not been reproduced for this paper. The result of the analysis is that engine size can be ignored when predicting lubricating-oil economy.

This does not conform with the general opinion that large engines are more economical in lubricating oil. The probable explanation for such a belief is that, if no differentiation is made between engine types, the large engines really show a superior economy. The reason is that crankcase compression engines, which are the poorest in lubricating-oil economy are built only in small sizes, while air-injection engines, which are best on lubricating oil, are built only in large sizes. This is the basis for the idea that large engines have better fuel economy. However, if the types are separated, it will be observed that it is the type and not the size which influences the economy.

Effect of Engine Speed. All of the engines listed in the Report are stationary engines connected to electric generators. Eighty-five per cent of them have a rated speed between 200 and 300 rpm. Only forty engines, listed with lubricating-oil figures, have lower than 200 rpm and twenty-five higher than 300 rpm. These figures are too scant to form the basis of a statistical analysis. Such individual cases, as No. 1220/3, a 27-hp, 1000-rpm engine giving 2922 rated hp-hr per gal of lubricating oil, lead to the belief that there is no correlation between engine speed and lubricating-oil economy in the field of generator-connected stationary engines.

Effect of Other Factors. The treatment of lubricating oil in the plant, such as settling, filtering, centrifuging, and chemical treatment, undoubtedly affects the lubricating-oil consumption. However, with a minor exception (3.86 per cent), all plants use some kind of purification (272 out of 441 centrifuge), and the difference in lubricating-oil consumption with various treatments is not pronounced.

The quality of the lubricating oil must also have some effect on the consumption but there is no ready way to measure lubricating-oil quality. The same thing is true to a greater degree of the quality of attendance and management. These are the factors which cause the wide spread in the plotted data.

Probable Lubricating-Oil Economy of Newly Purchased Engines

Fig. 4 sums up the results of the analysis of the lubricating-oil data in a simple, useful manner. It gives the probable lubricating-oil economy of newly purchased Diesel engines of various types. The figure is derived from Fig. 1 by taking the 1937 figures for 100 per cent engine-running capacity factor and connecting them with a straight line to the zero point. While

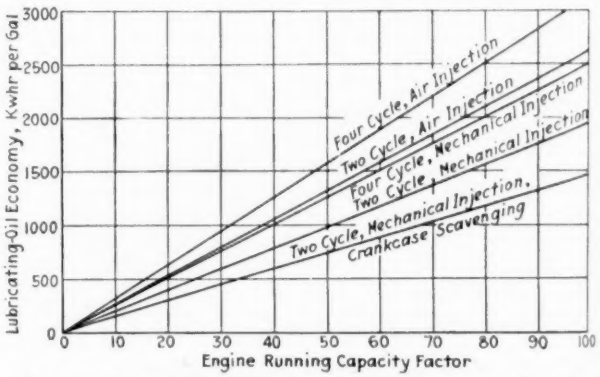

Fig. 4 Probable Lubricating-Oil Economy of Newly Purchased Diesel Engines

Fig. 4 shows probable consumption figures, it has been shown that considerable deviations from the listed values are possible. Consequently, in using Fig. 4 for predicting the lubricating-oil economy of a newly purchased engine, it should be realized that the probable deviation from the given values is about 50 per cent and the possible deviation more. This degree of uncertainty detracts from the value of the results. Nevertheless, it would be a mistake to consider the lubricating-oil statistics valueless, because without them knowledge of the matter is much less.

Factual Analysis of Fuel-Oil Economy

The result of fuel-oil analysis is shown in Fig. 5. The corrected kilowatthours are plotted against years of installation of the engine. In Fig. 6 the engine types are shown separately. The lines shown are ironed-out median lines and indicate the probable fuel consumption of engines.

Three factors have again been recognized, (1) engine load, (2) engine type, (3) year of manufacture.

Engine load is known to have an effect on fuel economy. It is unilluminating to compare the fuel economy of an engine running at half load with one running at full load. Fair comparison can be made either by separating the engines according to running capacity factor as was done in Fig. 3 of the Cost Report (see Appendix) or by correcting for running capacity factor (load) as

was done in Figs. 5 and 6. The latter course was chosen in order to permit the recognition of another relevant factor, the year of manufacture, in the chart.

Correction can be made for the load if, instead of plotting the actual kilowatthours produced by 1 gal of fuel, the kilowatthours are plotted that 1 gal would have produced if the engine had been running full load all the time. For such conversion, an empirical curve is required which shows how the fuel consumption in the average Diesel engine changes with the load. The typical curve the author has used is shown in Fig. 7.

There may be some inclination to accept the median line of the fuel-economy chart, Fig. 2 of the Cost Report, as a typical economy curve. This would be incorrect for the following reason: Older engines are more frequently operated at a low running capacity factor and modern engines at a high running capacity factor. Consequently, the fuel economy for points at the left end of the curve is low not only because of the low load but because of greater obsolescence. If correction is made for obsolescence, a curve is obtained, Fig. 8, which is almost the same as Fig. 7.

Figs. 5 and 6 were so constructed that the actual fuel economy of each point was multiplied by a fraction, the numerator of

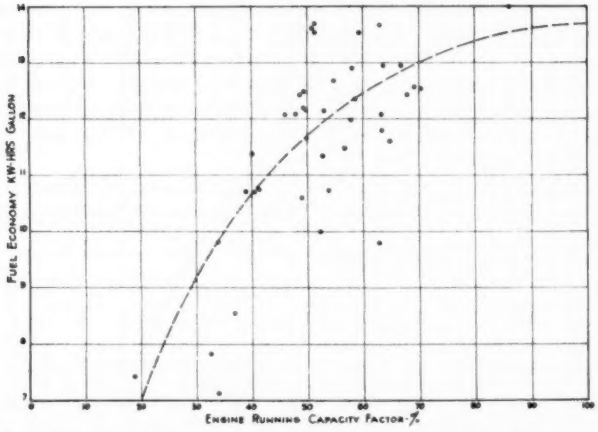

FIG. 8 FUEL ECONOMY OF FOUR-STROKE, MECHANICAL-INJECTION DIESEL ENGINES (CORRECTED FOR OBSOLESCENCE)

which is 1 and the denominator the height of, the typical curve, Fig. 7, at the corresponding running-engine capacity factor.[2] Giving consideration to the engine type, they permit a fair estimation of the fuel economy of an engine. The actually observed fuel economies listed differ from the curves by an average of 7 per cent, the actual deviations being as follows:

Four-stroke, air-injection, per cent	6.82
Two-stroke, air-injection, per cent	4.84
Four-stroke, mechanical-injection, per cent	7.76
Two-stroke, mechanical-injection, per cent	7.64
Two-stroke, mechanical-injection, crankcase-scavenging, per cent	14.1

The curves drawn represent the probable fuel economies. The spread between the probable curve and the individual points is relatively small.

INTERPRETATIVE ANALYSIS OF FUEL-OIL ECONOMY

The factors which might possibly influence fuel economy are:

1 Load conditions
2 Inlet air pressure (altitude) and temperature
3 Engine type
4 Size (rating)
5 Make and model
6 Year of manufacture
7 Age of engine
8 Workmanship
9 Condition of moving parts
10 Fuel gravity
11 Heat content
12 Viscosity
13 Cetane number
14 Quality of attendance
15 Instruments used (pyrometer, smoke meter, flowmeter, etc.)

It is a problem to determine which of these numerous factors are the most pertinent.

The importance of the load conditions is generally recognized by relating the fuel economy to the running-engine capacity factor as in Fig. 3 of the Cost Report. Figs. 5 and 6 have been corrected for running-engine capacity factor by means of a typical curve, Fig. 7.

The effect of inlet air pressure (altitude) and temperature on fuel economy is probably small in so far as stationary engines are concerned. The item was not suitable for statistical investigation.

The effect of engine type has been investigated and the result shows that it is not very pronounced. According to Fig. 5, of the recently manufactured engines the four-stroke-cycle, mechanical-injection engines have the best and the two-stroke-cycle, air-injection engines the poorest fuel economy but the total difference is less than 7 per cent. Of the earlier manufactured engines the two-stroke-cycle, crankcase-scavenged engines showed an appreciably poorer fuel economy but they have improved considerably in later years.

Effect of Engine Size. Whether the engine size has any appreciable influence upon the fuel economy can best be decided on a statistical basis. In Fig. 6 the fuel economies of various types of engines are plotted and median lines drawn. About one half of the engines are above and one half below the median lines. If the average horsepower of the better than median engines and the average horsepower of the poorer than median engines are calculated and they do not differ greatly, then it is justifiable to conclude that the effect of engine size is unimportant. However, if there is a great difference between the two averages, then the engine size probably has a considerable effect on the fuel economy. The result of the calculation is shown in Table 2.

In Table 2, columns (1) and (2) show the number of engines of the particular type listed in the Cost Report and their average ratings. Column (3) shows the average horsepower of the larger half of all engines of the type and column (4) that of the smaller half, assuming that the engines were divided in two parts strictly according to size. Columns (5) and (6) show the average horsepower of the engines above and below the median lines, Fig. 6. Column (7) is the ratio of columns (5–6)/(3–4).

It is clear that, if fuel economy would consistently increase with engine size, all large engines would be above the median and all small engines would be below it. Then the figure in column (7) would always be 1. On the other hand, if engine size were to have no effect whatever upon fuel economy, large and small engines would group about equally on both sides of the economy medians and the figure in the last column would approach 0. The average ratio is 0.238 which shows that the engine size has only a small influence on fuel economy. With two-stroke, mechanical-injection, separate-scavenging engines it is the greatest, probably because the design of this type of engine in small sizes has not yet been mastered. The effect of size on the economy of four-stroke, air-injection engines and two-stroke, crankcase-scavenged, mechanical-injection engines is practically negligible.

The make and model of the engines probably have some effect on the fuel economy but it was not investigated.

Effect of Engine Age. It was noted from Fig. 5 that the year of installation has a marked effect on fuel economy. Taking a 15-yr period from 1922 to 1937 the increases of the medians were as follows:

Four-stroke, air-injection ..... from 10.8 to 12.8 kwhr—18.5 per cent

[2] Five out of fifty-one separately scavenged two-stroke engines had independently driven blowers. The power required to drive these blowers was estimated as 10 per cent of the output and deducted from it in plotting fuel economy

Four-stroke, mechanical-injection ..... from 10.4 to 13.8 kwhr—32.6 per cent
Two-stroke, air-injection ..... from 11.2 to 12.3 kwhr—10.0 per cent
Two-stroke, mechanical-injection, separate-scavenging ..... from 10.7 to 13.4 kwhr—25.2 per cent
Two-stroke, mechanical-injection, crankcase-scavenging ..... from 9.1 to 12.4 kwhr—36.2 per cent

The mechanical-injection engines demonstrated a phenomenal improvement in their fuel economy and took the leadership from the air-injection engines, although the latter recorded some improvement also. It is obvious that estimating the probable fuel economy of a modern engine from statistical figures which included engines of various ages would be very misleading.

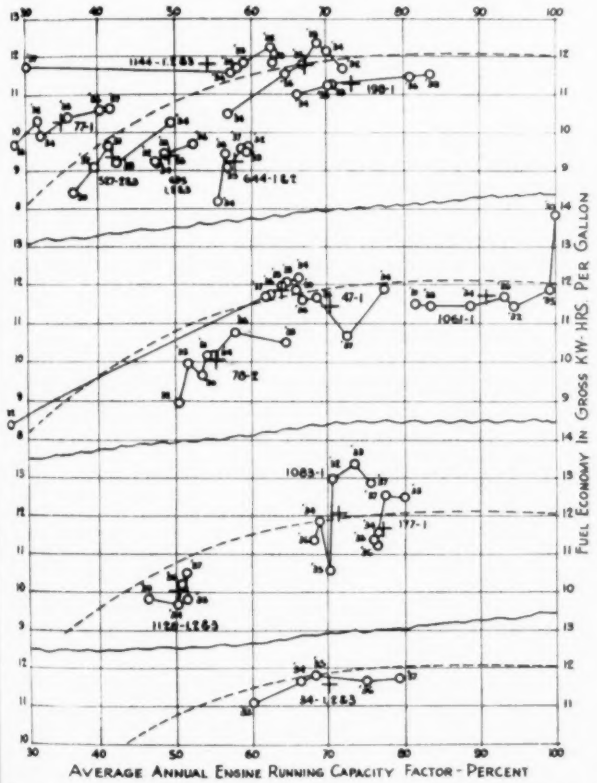

FIG. 9 ANNUAL AVERAGE FUEL ECONOMIES OF 25 DIESEL-GENERATOR SETS, OPERATED OVER 10,000 HR OR MORE EACH (REED)

The question arises, is the improvement due to the better mechanical condition of the new engines or to improvement in design and construction? The answer is that the improvement is almost entirely due to better design and construction. M. J. Reed has investigated the history of the twenty-eight engines which have reported fuel economies successively for 5 years or more. Of these, three operated for less than 10,000 hr total in the longest continuous period and were therefore eliminated. The data for the remaining twenty-five units are shown diagrammatically in Fig. 9.

Examination of Fig. 9 does not indicate that fuel economy deteriorates progressively. Eighteen out of the twenty-five units show better economy in the last year than the average reported. This should prove that the engine age as such has no pronounced effect on the fuel economy.

No data are available on the workmanship and the condition of the moving parts of the engines listed in the Cost Report.

Of the fuel properties probably several have an influence on fuel economy but the evidence is inconclusive.

Effect of Fuel Gravity. If the heat content of 1 lb of fuel is considered constant, which is approximately correct, the heat content of 1 gal of fuel increases with an increase in its specific gravity. An empirical formula expresses the relation of heat content to A.P.I. gravity. Higher heat content Btu per gallon =

$$\frac{1180[49(\text{deg A.P.I.} - 10) + 18650]}{\text{deg A.P.I.} + 131.5}$$

According to this formula the heat content of various gravity fuels is as follows:

Gravity, deg A.P.I.	20	24	28	32	36
Heat content, Btu per gal.	148400	145800	143200	140900	138700

Theoretically, therefore, the 20-deg A.P.I. fuel should give 7 per cent better fuel economy than 36-deg A.P.I. fuel. Since heavy fuel does not cost more than light fuel (if anything it is cheaper), it appears that there would be an incentive for using heavy fuels.

Of the 441 engines listed, fuel gravity was reported for 177. The gravities reported vary from 19 to 40 deg A.P.I. The average gravity of the fuels used in air-injection engines was 26.2 deg A.P.I., while that in mechanical-injection engines was 31.3 deg A.P.I. Otherwise, the type had practically no effect on the fuel used, the averages being 31.4, 31.2, and 31.3 for four-stroke, two-stroke, separate-scavenging and two-stroke, crankcase-scavenging engines, respectively, among the mechanical-injection engines.

Separating the engines according to their fuel economy, with the exception of the four-stroke, mechanical-injection engines, no appreciable difference is noted in fuel gravity, shown by Table 3.

With the four-stroke, mechanical-injection engines, the heavier fuels show better than average economy but the differences in gravity are moderate. In other types there is no appreciable correlation between gravity and fuel economy. As a whole, the data failed to substantiate the theory that heavy fuels have a better fuel economy. The probable reason is that, while the heat content of the heavy fuels is naturally greater, they burn less completely, which neutralizes the gain in heat content.

EFFECT OF FUEL VISCOSITY

Out of 441 engines listed only 125 reported fuel-oil viscosity. The viscosities reported vary from 33 to 112 sec Saybolt Universal at 100 F, except two engines with 1500 sec Saybolt Universal. The average viscosity used is 79.1 sec Saybolt Universal. Separating according to type of engines, the effect of viscosity on fuel economy is indicated in Table 4.

TABLE 3 EFFECT OF FUEL GRAVITY (A.P.I.) ON FUEL ECONOMY

Engine type	No. of engines (1)	Average gravity (2)	Average heavy (3)	Gravity light (4)	Average gravity—Above median (5)	Average gravity—Below median (6)	Ratio—Above-below / Heavy-light (7)
Four-stroke, air-injection	42	26.4	23.0	29.7	26.5	26.1	−0.06
Two-stroke, air-injection	12	26.0	19.7	32.4	26.9	25.5	0.11
Four-stroke, mechanical-injection	31	31.4	29.1	33.9	29.5	35.3	0.82
Two-stroke, mechanical-injection	38	31.2	28.1	34.3	30.3	32.1	0.29
Two-stroke, crankcase-scavenging	54	31.3	28.1	34.4	30.9	31.8	0.143

TABLE 4 EFFECT OF VISCOSITY ON FUEL ECONOMY

Engine type	No. of engines	Average vis sec SU at 100 F	Average viscosity Above median	Average viscosity Below median
Four-stroke, air-injection	32	132.2	85.3	200.7
Two-stroke, air-injection	11	61.7	73.3	44.4
Four-stroke, mechanical-injection	26	66	67	65
Two-stroke, mechanical-injection	22	56.1	68.3	41.1
Two-stroke, crankcase-scavenging	34	59.7	62.8	53.2

There is not much that can be learned from Table 4. Viscosity apparently has no deciding effect on fuel economy so long as it is not too high. In some four-stroke, air-injection engines (like No. 212/1 and No. 212/2) viscosity apparently was too high. The small number of viscosity data do not permit serious analysis.

Effect of Ignition Quality on Fuel Economy

The number of stations reporting fuel-ignition quality is still smaller, including only 42 engines, 23 of which reported cetane numbers, and 25 Diesel index numbers and 6 both. Changing Diesel index numbers to cetane numbers, the average ignition quality reported is 46 cetane numbers. Separately, according to engine types Table 5 gives the information.

TABLE 5 EFFECT OF IGNITION QUALITY (CETANE NUMBER) ON FUEL ECONOMY

Engine type	No. of engines reporting: Better than average fuel economy	Poorer than average fuel economy	Cetane (max)	Cetane (min)	Cetane no. (average)
4-stroke, air-injection	11	2	55	30.4	43.4
2-stroke, air-injection	..	..	..	..	...
4-stroke, mechanical-injection	7	1	45	30	36.75
2-stroke, mechanical-injection	1	5	65	36	49.9
2-stroke, crankcase-scavenging	12	3	61.5	40	51.62

The extremes reported are 30 and 65 cetane numbers. It is significant that out of the forty-two engines that reported fuel-ignition quality, thirty one were better than average and only eleven poorer than average in fuel economy. But this only proves that fuel economy is better with a wide-awake management. No significant differences appear between various engine types in Table 5.

Obviously, quality of attendance and management and the intelligent use of instruments, such as pyrometer, smoke meter, flowmeter, water thermometers, etc., for setting and correcting engine adjustments and ordering repairs have a considerable effect on the yearly fuel economy. It is unfortunate that the data available did not permit such a study.

Probable Fuel Economy of Newly Purchased Engines

Ignoring the factors, the effect of which are unknown or negligible, Fig. 10 shows the most probable fuel consumptions of newly purchased Diesel engines separated according to type and plotted against running-engine capacity factor. The fuel

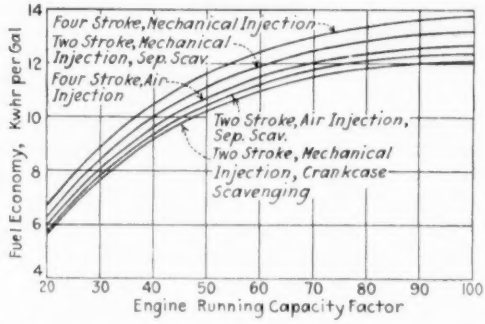

Fig. 10 Probable Fuel Economy of Newly Purchased Diesel Engines

economy actually obtained may differ from these values a certain amount. The variations will probably be less than 7 per cent one way or the other.

Although they mean little to the engine user or prospective purchaser, a tabulation of the average fuel-oil and lubricating-oil consumptions of the plants included in the A.S.M.E. Report follows:

Total number of plants reporting fuel-oil consumption	154
Their total fuel consumption, gal	31,223,511
Their total gross output, kwhr	394,794,626
Average fuel economy, kwhr per gal	12.6
Total number of plants reporting lubricating-oil consumption	146
Their total lubricating-oil consumption, gal	252,139
Their total gross output, kwhr	352,073,079
Average lubricating oil, kwhr per gal	1390

In view of the foregoing, these figures cannot serve as guides to engine users or prospective purchasers, but they may be of some interest to the oil vendors.

Acknowledgment is made to L. A. Ward and Hans Stern who assisted the author in carrying through the calculations in this paper.

Discussion

L. H. MORRISON.[3] The author points out that the engine built today has a better lubricating-oil consumption than older engines. Likewise, he makes a declaration that the modern engine has a better fuel consumption than an engine built 10 years ago. However, the writer believes he has fallen into error in not considering that the engines built 10 years ago have been running 10 years.

If he wished to plot these factors indicatively, he should have taken the lubricating-oil consumption this year of an engine that was placed in service last year, and then the lubricating-oil consumption of 9 years ago of an engine that was installed 10 years ago. This would constitute the lubricating-oil record for an engine 1 year after it was installed. If that were done, he would find that many of the discrepancies would disappear. Plotting on such a basis will show that the lubricating-oil consumption of a particular engine will gradually increase and then, due to a major overhaul, there is a short improvement in lubricating-oil consumption at the end of some definite period.

We find lubricating-oil consumption and fuel-oil consumption plotted by plants. The writer does not believe that to be indicative. Such plots should be made by engines because, in plotting by plants, a record of operation is shown but not a record of the engines.

It is the writer's belief that the report of the Diesel Users' Association of England is of great value because it contains statements of the operators and managers of plants on why certain figures appear in the cost report. It is highly illuminating to know that, in a certain plant this year, one of the engines had a major overhaul, another experienced piston trouble or what not. It would be illuminating to users if the A.S.M.E. Oil-Engine Power Cost Report contained similar information.

EDGAR J. KATES.[4] The nature of the discussion that has already arisen in connection with this paper justifies the practice of the Oil Engine Power Cost Committee in not itself interpreting the data which it collects and publishes. Probably everyone agrees that the data may be made more helpful to the general user if served in predigested form. However, most analyses and interpretations require the application of opinion or judgment and, since there are so many different ways in which the same data may be interpreted, it would seem better that the work of the Cost Committee itself be confined to gathering, tabulating, and publishing the data in purely statistical form (including simple graphs), and that the interpretations be left for individuals to do in the way Professor Schweitzer has done in the paper under discussion.

The author has made a fine effort to interpret fuel- and lubricating-oil efficiencies, and the suggestion is made that he or someone else should endeavor to apply the same interpretative methods to maintenance and attendance costs.

There are several minor points in connection with Professor Schweitzer's analysis that seem worthy of mention.

In order to show the effects of improvements in design and construction upon the lubricating-oil consumption, the author has assumed that the lubricating-oil economy of any one engine, as expressed by rated horsepower-hours per gallon, does not vary with the load of the engine. In other words, he has referred all of his data to a basis of 100 per cent load, and has assumed, in so doing, that the rated horsepower-hours per gallon at any load is a constant. The writer does not believe that to be a fact. At least, many records have been studied which show that lubricating-oil efficiency is poorer at heavy loads than it is at light loads; consequently, conclusions based on this assumption may be in error.

A similar question arises with respect to the fuel-oil economy. Again the author, endeavoring to correlate fuel economy with the period of design of the engine, eliminates the factor of load by the use of a curve to show the relative fuel economy of the "typical" modern Diesel engine. That curve is subject to wide variations for different engines. It will vary with the type of combustion system used in the engine, and by that is meant the entire shape of the curve will vary, not merely that the whole curve will be proportionately higher or lower. Further, the shape of the curve will vary with the engine manufacturer's rating policy. One manufacturer, who rates his engine conservatively, will get the best economy at full load, as is indicated by the curve in the paper. Another manufacturer, who rates less conservatively, will have his full-load point beyond the 100 per cent point in Fig. 7, and the fuel economy of his engines will be slightly worse at full load than around three-quarter load. Now obviously, if the shape of a curve varies for the different engines reported on, the proportioning which the author does to find the fuel economy at full load so that he may make comparison of the fuel economies at full load of engines built in different years will not be valid. It seems to the writer that the problem has been somewhat oversimplified by using such a curve.

T. M. ROBIE.[5] Referring to Figs. 2 and 6, the writer would like to call attention to the median lines for the crankcase-scavenging engines in respect to the number of plants involved for the later years. The author states that, while the straight-line medians, Figs. 1 and 2, represent the probable lubricating-oil consumption of various type engines, the lubricating-oil data actually observed deviate considerably from the medians.

Now, in constructing any median lines, the individual writer of the paper has to assume certain factors. You will note in the upper right-hand corner of Fig. 2, there are 4 engines below the median line and 12 above it. The engines that are above it are quite far above, so that the median line for the two years at the right is certainly very much too low and does not show a true picture of the present development of two-cycle crankcase-scavenging engines, as regards lubricating-oil consumption.

Similarly, for the fuel consumption of the two-stroke mechanical-injection crankcase-scavenging engine, there is only one engine below the median line in Fig. 6 for the last three years and about 12 above it.

The writer's company is probably the largest contributor to the engine installations on that curve, and we feel that our fuel consumptions are second to none in our present-day crankcase-scavenging engines, so it is felt that the median lines as drawn do not present a true picture.

That brings up another point in connection with a study of these reports or their interpretation. While it is true that they are important, still the manufacturer's guarantees of the engines which he is proposing for sale are also important and should be considered. There is the possibility that a more or less careless salesman may show some of these median lines to an unsuspecting purchaser and, without going into a detailed explanation, lead the purchaser to believe that for a given type he can expect results in accordance with the median lines, whereas reputable manufacturers are willing to demonstrate with tests the actual performance of the engines which they are proposing.

R. D. CAMPBELL.[6] The writer wishes to ask if the author obtained all the data which were used in this analysis directly from the Oil-Engine Power Report? My thought is that if all of this

[3] Editor, *Diesel Power*, New York, N. Y. Mem. A.S.M.E.

[5] Fairbanks-Morse & Company, Chicago, Ill.
[6] Shell Oil Company, St. Louis, Mo.

information were available in the reports, then anyone can plot any curve in which he is interested.

It is conceivable that an engine designer would be interested in types of combustion chambers. Once having identified the engine, he can proceed to plot the economy against either the type of combustion chamber, the piston speed, or any other variable he may see fit to select. It can also be conceived that a man in Mr. Kates's position as a consultant would be interested in knowing whether it is a stand-by plant or in irrigation service or a municipal power plant, and so he would study the different load curves against a different type of engine; in other words, the service of the engine against its type or any other factor, because from his standpoint he wants the over-all economies, whereas the engine designer may be interested in only the technical side of it.

So it seems to the writer that the Committee has chosen a rather wise course in incorporating a wealth of information in the report and drawing as few conclusions as possible. A very voluminous report might be made if the Committee wished to plot all the curves and draw all the conclusions in which any one of us might be interested.

LEE SCHNEITTER.[7] The author has given an excellent analysis and interpretation of certain conditions revealed by fuel and lubricating data in the Oil-Engine Power Cost Report. It is felt, however, that the author has missed the real purpose of data presented in reports during the last 9 years. As the writer sees it, the author devotes all of his paper to proving that engines built in 1937 are more economical in use of fuel and lubricating oil than engines built several years earlier. While the author's analyses are most interesting, the purpose of presenting oil-engine cost data by years for a large number of plants is far different from what the author indicates.

In the third paragraph of the paper he states: "A most legitimate object of the Power Cost Report is to enable a prospective purchaser of a Diesel plant to estimate his probable operating costs." The writer agrees that this is the real purpose of the report and that data on plants listed in the report over a long term of years can be used as a guide to forecast operating costs of a given plant over a reasonable period, perhaps for the economic life of the plant.

In referring to Fig. 7, the writer is sure that the author has committed a serious error in selecting a fuel-consumption curve for "the average Diesel engine." There is no standard curve that will suit all engine types. The shape and characteristics of such a curve will vary with engine make, speed, design, and type.

The author's conclusions are presented in two curves, Figs. 4 and 10, showing, respectively, probable lubricating-oil and fuel-oil economies for new engines. It is felt that a prospective purchaser of an engine would much prefer to obtain these data in the form of guarantees as customarily offered by all engine manufacturers. A series of calculated curves, as presented by the author, would not be as reliable as data obtained from manufacturers on specific engine types.

In presenting Fig. 10, it is suggested that the author specify heating value of fuel, if output in kilowatthours per gallon is to mean anything. Also, is the output in kilowatthours gross or net?

On the subject of lubricating-oil consumption, we must agree that there has been much improvement. Consumption has been reduced in the last 6 or 8 years. Betterments are due to a number of factors already mentioned in the paper. Operators are able to obtain better lubricants; in addition, the oils last longer, being of higher grade. Purification systems have been improved and engine designs have been modified to overcome some of the old problems of lubrication. Consequently, it is felt that the Oil-Engine Power Cost Committee can take cognizance of the fact that the records show some improvement in consumption of lubricating oil.

The author states that he found no difference in the economy of lubricating oil on large and small engines. The statement is made that size is not important, but type is. It seems to me that engine size is somewhat interrelated with type so that it is almost impossible to discriminate between them. Other factors must be considered when analyzing figures on lubricating-oil consumption and, in the case of the very small engine, speed is an important factor. In fact, an average of data presented by the author in Table 1 shows that engines under 500 hp gave about 3000 rated hp-hr per gal while those over 1000 hp in size produced almost 4000 rated hp-hr per gal. This would indicate that larger engines are more economical in lubricating-oil consumption.

V. L. MALEEV.[8] The writer does not quite agree with the author that he is doing an interpretation. He simply does a breakdown analysis of figures. In respect to Diesel engines, the most important subdivision is one that Professor Schweitzer pointed out, that is, dividing by the type of engines: Mechanical-injection two-stroke cycle, air-injection four-stroke cycle, crankcase-scavenging, and separate-pump scavenging. With these subdivisions, we get groups which can be compared rather than interpreted, simplified, or used for a different purpose.

Someone raised the question: "How valuable is a median if it is only within a plus or minus 50 per cent?" It may not be as valuable as we would like to have it. Unfortunately we have cases when this wide deviation is unavoidable. For example, at one time, we had two identical 6-cylinder 300-hp marine engines in operation, which were differing by 30 per cent in their lubricating-oil consumption. At first we were puzzled as to the explanation. Then we happened to notice that one was an installation on a fishing boat; the second was in a yacht and was equipped with counterweights. The yacht engine had to operate as smoothly as possible and, although it did not need counterweights, it operated more smoothly with them. The installation of counterweights increased the oil consumption by 30 per cent.

Also, as far as lubricating-oil consumption is concerned, there is a very great influence from the human element. In another plant, the writer installed 2000-hp gas-engine-driven compressors, using ten 200-hp engines. The installation was made with newly designed engines which had been developed and tested very thoroughly in the factory. We had given a guarantee for lubricating-oil consumption, and instructions on how to run the engines. A few months after the engines were installed, we had a complaint that the lubricating-oil consumption was almost twice as much as that guaranteed. These engines were furnished with equipment for regulating the number of drops of lubricant to each feed line. Our instructions stated that for some points of lubrication, there should be 2 drops, in some 3, and in some 5 drops might be permitted. But the operator believed in safety, so he gave it all the oil he could, and not an outlet was feeding less than 15 drops, some up to 25 drops per min. When this condition was adjusted, the lubrication was all right.

We do not have control over what engine operators are doing. Quite often they will do very foolish things.

The writer is in agreement with one of the discussers that, probably, the curve representing lubricating-oil consumption, Fig. 2, of the crankcase-scavenging engines may be a little less favorable than it should be. In trying to sketch it according to his ideas, the writer finds that the left-hand end should be slightly dropped and the right-hand end raised. Instead of being

[7] Plant Betterment Engineer, Ebasco Services, Inc., New York, N. Y. Mem. A.S.M.E.

[8] Research Professor of Mechanical Engineering, Oklahoma A.&M. College, Stillwater, Okla. Mem. A.S.M.E.

about 15 deg from the horizontal, probably it would be about 30 deg; it would not change materially. The relative position would be the same.

In this connection it is suggested, in order to avoid arguments as to how such a curve should be drawn, to use the method of least squares, determining the probable errors of observation. If one takes a curve which should represent a median the best way, it should be checked by taking the vertical distances of all points, squaring them, and then adding the sums of those which are above and below. If the sum of the squares of distances above is equal to the sum of the squares below, there is no human element in the curve. If one draws such a line and finds, for instance, the sum of the squares of distances above not equal to that below, one can readily adjust it by checking and get a curve to which nobody can object.

Author's Closure

There is really only one challenge in Mr. Morrison's remarks; he suspects that it may be the engine's age and not its obsolescence which made the difference between the showing of the more recent engines and the older engines, and he suggests that should be taken into consideration.

Fortunately, this has been done. The answer is contained in Figs. 3 and 9 of the paper. These are the result of an investigation by Mr. Reed who determined how much of the improvement is due to better design and how much is due to a younger, more vigorous age; the result is rather conclusive.

In Fig. 3, the lubricating-oil performance of the same 74 Diesel engines has been compared by Mr. Reed in the years from 1930 to 1935. This demonstrates that engines get better with age instead of getting worse.

The same thing is true with fuel-oil economy. The age itself does not seem to make the engine bad, as shown by Fig. 9. It must be realized that every engine is overhauled at periodic intervals, every 5 or 6 years. Rings are replaced and frequently liners are either replaced or rebored; the engine is then again as good as new. As a matter of fact, the engines, in both lubricating-oil and fuel-oil economy, improve a little in the first year, then they get worse in the second, third, and fourth years, until they have a major overhaul; then the cycle repeats. It is improvement in design, no doubt, which makes recent engines better than older ones.

The author is in agreement with Mr. Kates regarding the lubricating-oil economy varying with the load, if the assumption that the rated kilowatthours per gallon of lubricating oil is practically independent from the load is incorrect. The explanation is that the author simply followed the Power Cost Committee, which has followed the British Diesel Engine Users' Association in this assumption. That association always lists the rated kilowatthours, and if not 100 per cent correct, at least it is approximately so. It is doubtful if any better assumption can be suggested.

The same thing holds true for the fuel consumption shown in Fig. 7. It should be realized that variations in the actual consumption per horsepower-hour do not affect the results, provided the per cent variations for various loads are the same. Here again the typical curve, which was felt to be necessary, checked so well with other authoritative sources that there was no hesitation in using it. The errors committed by the use of a single typical curve are probably negligible.

The attitude can be taken that a simplification by which the economy of various engines at various loads may be brought to a common denominator is neither permitted nor justified. That is a perfectly justifiable attitude but the opposite attitude may also be assumed that simplification is necessary in order to dispel the ignorance of those who know nothing about economy figures on Diesel installations. If we are to have simplifications, then the author would ask Mr. Kates, or others, what else can be proposed to take the place of the typical curve which has been used?

Mr. Robie complains about what he considers is an unfair presentation of the crankcase-scavenging engine in recent years. He did not object to the drawing of the lines in the period, say, before 1934 or 1935, but he thinks that the crankcase-scavenging engines have been making better showings than indicated on the curves in 1936 and 1937. Not only Mr. Robie but others will have objections regarding certain medians that have been shown.

The crankcase-scavenging engine does show remarkable improvement in the last 2 years. Perhaps he would have liked it better if the curve had bent up sharply for these years. That would have fitted the points better than the straight line does. The lines were drawn conservatively with no attempt to bend up any curves.

In answer to Mr. Campbell's inquiry, all of the types are indicated in the reports. However, in making up the Power Cost Report the prospective user was forgotten. The reports are valuable to the engine makers, to the oil salesman, to the utility salesman, and to the manufacturer. They are of some good to those who operate power plants. But it is felt they are of no practical value to the man who is interested in installing a Diesel power plant. That is the man the Power Cost Committee would do well to remember. The author approves of omitting interpretation from the reports, but a few more graphical presentations, judiciously plotted, would do a great deal of good to those most important readers of the Power Cost Report who want to use it in order to determine what they can expect of the engine they have in mind.

With reference to Mr. Schneitter's comments, these curves were drawn from the raw material available. The Btu content of the fuel used is not listed in the Power Cost Report. These are not assumed or proposed curves but are the results of actual statistical evidence. There is a certain amount of interpretation in the second part of the paper which is so termed. This may be out of place in the cost report.

The cost report includes individual engines, and only the data for individual engines have been used in the chart. Btu content has been ignored because there was no information available, but the next best thing is gravity. There is a rather close correlation between Btu and gravity in ordinary petroleum fuels. In general the heavier fuels are no better or worse but about the same as the lighter fuels in economy. My conclusion was, again interpretatively, that there was no effect of fuel gravity, generally speaking, on economy. It is true the heavier fuels have more heating value, but generally their combustion is less complete, which about makes up for the difference in Btu content.

The author is in agreement with Mr. Schneitter that, if size and type cannot be separated, then there is justification in the notion that the large engines are better in lubricating-oil economy than the small engines. But, if separated as was done in the paper, it becomes clear that within the types there is no correlation. If the crankcase-scavenging engine is studied alone or the two-cycle air-injection engine alone, then one cannot say that the large engine is better than the small engine. They are about the same, broadly speaking.

In connection with Professor Maleev's interpretation of Fig. 2, there is no doubt that others can and would draw the curves differently. Perhaps some of the material that was put under the heading of factual presentation should have gone into interpretation, though nothing was done but present the points as they were taken from the Power Cost Report, leaving out none no matter how improbable or erroneous some of them might be.

If figures such as Figs. 2 and 6 should be included in the Power Cost Report, the author would agree to leave out the lines altogether. These lines were drawn conservatively. While we have

not used the method of least squares, we have used something approaching it. If medians are used rather than averages, then the least-squares method is probably out of order.

Professor Maleev is perfectly correct that, when it comes to lubricating-oil consumption, the human element and some uncontrolled factors play a great part. We know that many operators overlubricate their engines, sometimes to be on the safe side and sometimes because of ignorance. If we know the probable lubricating-oil economy, plus or minus 50 per cent, that is worth more than nothing, and when it comes to fuel-oil economy, then the estimate narrows down to about plus or minus 7 per cent.

Stability of Crankcase Oils

By W. F. WEILAND,[1] LINCOLN, NEB.

In this paper the author attempts to answer two vital questions concerning lubricating oils, i.e., performance and useful life. Oxidation and corrosion tendencies constitute the major elements in the deterioration of crankcase oils. The essential requirements for conducting oxidation tests are outlined in the paper and the procedure and results of tests are indicated. Observations on the behavior of oils in service also offer a means for predicting oil performance. Acid-vapor tests to determine oil breakdown are discussed and the results of corrosion studies detailed.

IN CONNECTION with lubricating oils, there are two questions which engineers would like to have answered: (1) How can the performance of an oil be predicted? (2) When is an oil worn out?

The advent of the modern high-compression internal-combustion engine has brought to light many lubrication problems which formerly were not apparent. Foremost among these problems are the oxidation and corrosion characteristics of the crankcase oils. More or less rapid oxidation of the lubricating oils, subjected to temperatures as they exist in modern engines, results in the formation of gums and sludges which in themselves constitute an endless source of trouble. Furthermore, as oxidation progresses corrosion difficulties arise due to a gradual lowering of the temperature at which corrosive products of oxidation form.

An oxidation test to be successful must simulate engine conditions as nearly as possible. The duration of the test should be within reason to make it commercially practical as a routine test; it should be simple to perform; different observers should be able to check results within limits; and last, but not least, a close correlation should exist between test results and oil performance in an engine.

A suitable temperature at which to run an oxidation test must be selected largely by deduction. If one considers the jacket temperature, a temperature gradient through the cylinder walls, the usual polished and unburned surface of the piston-swept walls of an engine in good condition, and the rate of deterioration of the crankcase oil, then, with all of these factors taken into account, an oxidation temperature of 300 F is at least reasonable. The logic of this assumption will be further emphasized later.

A second condition to be applied in an oxidation test is aeration. The question sometimes arises whether oxygen from the combustion chamber contributes to disintegration of the oil, but this presumption may not be a major contributing factor. Abundant air is whipped into the oil as it is splashed around and churned in the crankcase. It is only necessary to expose this oil saturated with air to the heat of the piston and cylinder walls to accelerate oil breakdown.

Other conditions which may affect oxidation are pressure, foreign solids such as road-dust and carbon particles, dilution, products of incomplete combustion, and metallic catalysts.

A laboratory setup which at least partially fulfills the conditions enumerated has been described previously by the author.[2]

Measuring the Extent of Oxidation

The extent to which oxidation has progressed is based on the relative change in color density in the oxidized oil compared with the original oil. To measure this color change, fill one glass-bottom tube of the comparison apparatus to a depth of 1/4 in. with the oxidized oil. Pour from the original oil into the other measuring tube until the two oil columns show the same color density as observed by looking down through both columns simultaneously. The ratio of the height of the column of the original oil to the height of the column of oxidized oil is the "oxidation number" for that particular oxidation period.

The oils reported in this paper have been given code numbers which can be partially deciphered, namely, the hundreds digit indicates the S.A.E. viscosity, while the tens and units digits indicate the house brand. For instance, oil number 124 is S.A.E. 10 oil of brand 24, and 224 is S.A.E. 20 oil of the same brand.

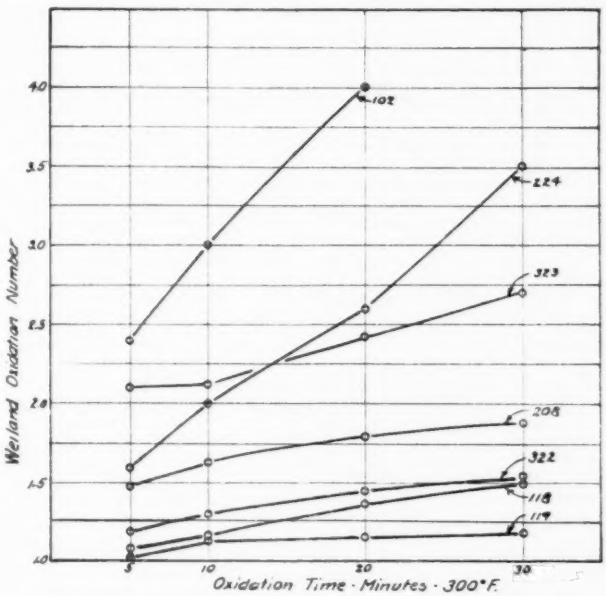

Fig. 1 Variations in Oxidation Characteristics of Oils Commercially Available

Fig. 1 illustrates the wide variation that can be expected in the oxidation characteristics of oils on the market. Oxidation numbers at 300 F are plotted against the oxidation period in minutes. A considerable percentage of the usual oils falls between Nos. 118 and 224. In so far as oxidation is concerned, oil No. 322 still has acceptable characteristics but oils above this curve must be used cautiously; oils above No. 224 had better not be used at all for internal-combustion-engine lubrication.

Since Fig. 1 includes a miscellaneous assortment of house brands, it shows that in general the weight of the oil is no index of its resistance to oxidation. It will be noted that both of the ex-

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[2] "Measuring Sludging Characteristics of Lubricating Oils," by W. F. Weiland, *Oil and Gas Journal*, Jan. 20, 1938, pp. 83, 86, and 93.

treme curves are S.A.E. 10 oils. Even oil weights of one brand do not necessarily fall in logical order as is shown in Fig. 2. Here the S.A.E. 40 oil, except for short oxidation periods, is less resistant than No. 324. No. 524 is of doubtful quality because of the initially high oxidation rate. Even No. 624 falls above No. 322 of Fig. 1.

On the other hand, Fig. 3 represents the S.A.E. 10, 20, and 60 code No. 1 oils which are superior in quality. The boiling range of each weight is controlled within narrow limits in contrast to the code No. 24 oils represented in Fig. 2, where the several oil

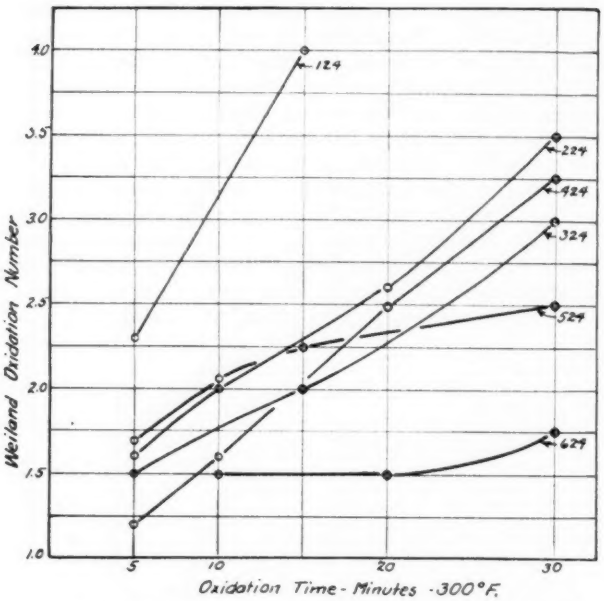

FIG. 2 OXIDATION CHARACTERISTICS, OIL BRAND 24

weights are obtained by blending. Oxidation numbers at 350 F instead of 300 F for code No. 1 oils were plotted principally to separate the curves more than would be the case at 300 F oxidation temperature.

EFFECT OF TEMPERATURE ON OXIDATION

This brings up the question of the effect of temperature on oxidation which is illustrated in Fig. 4. Oxidation numbers for 5 min, 15 min, and 30 min are given for several oils oxidized at temperatures ranging from 275 to 350 F. The oxidation numbers may be visualized as oxidation rates for the time specified. It is apparent that the oxidation numbers may be closely approximated by a more or less complex exponential function of the temperature of the general form

$$n = A(T + C)^x$$

where

n is the oxidation number
A is a factor which will include such variables as aeration, pressure, effect of catalysts, etc.
T is the temperature in degrees
C is a temperature factor

The exponent x in turn is a variable of the general form

$$x = \frac{n^k}{(T + C)}$$

This equation for the oxidation number as a function of the temperature will in general involve too much labor to be of any practical value. It is inserted only to give a conception of the increase in rate of oil breakdown with temperature, a fact which many engineers have probably sensed.

Investigators have observed changes in properties of some oils exposed to atmospheric conditions for long periods of time. Some tangible evidence of such changes is shown in Table 1. Air was bubbled vigorously through these oils at atmospheric pressure and room temperature, for periods indicated in column two. No attempt was made in these tests to obtain quantitative results. Column three shows the usual oxidation numbers for a 30-min period at 300 F. Comparison of aerated samples with the new oil shows only a faint to no color change, but an entirely different picture presents itself after a 30-min oxidation period at 300 F as indicated in the last column. Preliminary aeration has little or no effect on oils Nos. 309, 411, 412. The ratio of the oxidation numbers after aeration to the numbers before aeration for oils 214, 215, and 226 is approximately 1.3, while for oils 101, 105,

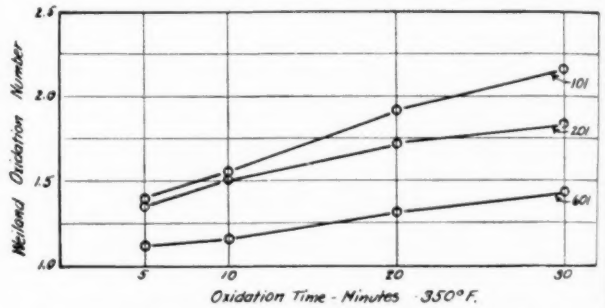

FIG. 3 OXIDATION CHARACTERISTICS OF S.A.E. 10, 20, AND 60 CODE NO. 1 OILS

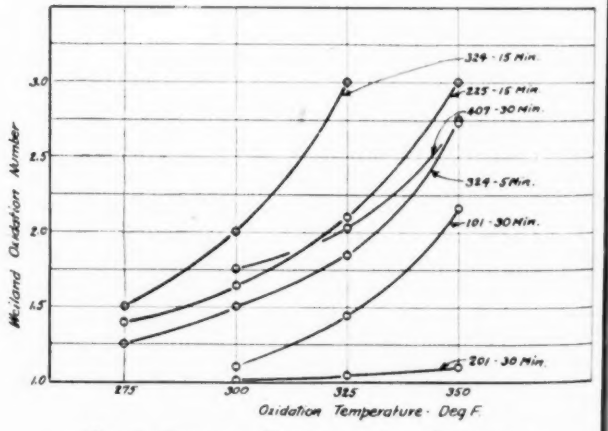

FIG. 4 EFFECT OF TEMPERATURE ON OXIDATION

and 408, the ratio is slightly over 1.4 and for oil 204 it is nearly 1.9. It is evident then that some oils will not stand up as well under the beating they get in an internal-combustion engine.

The upper curve of Fig. 5 is a service demonstration of this point. This oil had been used 2000 miles in an oil-bath air cleaner.

TABLE 1 EFFECT OF AERATION ON OXIDATION

Oil	Aeration period, hr	Oxidation numbers — 30 min 300 F before aeration	Aeration only	30 min 300 F after aeration
101	27½	1.12	1.00	1.64
204	26½	1.02	1.12	1.92
105	26½	1.04	1.00	1.48
408	26½	1.92	1.08	2.76
309	26½	1.28	1.08	1.32
411	26½	1.52	1.00	1.52
412	26½	1.20	1.00	1.20
214	33	1.28	1.00	1.56
215	21½	2.84	1.04	3.68
226	26½	1.04	1.04	1.34

TABLE 2 OXIDATION NUMBERS WITH COPPER STRIP

Oil	30 min 300 F	30 min 300 F with copper strip
101	1.12	13.70
203	1.56	13.48
206	1.28	4.34
206	1.80[a]	12.16[b]
208	1.88	5.00
112	1.32	4.36
120	1.32	1.96

[a] 6 hr 300 F
[b] 5½ hr 300 F with aluminum strip.

The 30-min 300-F oxidation number is 4.3 times the similar number on new oil.

Presence of metals in the oil sample during oxidation has a variable effect which is quite alarming with some oils. The oxidation number obtained in the usual way is positively no indication of the number obtained by oxidation with a copper strip as shown in Table 2. Oxidation of oil No. 203 for example has proceeded so far in 30 min ($n = 13.48$) that the oil has become supersaturated with sludge even though this is an oil with high gum-solvent characteristics. Oil 120 is far superior to the other examples in resisting what is very likely a catalytic action of copper. No information is available at present regarding the behavior of this oil in the presence of other metals.

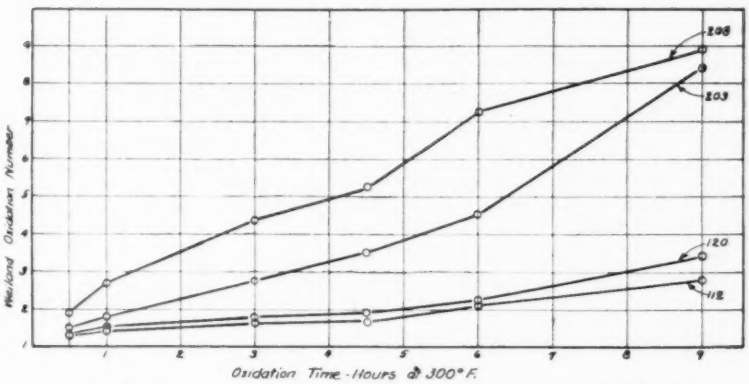

FIG. 6 RESULTS ON OILS OXIDIZED AT 300 F FOR PERIODS UP TO 9 HR

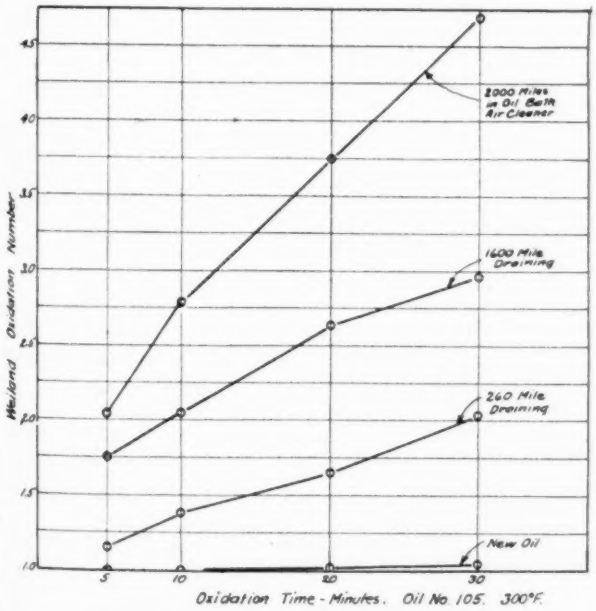

FIG. 5 SERVICE RESULTS WITH OIL NO. 105

Oil No. 206 behaves none too well in the presence of copper and it likewise performs badly in the presence of a strip of aluminum alloy cut from a new piston. This oil shows a high resistance to oxidation when the test is conducted in the usual manner.

It may seem rather strange to some that a mere change in color density of an oil is an indication of the extent to which oxidation has progressed. Some rather conclusive evidence has been presented[2] which shows the relation of the oxidation numbers to a sulphuric-acid test and also to Indiana values. To provide further and more tangible evidence, a number of oils were oxidized at 300 F for long periods of time. Results of some of these oils up to 9-hr oxidation time are included in Table 3 and Fig. 6. It is noted from the table that oxidation numbers for 5 min, 10 min, and 30 min are continuous with oxidation numbers for longer periods of time. Also that the most abrupt change occurs in the first 5 min, with very few exceptions. This last statement is made on the basis of tests on nearly 100 oils, representing over 60 trade brands.

The last column in Table 3 is highly significant in that it indicates the limit of solubility of the products of oxidation in the oil. It is probable that external influences may readily change the solubility characteristics. Nevertheless, when these gums can no longer be carried in solution, they will be deposited on vital engine parts and, by a process of accumulation, gradually build up to a dangerous point.

TABLE 3 LONG-TIME OXIDATION, 300 F

(Oxidation numbers—acid-vapor temperature, degrees F)

	Minutes			Hours					
Oil	5	10	30	1	3	4.5	6	9	Visible[a] sludge
203	1.28	1.28	1.56	1.88	2.80	3.52	4.52	8.46	10+
280°	270°	270°	260°	260°	220°	..	220°	..	
206	1.16	1.28	1.28	1.4	..	1.76	1.8	2.86	10+
290°	290°	270°	270°	280°	..	..	260°	..	
208	1.48	1.64	1.88	2.72	4.40	5.24	7.25	8.9	8
310°	290°	265°	265°	265°	250°	..	260°	230°	
112	1.12	1.16	1.32	1.48	1.60	1.68	2.16	2.80	10+
250°	250°	250°	240°	240°	..	..	240°	..	
120	1.16	1.17	1.32	1.52	1.80	1.92	2.28	3.44	10+
270°	260°	230°	265°	250°	240°	..	210°	..	

[a] Visible sludge, as indicated by muddy color or by black streaks in the oil, appears when the oxidation number reaches the approximate figure given in this column.

Concentration of gums or, more generally, the products of oxidation, need not reach the saturation point in the entire batch of oil in the crankcase before deposition begins. Local supersaturation may occur at any time in regions in the engine where these gums form most readily and especially where the oil is not generously and continuously replaced. The danger point of an oil may be reached even though the stick to all appearances is "clean."

PREDICTING OIL PERFORMANCE

Observations on the behavior of oils in engines, examination of the drainings, filter cartridges, gasoline used, and examination of the sludges have led to an attempt to predict the performance of an oil at least as far as oxidation is concerned. It must be clearly understood that oil performance is subject to many variables and that any predictions must likewise be accepted with an open mind. The estimate is based on the average slope of the oxidation number-time curve, stated as a percentage and is obtained as follows:

Assume an oil with oxidation numbers 1.20, 1.32, 1.40, and 1.40 for 5 min, 10 min, 20 min, and 30 min, respectively. Then

Change in the first 5 min = 0.20

Change per min $= \frac{0.20}{5}$ = 0.040

Change from 5 min to 10 min = 1.32 — 1.20 = 0.12

Change per min from 5 min to 10 min $= \frac{0.12}{5}$ = 0.024

Change from 10 min to 20 min = 1.40 — 1.32 = 0.08

Change per min from 10 min to 20 min $= \frac{0.08}{10}$ = 0.008

Change from 20 min to 30 min = 1.40 — 1.40 = 0.00

Change per min from 20 min to 30 min = 0.000

Average rate from 0 to 30 min = (0.040 + 0.024 + 0.008 + 0.00) ÷ 4 = 0.018, which stated as a percentage is 1.8 per cent.

This oxidation percentage divided into 100 gives 56, a number closely related to the maximum hours of useful service which the oil may be expected to give; and if a speed of 40 mph is assumed, the useful service is 2200 miles.

As a check on these calculations, Table 3 gives oil No. 206 as showing visible sludge at an oxidation number of slightly over 10. The oxidation per cent for the first 30 min for this oil is 1.87 per cent or the equivalent of 2100 miles. Table 4 shows oil No. 206 after 2000 miles of service. The oxidation number of these drainings after filtering through the usual laboratory filter paper is given in column 4 as 10.1 which checks well with Table 3.

TABLE 4 OXIDATION OF DRAININGS

Oil miles	New oil 30 min 300 F	Drainings 30 min 300 F to drainings	Drainings to new oil	Oxidation new oil per cent	Oxidation drainings per cent
206–2000	1.28	1.68	10.10	1.87	53.3
107–1600	1.46	2.16	9.93	2.60	68.3
208–1500	1.88	5.21	20.00	4.63	[a]
119–1100	1.19	2.67	4.26	0.85	34.6
119–1400	1.19	1.96	4.05	0.85	23.1
322–37 hr	1.56	2.50	5.65	2.20	43.7
327–39 hr	1.40	3.30	3.25	1.80	32.4
101–446	1.12	1.72—Ford V-8 moderate speed—long trip			
101–519	1.12	1.68—Ford V-8 city driving			
101–1150	1.12	1.41—Ford V-8 city driving—cold weather			
101–1000	1.12	2.42—Ford V-8 transport truck			

[a] This oil has outlived its usefulness. The calculated oxidation per cent for the drainings is well over 300.

A further check of the drainings is of value. The filtered drainings are oxidized 30 min at 300 F in the usual manner. The oxidation number as compared with the drainings is given in column 3 of Table 4 as 1.68. Then proceeding as in the calculation for oxidation percentage of the new oil:

$$\frac{(1.68 \times 10.1) - 1}{30} = 53.3 \text{ per cent}$$

Observations of drainings indicate that the oil has passed its service peak and is rapidly declining in usefulness as a lubricant when this "oxidation per cent" of the drainings passes the 50 per cent mark.

Oil No. 107 from Table 4 has outlived its usefulness. The casual observer would come to this conclusion from a mere inspection of these drainings.

Oil No. 208 in Table 4 has far outlived its usefulness. The oxidation number of the filtered drainings is 20.0 while Table 3 shows this oil reaches its useful limit at a sludging number of 8.

The 1100-mile draining of oil No. 119 is in worse condition than the 1400-mile draining of the same oil. This is readily explained in that the effective compression ratio of the engine from which the 1400-mile drainings were taken is considerably less because of poor valve timing than the engine using the same brand oil for 1100 miles. The better engine, as would be expected, is more severe on the lubricating oil. Both automobiles were operated under very similar conditions.

A still further example of the variable oil performance to be expected, even in the same or similar engines, is shown in the four examples of drainings of oil No. 101.

Fig. 5 is of interest as it illustrates the progressive increase in oxidation rate of oil in service. Both drainings were obtained from the same automobile operating in each instance under similar conditions.

All readings were made with a Weston electric meter on oil depths of $^1/_4$ in. and for this reason are not exactly comparable to other oxidation numbers reported in this paper. An electric-meter reading is a measure of the amount of light that passes through the oil, irrespective of color or color density. Furthermore, sludges and solid particles tend to disperse the light and may actually increase the meter reading in some instances and, at other times, give a lower reading because of the simultaneous blocking effect of colloidal particles. Many tests were made with the electric meter on various new oils and on drainings, but the method was finally abandoned in favor of visual inspection.

The per cent oxidation computed in the usual manner for the new oil, Fig. 5, is 0.15 per cent, for the 260-mile draining is 3.5 per cent, for 1600-mile draining is 7.55 per cent, and for the 2000-mile air-cleaner draining is 13.85 per cent. Total oxidation based on the new oil is 9.8 per cent for the 260-mile draining, 50.5 per cent for the 1600-mile draining, and 18.2 per cent for the air-cleaner draining. Sludge formation in the 1600-mile draining during the laboratory oxidation was noticeably rapid, which is further evidence of the desirability of an oil change when the oxidation per cent of the drainings reaches the 50 per cent point.

Acid Products From Oil Breakdown

It has been known for some time that oil breakdown is attended by the formation of more-or-less acid products. The exact nature of these products, general rules governing their formation, methods of their detection, and their effects are not so well known. In the practical analysis of this problem, their exact nature is of less importance than a knowledge of the conditions under which these products are formed and evidence of their effect. It must be clearly understood that the standard acid test for lubricating oils is of no value in the detection of these acid products, as they are given off by the oil principally as vapors, hence, the designation "acid vapor."

Acid-Vapor Test. The oxidation apparatus is slightly modified by placing a 1-in. diameter × 3-in. length glass tube in a vertical position in the suction line leading from the test tube and as near the test tube as practical. An acid indicator such as blue litmus is suspended in this tube.

Procedure. Heat the oil bath to 350 to 360 F and maintain the temperature within these limits. Place about 25 cc of oil in the test tube and adjust the air suction to 4 in. of water. When the first trace of color change appears on the litmus, note the temperature of the oil sample. This reading is recorded as the "acid-vapor temperature."

In the average run of oils, the acid-vapor temperature drops rapidly as oxidation proceeds. The lower row of figures under each oil in Table 3 gives some of these temperatures for the long-time laboratory oxidation tests. The acid-vapor temperature of the new oil is no definite prediction of what happens later. However, a strong acid-vapor indication in a new oil containing fatty additives is open to suspicion. Such is the case of the oil of Fig 5, which showed a relatively high resistance to oxidation by the usual test, but the 1600-mile draining broke down very rapidly.

Fig 7 shows graphically the trend in acid-vapor temperatures of three of the oils of Table 3. Oxidation for several points on these curves was forced to obtain a few of the acid-vapor temperatures not included in the table. The acid-vapor temperature appears to reach a near-minimum value and, when this occurs,

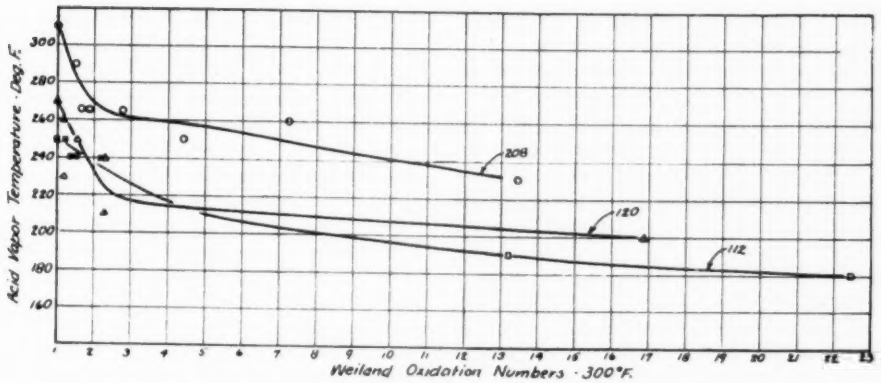

FIG. 7 GRAPHIC INDICATION OF TREND IN ACID-VAPOR TEMPERATURES

visible sludges begin to make their appearance in the oil, the oil being oxidized in the usual manner.

For low oxidation numbers the acid-vapor temperatures may be more or less erratic, especially for built-up oils containing a miscellaneous assortment of additives, as oil No. 120. Such oils are likely to approach the near-minimum, acid-vapor temperature much sooner than a straight-cut oil and, therefore, are again open to strong suspicion.

Acid-vapor temperatures as low as 180 F have been observed in oils oxidized in the laboratory, and as low as 140 F in crankcase drainings. There is no record as yet that any of these oils has shown the presence of acid by the standard acid test.

The minimum acid-vapor temperature and possibly the rate of drop in acid-vapor temperature are in themselves only an indication of what may be expected to happen in an engine specifically from the point of view of corrosion. To throw some light on this question, a number of new oils and drainings were heated at 300 F in the oxidation apparatus with air bubbling through in the usual manner for 3-hr periods. Carefully weighed strips of metal were placed in each sample of oil. Tests were made with cadmium-copper-silver bearing-metal strips, and repeated with fresh oil samples on polished copper strips as well as on pieces of aluminum alloy. At the close of the test period, the metal strips were removed and carefully washed with benzol and with carbon tetrachloride and allowed to dry. The metal strips were weighed again and the loss in weight in per cent calculated. It is well appreciated that there may be a slight increase in weight of the metal due to possible adsorption of hydrogen and nitrogen, or chemical combination or alloying with carbon, oxygen, sulphur, etc. A metallographic study or even a chemical analysis may be advantageous in the final study of this problem.

TABLE 5 CORROSION STUDIES, 300 F

Oil	Acid-vapor temperature, F	Loss in weight in 3 hr, per cent: Cadmium-copper-silver	Copper strip	Aluminum permite No. 3
101 new	290	0.0000	0.0208	...
101–1000 miles	230	0.0000	0.0208	...
102 new	285	0.0000	0.0386	0.0053
102–1000 miles	220	0.0390	0.0560	...
403 new	320	....	0.0110	0.0140
403–450 hr	240	0.0026	0.0322	0.0032
105–1600 miles	165	0.2950	0.0680	...
107–1000 miles	250	0.1240	0.0000	...
410 new	270	0.0013	0.1520	...
410–450 hr	200	0.0000	0.1180	0.0046
417–450 hr	210	0.0000	0.0234	0.0036
119–1100 miles	210	0.0440	0.0000	...

A few instances are reported in Table 5 which indicate no loss in weight. Attention is directed to the outstanding losses of the 410 new oil on copper strip, and the 105 and 107 drainings on the cadmium copper silver. The oxidation curves for oil No. 105 have been referred to in Fig. 5. Oil No. 107 is similar to oil No. 208 of Figs. 6, 7, and 8. With the notable exception of oil 410, the drainings generally show more rapid corrosion than the new oil, which is to be expected. Exceptions need explanation. Oil 410 is a Diesel oil with additives. When the additives have been disintegrated, the oil assumes a more normal status. However, in the meantime, as the oil wears down to a normal condition, the engine must suffer. Such was actually the case. The engine using this oil showed excessive wear and was ready for a major overhaul

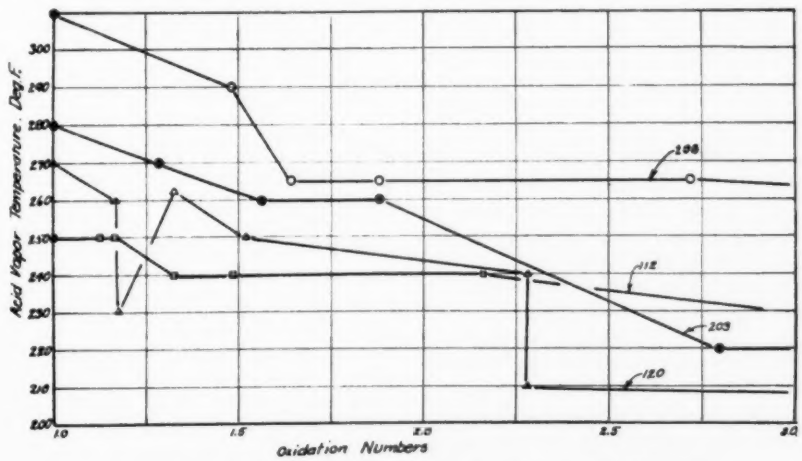

FIG. 8 ACID-VAPOR TEMPERATURES FOR LOW OXIDATION NUMBERS

in 450 hr. When oil No. 410 was replaced by oil No. 403, engine wear became negligible at least for the 450-hr period.

Loss in weight of the aluminum alloy was not anticipated. These losses are slight but they nevertheless exist, and lead to the question of possible corrosion with other metals used in the internal-combustion engine.

Drainings that show the lowest acid-vapor temperature are not necessarily the poorest oils, at least as far as the metals reported in these tests were concerned as in examples Nos. 107, 119, and 417.

It is quite probable that dilution has some bearing on the acid-vapor temperature and on the oxidation characteristics of the drainings. To the author's knowledge, no satisfactory method has been devised to remove dilution without the danger of changing the oil characteristics.

In conclusion, it is felt that the question of stability, or better, the lack of stability of crankcase oils has been only partially solved. Oxidation characteristics of the oils are the starting point from which to attack the problem. In this respect the performance of an oil can be predicted with only a fair degree of certainty. As the temperatures of engines go up, a temperature exponent may be introduced to modify the oxidation numbers. More information is needed concerning the catalytic action of metals on oil oxidation. In the final analysis, either the metals or the oils may be standardized; as a makeshift, oil A may be definitely recommended for engine x.

Oil breakdown is very definitely associated with a near-minimum, acid-vapor temperature, which in turn has its bad effects on at least some of the engine metals.

Formation of visible sludge is closely associated with oil breakdown and near-minimum, acid-vapor temperature. Evidence indicates that visible sludge is a warning to change the oil.

The acid-vapor problem throws an entirely new light on oil filters. Filters can be made to remove solids and some sludges; they can be chemical in action to neutralize acids that might exist in the oil. But these acid vapors which form more or less continuously at vital points in an engine never come near the oil filter.

As a final thought, perhaps the oil should be changed more frequently.

Discussion

GEORGE ROUND.[3] Every oil refiner is deeply interested in the subject of this paper and many dollars have been spent on it, but as yet without any conclusive answer being obtained. Whether the author has discovered the final answer with the particular oxidation test which he has developed is difficult to say, but we venture to hazard a guess that he himself would not be so bold as to say that it would be a substitute in every case for engine tests.

Most of the oxidation tests, which have been developed thus far, represent an attempt to predict, from a relatively short-time test, what is going to happen in an engine in a few hundred or a few thousand miles. The author's test takes less time than any other of which we know for making such a prediction. Any such accelerated test is always open to question even though in this instance the temperatures are not abnormal and below those of several oxidation-test procedures developed by others.

Before any test of this sort can be used with any degree of assurance whatsoever, it must be correlated with very extensive field and laboratory test work, particularly the former. In stating this, we wish to emphasize that it is the appearance and condition of the engine itself rather than that of the crankcase oil which counts. Hence, reliance on the analysis of crankcase-oil samples alone in judging the performance of oil is likely to be misleading. We must know what happens to the engine itself.

While it is possible to develop an oxidation test which will give reasonably consistent results on a single oil, the engine itself gives widely inconsistent results. For example, we could cite a case where a certain make of engine under certain operating conditions gave a great deal of trouble from lacquer deposits on certain parts, the engine and the filter otherwise being exceptionally clean. Laboratory oxidation tests indicated that the oil was exceptionally stable. When an attempt was made to duplicate the field condition in the laboratory, using the same make of engine and oil from the same containers, the engine ran perfectly and no sign of lacquer developed. Why this should be still remains a puzzle which apparently cannot be answered by any laboratory test, yet it presents for solution a very important commercial problem. If the author's oxidation test will give any clue toward answering the question of why the same oil gives satisfactory results in some engines and not in others, or in the same engine under one set of conditions and not in another, even under accelerated operating conditions, he has made a very valuable contribution to a lubrication problem.

There are some statements in the paper which we believe are not always consistent with the facts. For example, the author states, "the better engine, as would be expected, is more severe on the lubricating oil." This is not always the case. In fact, we find that in many instances, the oil deteriorates much less rapidly and the engine stays much cleaner when the rings are new and in good condition than they do when these parts have become worn. The answer appears to be in the fact that products of incomplete combustion and decomposition of the fuel get into the crankcase and contaminate the oil much more rapidly in worn engines than in those in good condition. Thus far it does not appear to be possible to differentiate between oxidation products from the fuel and from the lubricating oil.

The author speaks of oils containing fatty additives. We know of none being offered today for motorcar lubrication.

The author again refers to additives in Diesel oils as affecting oil performance in an adverse way. We wonder if he appreciates that it is impossible to lubricate satisfactorily certain makes of Diesel engines with oils not containing additives.

There is an implication in these references to additives which might lead one to feel that oils containing them are not all they should be. The facts of the matter are that with present and expected developments in both carburetor- and Diesel-type engines, it is going to be necessary to use additives of various sorts, because it is impossible to build into lubricating oils all of the characteristics that are required by these new engines.

T. H. ROGERS.[4] As indicated in his introduction, the author attempts to answer two questions:

1 How can the performance of an oil be predicted? A comparative test for color formation at 300 F is proposed as a measure of the performance but little or no data are given to show that this test correlates with performance of the oil.

2 When is an oil worn-out? The author at various points indicates limits of usability of oils based on the color-stability test, but provides no adequate basis for the limits selected.

It has long been appreciated by oil technologists that color formation is a qualitative indication of the oxidation behavior of lubricating oils, but few of them would agree that comparative color formation is an adequate quantitative measure of such behavior. In certain cases, for example, by the use of some inhibitors, this qualitative correlation is entirely upset. The oxidation of lubricating oil is of itself an extremely complicated

[3] Socony-Vacuum Oil Company, New York, N. Y.

[4] Standard Oil Company of Indiana, Whiting, Ind.

phenomenon, aside from the varied conditions involved in the service of such oils. We definitely question whether a brief color-stability test, under comparatively mild conditions, properly takes account of the situation. We note that the author states that his tests correlate with the Indiana oxidation test. However, the comparison made was with one single point on the asphaltene-time curve afforded by the Indiana test. In presenting the Indiana test and in our subsequent use of it, we have stressed that a single point on this curve is not a complete measure of the oxidation behavior of the oil, and we feel that various other aspects of the oxidation behavior are necessary to evaluate the oil completely.

To summarize briefly the status of the problem of the stability of crankcase oils, we would say that the following aspects are apparent in terms of the performance behavior of the oil: (*a*) Asphaltene formation, (*b*) viscosity increase, (*c*) corrosiveness toward certain metals, and (*d*) varnish formation.

These several aspects of oil oxidation or deterioration require separate consideration from the performance standpoint, and variations in the conditions of use will change the emphasis which is to be placed upon the different aspects. Furthermore, from the standpoint of oxidation tests, it is definitely known that these four aspects of oil oxidation do not correlate with each other; that is to say, it is not possible to measure asphaltene formation (or any other one feature) and then predict any one of the other three. No one of the aspects of oxidation can be used as a single criterion. Also, it has not yet been found possible to study the problem of corrosiveness by measuring the amount and strength of acids, but actual corrosive behavior toward metals is necessary.

The oxidation number, based on color development, used by the author, is not a real measure of any one of the previously mentioned aspects, but may be considered to be somewhat related to (*a*). On the basis of these considerations, it must be said that the calculations of the author as to per cent oxidation and the limits of usability of oil based on the color-stability test seem quite arbitrary. The observations of the author regarding the vapor temperature of acidity development are interesting. It would appear to be desirable to correlate these with actual corrosion tests.

H. M. Rugg.[5] For nearly two years, the Pennsylvania Grade Crude Oil Association has been conducting a very intensive and fundamental study of oxidation. The results of this study seem to disprove the statements that the extent to which oxidation has progressed may be predicted by the change of color density in the oxidized oil, and also that the grade of oil is no index of its resistance to oxidation.

In this research work, carefully prepared fractions of oil of varying molecular structure are studied to obtain variations in their susceptibility to the absorption of oxygen. To avoid the effect of other variables, pure oxygen has been used, thus, at the same time, accelerating the tests so that the results are equivalent to many times the expected use of an oil. Even though the Pennsylvania region has been manufacturing and studying petroleum products for over 75 years, much new knowledge is being developed in this research. Analysis of these oxidized fractions shows that the process of oxidation is a very complicated one. Data are obtained showing the distribution of oxygen into such products as carbon monoxide, carbon dioxide, water, volatile and fixed acids, and sludge, the sludge being further divided into lacquer-type, oil-soluble, and naphtha-insoluble fractions. The different fractions show varying tendencies in the absorption of oxygen; also, temperature vitally affects these tendencies.

These points are mentioned to show that, where such large differences occur in carefully controlled laboratory tests, any attempt to make quick analyses of oils used under the promiscuous operating conditions of an engine is simply futile.

Then there are the differences in the lubricating oils themselves which will undoubtedly make a color comparison of oxidation unreliable. This is probably why, in Fig. 1 of the paper, the oxidation rates of different oils seem to cross. With differences in crude source, where quite wide variation in oxidation stability occurs, differences in process of manufacture, conventionally refined, solvent-refined, long residuum oils, together with blends of these products, color comparisons will be of little value for oxidation data. We can find heavily oxidized oils light in color that are unfit for use and, in contrast, oils dark in color that are not oxidized to harmful degree.

A study of present-day engine designs, as well as future tendencies, and a study of the practices of a majority of automotive-vehicle owners and users indicate very plainly that a return to the former recommendations for frequent draining and occasional flushing will, in the end, be less expensive and give less trouble, notwithstanding the development of any special tests such as the author has described.

The automotive industry wants and receives from petroleum something that will burn freely and clean, producing all possible power. This is accomplished by uniting it chemically with oxygen. In other words a high-grade fuel is required. At the same time, it happens that this same medium, petroleum, has proved that a part of it makes a good lubricant. Therefore, it is required to take from this medium something else which will resist the reaction with oxygen, will not burn or oxidize, when such a reaction is really both natural and potent.

The petroleum industry is doing and has done a very good job in meeting these conditions but the users of these products must take into consideration the fact that petroleum, like all other materials prepared from matter, has certain physical limitations. The petroleum industry has no data, as yet, on what the "factor of safety" is in lubricants. For that reason, how do we know how much it will resist oxidation or what the thin film of oil on the cylinder wall will do? We do not like to see engine builders or designers go to the point of pressing that film until the thickness has to be measured in molecules rather than fractions of an inch, and the circulation drastically reduced to obtain "oil economy," then expect it to withstand the high temperatures and pressures of present-day designs.

A great deal of work has been done with additives, and many jobs seem to require them. However, all will agree that, where additives have been used to improve or correct one condition, almost invariably other difficulties have been encountered. We are not convinced that additives are absolutely necessary, but believe that, through our research studies, it will be possible to produce the proper qualities, namely, oxidation resistance, corrosion resistance, etc., in the lubricating oil by the method of processing it, and avoid the worries and troubles resulting from the use of chemical nonpetroleum additives.

E. T. Vincent.[6] The writer would like to indicate something of the engine-users' points of view, with the purpose of establishing some relation between the oxidation tests and actual performance. We had a problem some time ago involving an air-cooled aircraft engine in which considerable trouble from gum and carbon formations was experienced. One of the regular oxidation tests was tried. Unfortunately, the oil which performed best in the engine, giving almost no gum, was practically a tarry mass soon after the oxidation tests had started. It is therefore believed that engine tests should be conducted at the

[5] Pennsylvania Grade Crude Oil Association, Oil City, Pa.

[6] University of Michigan, Ann Arbor, Mich.

same time to establish some basis of comparison with the oxidation tests, because apparently they do not correlate.

The question of temperature is often raised in connection with oil engines. Everyone says the Diesel engine is hot, and that is why we get so much gum. The writer does not think that is the case, for several reasons. Jacket losses are much lower than with the gasoline engine, therefore, the temperature difference between the inside and the outside of the cylinder oil film must be lower. It is well known that heat flow depends upon temperature difference so, if the heat flow is less, temperature difference is less. A gasoline engine, comparable in size to a given Diesel engine, has higher piston temperatures. Therefore, the question is not wholly one of temperatures.

An experience of the writer's some years ago attests to this fact. While testing a completely new engine, using a high-grade lubricating oil, we were motoring it by means of the dynamometer, with no fuel in the engine. Therefore, the temperature differences were extremely low; just whatever the jacket-water temperature happened to be, due to the compression. We motored the engine for about 4 hr and then went to lunch. On returning, the engine could not be turned around. The gum formation which had occurred in 4 hr was so great that, when the engine stopped, it was actually stuck together. We used solvents to get the engine dismantled.

That same engine, with the same lubricating oil, was then put on fuel. With fuel oil and with higher temperatures, running on load, gum formation did not occur. Therefore, we can definitely rule that temperature is not the only cause of such formation. (The engine was of the sleeve-valve type and probably sensitive to blow-by, until the sleeves and rings were sealed in.)

In the writer's opinion oxygen content is the chief cause of gum formation. In the Diesel engine, when running on load, there is an excess of air which the gasoline engine does not have. The gasoline engine is usually running on a rich mixture with practically no oxygen at all in the blow-by gas. That consideration should be taken into account when dealing with Diesel engines.

L. A. Blanc.[7] In corroboration of Professor Vincent's opinion about oxygen in the blow-by, we have analyzed a number of blow-by gases on Diesel engines and have found that in all cases oxygen is never less than 20 per cent, regardless of load on the engine, and over a wide range of blow-by.

Author's Closure

There seems to be some misunderstanding in regard to color change in the oil. It will be noted that the paper did not say "color change" but rather considers and measures oxidation as a change in density of a given color, as compared with the original oil.

In regard to life of the oil, tests up to 12 and 24 hr have been run on oils of Fig. 6, since this paper was written. Oxidation of oil No. 208 continues approximately as a straight line until at 12 hr the oxidation number is 13.5 and, at 24 hr, it is 31.

Oil No. 120 seems to be quite good up to about 9 hr, when oxidation breaks sharply to give 12.8 at 12 hr and 90 at 24 hr. Visible sludge begins to form between 9 and 12 hr. This is a built-up oil which seems to be quite stable until the additives begin to break down. Thus, in predicting the useful life of an oil from short-time oxidation tests, the prediction holds fairly well, except for oils with additives, when longer oxidation periods must be used.

A study of oxidation rates and acid-vapor-formation temperatures in the presence of metallic catalysts should give some information relative to the effect of additives. It is true that some additives will perform well in certain engines but poorly in others. Reference is made to an oil not reported in the paper. This oil is built up especially for engines containing copper-base bearing metals. When this oil is oxidized in the presence of copper, very little change occurs, but other metals such as mild steel, cast iron, aluminum, and babbitt, all act as powerful catalysts to accelerate oxidation and reduce the acid-vapor temperature. Tests show that metallic catalysts, as a general rule, will lower the acid-vapor-formation temperature a good deal faster than the oxidation number increases. It is believed that tests in the presence of catalysts will in part answer some of the discrepancies which so often occur in engine tests, as well as in laboratory tests, and help to enumerate more of the variables that affect oil performance.

A question was raised by Mr. Round relative to performance of oil in the better engine. The term "better" refers to engine design, as both engines were relatively new and operating conditions were similar. The effective compression ratio of one of these engines was much below the nominal because of relatively poor valve timing.

It appears that Mr. Rugg contradicts his own statement that grade of an oil is an index of its resistance to oxidation. The statement is true for close-cut oils, such as in Fig. 3, but for the general run of oils on the market, viscosity cannot be considered an index of resistance to oxidation (refer to Figs. 1 and 2 of the paper).

The feasibility of predicting the useful life of an oil from these oxidation tests was questioned by several discussers. Their attention is called to the last column of Table 3, listing the oxidation number at which visible sludge appears, and to the subsequent section "Predicting Oil Performance." Furthermore, the appearance of visible sludge is very closely associated with the minimum acid-vapor-formation temperature which appears to be just as important as the oxidation number, as a gage to determine the useful life of an oil.

It is not necessary to assume blow-by as a specific contributor to oxidation. The air in the crankcase is beaten into the oil during operation and, upon subsequent heating, oil oxidation results. Table 1 shows that, in general, oil deteriorates faster when it is saturated with air.

In conclusion, a point was raised in regard to the effect of pressure on oil breakdown. A few tests have been made in an extreme-pressure machine. As an example, it was found that for oil No. 208, 6-min operation in the extreme-pressure machine was equivalent to 30-min oxidation, both as regards oxidation number and acid-vapor temperature.

Whip Stress in a Locomotive Main Rod at 100 Miles per Hour

By M. W. DAVIDSON,[1] VERMILLION, S. DAK.

Older railway motive-power units are being operated at, and new equipment is being designed for, higher speed than has prevailed in the recent past. The paper presents a precise method for the determination of inertia flexural, or whip, stress in locomotive main rods.

One hundred miles per hour is the speed that is chosen for illustrating the method, and for exhibiting the stresses which are developed; since at the present time that seems to be the general operating goal for fast rail traffic. Also, speeds of this order are frequently attained by the main rod and the mechanism in general when locomotives are slipping.

Accurate equations for the inertia forces and couples are obtained for use in determining the inertia reactions and loads. These equations are of universal applicability to all the parts and fractional parts of the mechanism.

The rod bending moments and accompanying stresses were determined through the use of the external wrist-pin reactions in combination with the distributed rod-inertia loading. The moments and stresses were found for six or seven sections along the body of the rod for each of twelve crank positions spaced at 15-deg intervals. Finally the total tensile unit stress is found for each section and crank position, by combining that which is due to whip, with that which results from rod axial-inertia forces and the force of the steam.

RAILWAY TRAINS which operate at sustained speeds approaching a hundred miles per hour are rapidly increasing in number. Because of this trend it has interested the writer to make something of a detailed study of the flexural or "whip" stress which develops in a conventional locomotive I-section main rod when the locomotive is running at 100 mph, and also to follow this with an examination of the total tensile stress which results when the whip stress is combined with that due to the inertia of the reciprocating parts, the fraction of the main rod itself, the steam force, and the component of the normal guide reaction which is due to the inertia of the rod.

In order to make this study accurate, it seemed desirable to employ accurate characteristic expressions, which apply to the slide-crank mechanism for the determination of its inertia forces and couples. These characteristic expressions may readily be obtained by the use of the differential calculus for the construction of formulas which give the linear acceleration of a point on the axis of the rod, and the angular acceleration of the rod. The procedure is first to express in terms of the crank angle the displacements of a point on the rod axis from its zero-displacement or dead-center position, both along the engine axis, and transverse to that axis. Then the second derivative of displacement with respect to time for each of the two expressions will give, respectively, expressions for the point's axial and transverse accelerations, and the product of these latter by the rod's mass will give the expressions for the corresponding components of its linear-inertia force. In like manner the angular acceleration of the rod may be obtained, if the same treatment be given the expression for the angular displacement. The product of this acceleration by the rod's moment of inertia about its mass-center axis yields the expression for the angular-inertia torque or couple about that axis. With these formulas the dynamic effect of the rod as a whole, or of any part of the rod may be completely determined.

The form of the expressions used herein departs from the conventional, in that the variables are expressed as lengths of the mechanism diagram, rather than as functions of the crank angle. These forms are thought to lend themselves conveniently to the determination of the desired quantities either by simple computation or by diagram scaling.

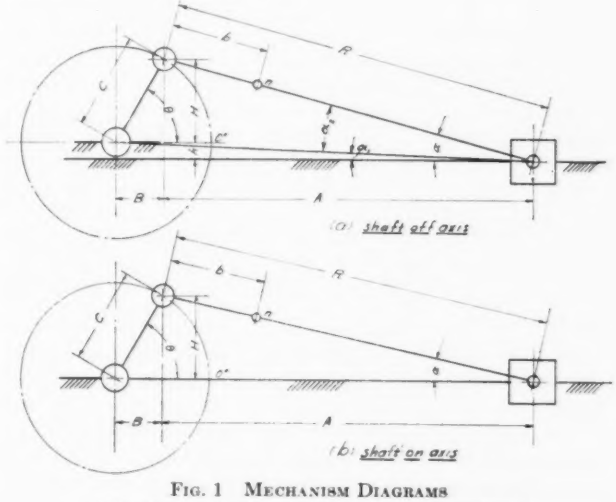

FIG. 1 MECHANISM DIAGRAMS
(The stroke-end value of α_1 is used in the equations.)

Fig. 1*a* represents the arrangement of the slide and crank with the crank center offset from the path of reciprocation, and Fig. 1*b* the usual arrangement with the crank center on that path. In addition to the quantities shown in Fig. 1, where all distances are in feet, the following notation is used:

- F_A = the horizontal or axial component of the linear-inertia force of any mass of which the mass center is at any point n in the axis of the connecting rod, lb
- F_v = vertical or transverse component of the same force, lb
- T = the angular-inertia couple about its mass center of any mass of which the mass center lies in the axis of the connecting rod, lb-ft
- V = linear velocity of crank-pin center, fps
- W = weight of the accelerated mass, lb
- g = acceleration due to gravity, ft per sec per sec
- π = the constant 3.1416
- N = number of revolutions per sec

[1] Professor of Applied Science, University of South Dakota. Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Annual Meeting, Philadelphia, Pa., Dec. 4–8, 1939, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

I = moment of inertia of the accelerated mass about the mass-center axis which axis is perpendicular to the plane of motion of the connecting rod, slug-ft²

The desired equations are[2]

$$F_h = \frac{WV^2}{gC^2}\left[B + \frac{b}{R}\left(\frac{R^2B^2}{A^3} - \frac{H^2}{A} - \frac{kH}{A}\right)\right] \quad \text{Fig. 1}a\ [1]$$

$$F_h = \frac{WV^2}{gC^2}\left[B + \frac{b}{R}\left(\frac{R^2B^2}{A^3} - \frac{H^2}{A}\right)\right] \quad \text{Fig. 1}b\ [2]$$

$$F_v = \frac{WV^2}{gC^2}\left[H\left(1 - \frac{b}{R}\right)\right] \quad \text{Figs. 1}a, 1b\ [3]$$

$$T = 4\pi^2N^2I\left[\frac{H}{A^3}(R^2 - C^2) - \frac{kB^2}{A^3}\right] \quad \text{Fig. 1}a\ [4]$$

$$T = 4\pi^2N^2I(R^2 - C^2)H/A^3 \quad \text{Fig. 1}b\ [5]$$

In applying these equations, distances to the right and left of the crank axis are respectively plus and minus, and those above and below that axis are likewise respectively plus and minus.

Examination of the equations shows that if b, the distance from the crank-pin center of any point n in the rod's axis be made zero, then n becomes the center of the crank pin, and F_h and F_v are simply the axial and transverse components of the centrifugal-inertia force of a mass centered at that point. If b be made equal to R, then n becomes the wrist-pin center, and F_h will give the axial-inertia force of any mass, such as the reciprocating weights, which may be centered there, and F_v will become zero as there is no transverse acceleration of the mass so located. If b be taken as the distance to the rod's mass center, then n will be its mass center, and F_h and F_v will give, respectively, the axial and transverse components of the linear-inertia force of the connecting rod as a mass unit, and T will give its angular-inertia torque about the mass-center axis which is perpendicular to its plane of motion. Also if b be taken for *any* point in the rod, the axial and transverse components of the linear-inertia force and the angular-inertia torque of a unit mass so centered may be determined accurately by the use of the equations.

The Problem

The particular connecting rod, reciprocating weights, general dimensions, and quantities used in the study are from a class F-3, Chicago, Milwaukee, St. Paul and Pacific locomotive, having cylinders 23 in. in diameter and 28 in. stroke; driving wheels 79 in. in diameter; reciprocating parts weighing 1126 lb; I-section connecting rod, 116½ in. between wrist-pin and crank-pin centers, and weighing 877 lb. The mass center of the rod with journal brasses in place was found at 38 in. and 78½ in., respectively, from the crank-pin and wrist-pin centers. The moment of inertia of the complete rod about its mass-center axis was experimentally determined by observing its time of oscillation as a compound pendulum when suspended upon a knife-edge support set parallel to the wrist-pin axis and which made contact with the outer wrist-pin brass along its extreme outer bearing element. By checking the results obtained with geometrically shaped masses with the results obtained with the integral calculus for the same masses, the author has found this method for determining mass moment of inertia very accurate when carefully performed. The value of the rod's moment of inertia first obtained for the axis of suspension and then transferred to the parallel gravity axis gave a value about the latter axis of 405 slug-ft².

[2] The Appendix shows the derivation of the equations for the case of Fig. 1*b*.

The principal data for substitution in the equations for force and torque are given in Table 1. The friction effect upon the well-lubricated mechanism is relatively slight, and was considered to be zero. With this assumption the reaction of the crosshead guides at the wrist-pin end of the rod is normal to the path of reciprocation.

Using Equations [2], [3], and [5] for each 15 deg of crank angle, the data of Figs. 2, 3, 4, and 5 were computed. These give, respectively, the values for the rod's angular inertia in

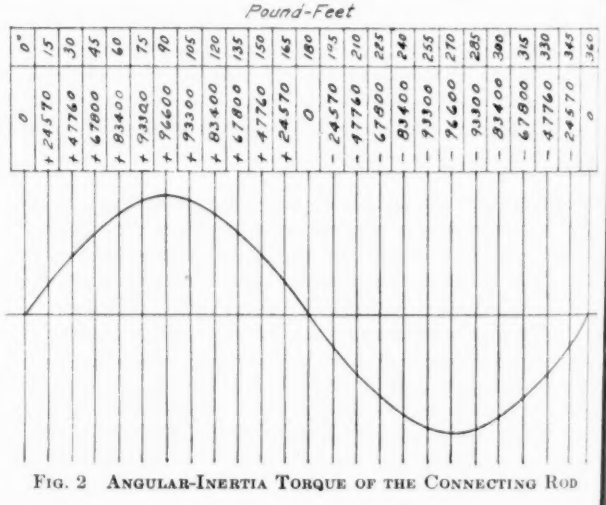

Fig. 2 Angular-Inertia Torque of the Connecting Rod

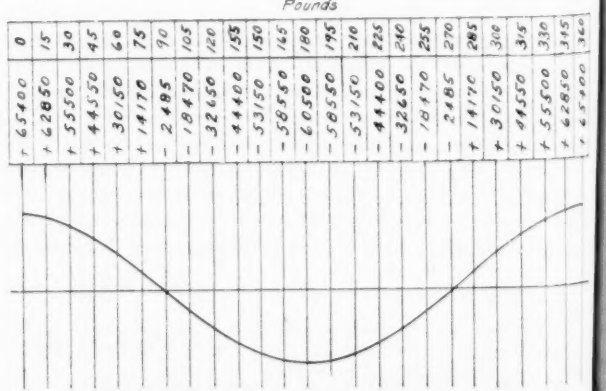

Fig. 3 The Axial Component of the Linear Inertia of the Connecting Rod

pound-feet, the component of its linear-inertia force parallel to the reciprocating path, the component of its linear-inertia force transverse to the reciprocating path, and the linear-inertia force of the reciprocating mass, all in pounds. Fig. 6 represents the net steam force for driving the piston, as obtained from a locomotive indicator card taken when the locomotive was running at high speed, though not at 100 mph.

Method for Determination of Whip Stress

The flexural or whip stresses which develop in the rod because of its inertia can be determined at any point in the rod and for any position in its motion cycle when the external bearing reactions and the distributed load due to its own inertia are known.

The d'Alembert principle was used as illustrated in Fig. 7 to determine the bearing reactions at twelve angular positions of the crank. The positions chosen were those which range through the arc which contains the position of maximum stress,

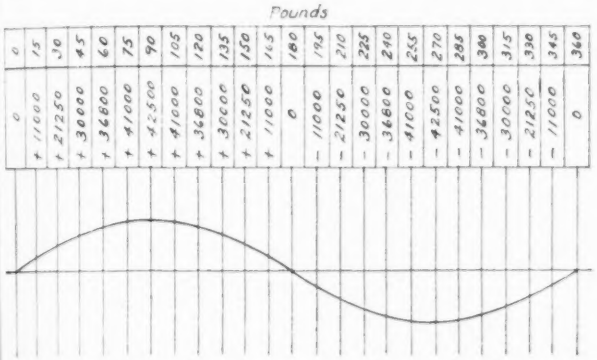

Fig. 4 The Cross Component of the Linear Inertia of the Connecting Rod

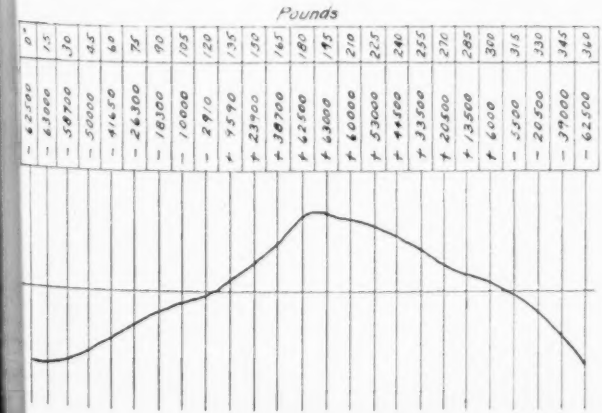

Fig 6 Effective Steam Force

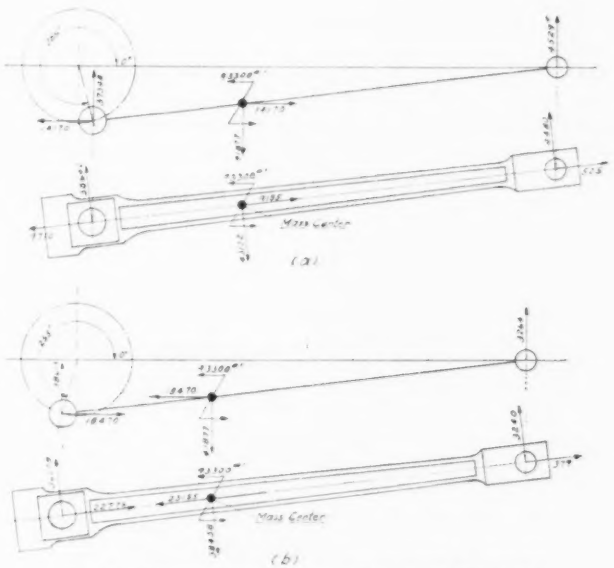

Fig. 7 Bearing Reactions, d'Alembert Principle
(Forces in pounds, couples in pound-feet.)

both when the rod is above and below the engine axis. These crank positions were spaced 15 deg apart and symmetrically with respect to that axis. This figure shows the application of the components of the rod's linear inertia at the mass center, the application of the angular-inertia torque for the mass-center axis, and the resulting reactions at the crank-pin and wrist-pin bearings when transformed into components which are parallel and perpendicular to the rod's axis.

In order to determine the manner of distribution of the axial- and transverse-inertia loads, beginning at the wrist-pin end of the rod the values of F_A, F_v, and T at seven points along the rod were determined for sections of the rod 1 in. in length. Using the first two of these values, the axial and transverse components of the 1-in. sections were found. The former for use in finding the rod's tensile effect upon itself, and the latter for determining the distribution of the transverse flexural load. The angular-inertia couples of the 1-in. sections have cumulatively very little flexural effect, but to make the study complete they were determined and used.

Fig. 8 shows the locations of the 1-in. sections for which the determinations were made, and gives the values as first obtained by the equations, and as transformed into components parallel and perpendicular to the rod's axis for the 285-deg position. As the weight of the rod has a slight effect upon the external reactions at the bearings, and also upon the distributed load, this was added to the inertia load, as it should be for rod positions below the engine axis. However, for rod positions above the axis the weight should be subtracted. And to that small extent the results which are correctly found for the lower positions are in error for those above.

Using the transverse unit loads, the six diagrams of transverse-inertia load were determined, Fig. 9; with the axial unit loads the four diagrams of axial-inertia load, Fig. 10, were constructed; and with the angular unit torques or couples the six angular-

load diagrams of Fig. 11 were determined. The angular positions called for on all of these diagrams refer to the angle θ in Fig. 1*b*.

As already stated, the sections chosen for the unit-load determinations are shown in the various figures, and it should be noted that section *e* represents the mass-center position of the rod. Four points were chosen along the I-section body of the rod, and three in the enlarged wrist-pin end. The load distribution over the body of the rod is accurately represented by the diagrams, and the section loads of the wrist-pin end are also accurate. Still the diagram at the end is not accurate, since the outline of this part of the load is formed by connecting with straight lines the points where the unit determinations are made. However, it seems to the author that the degree of accuracy employed here is ample when consideration is given

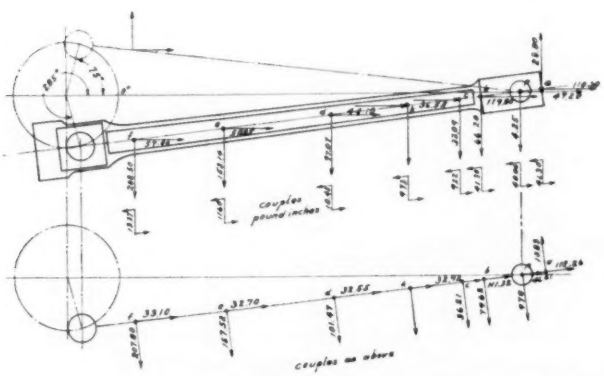

FIG. 8 INERTIA FORCES AND TORQUES FOR SECTIONS OF CONNECTING ROD 1 IN. LONG

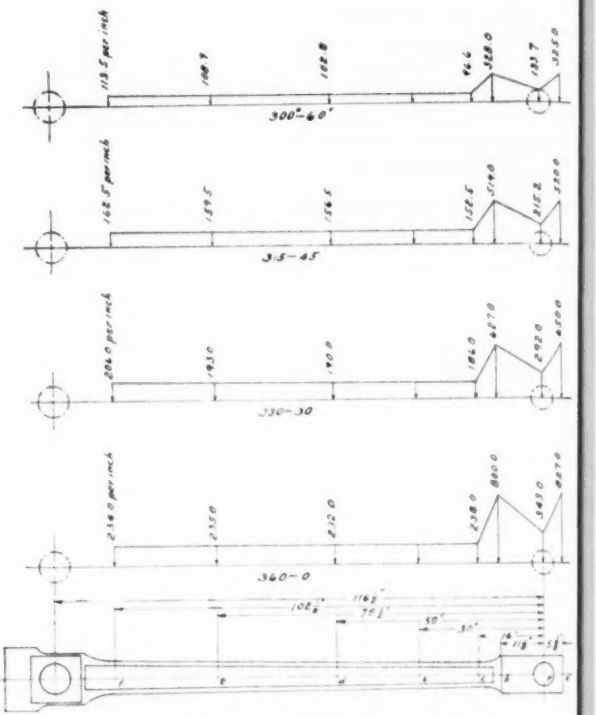

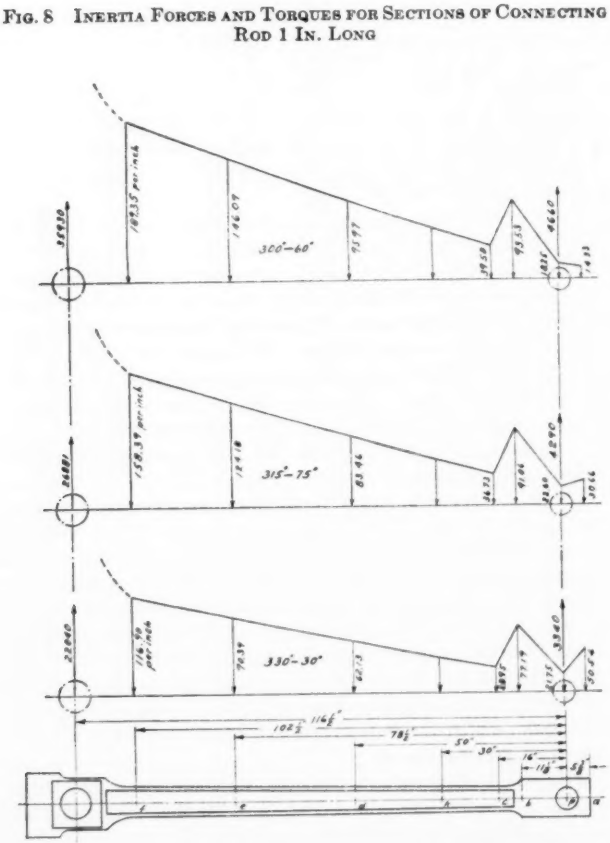

FIG. 10 DIAGRAMS OF AXIAL-INERTIA LOAD

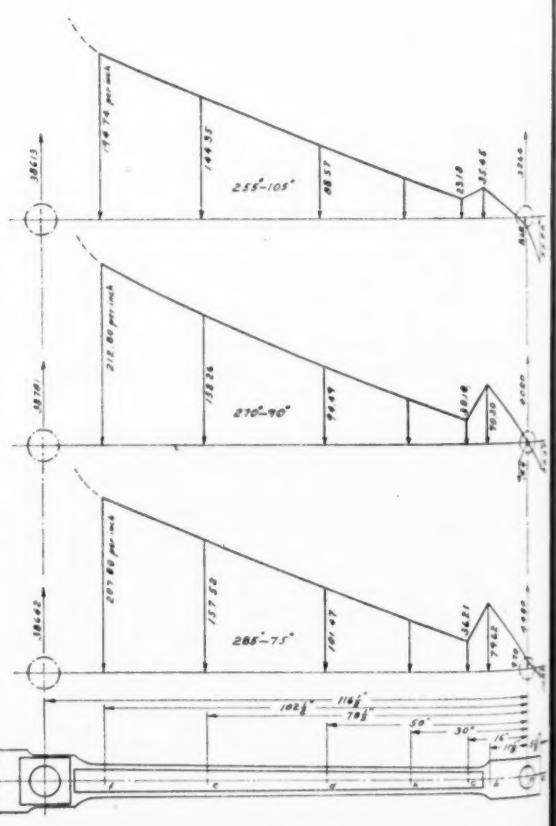

FIG. 9 DIAGRAMS OF TRANSVERSE-INERTIA LOAD

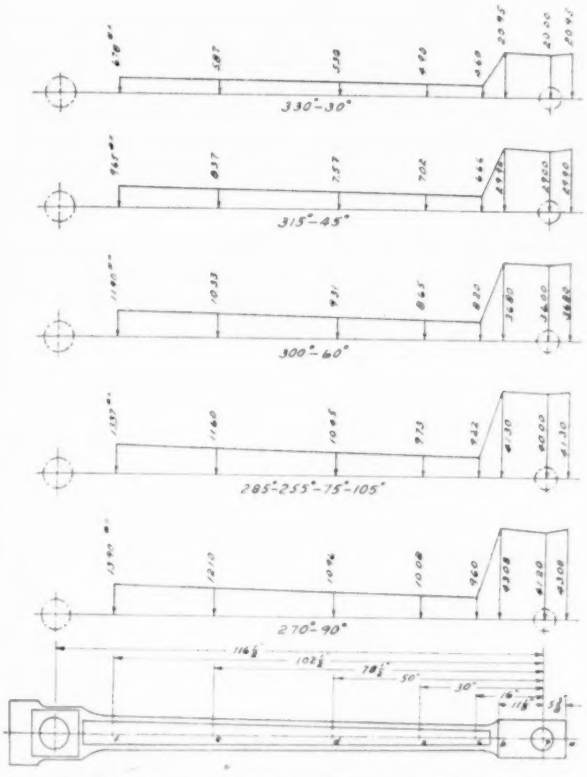

FIG. 11 DIAGRAMS OF INERTIA TORQUE OF 1-IN. SECTIONS

to the slight effect any further accuracy would have upon the results obtained. No determination of the inertia load of the crank-pin end of the rod was made, since this was not needed for finding the bending moments.

Referring to the various illustrations thus far given, and particularly to the diagrams of Fig. 9, it will be seen that the bending moment at any section of the rod will result from the combined effect of the wrist-pin reaction which is transverse to the rod, the action of the distributed transverse load, and the small cumulative effect of the torques of the individual 1-in. sections which are exerted about their individual mass-center axes.

In order to determine the magnitude of the transverse load from the rod end to the point of stress determination, the diagram area was found by planimeter. The center of pressure of the distributed load was found by carefully tracing the diagram upon drawing paper, cutting this out, and balancing over a knife-edge set perpendicular to the axis of the rod. When balance was obtained, the line of balance was accurately and quickly located by smartly striking the balanced paper load over the knife-edge with a weight.

The method of finding the bending moment is illustrated as follows: It will be seen in Fig. 9 for the 255- and 105-deg positions, that the transverse force at the wrist pin is 3264 lb upward. It is desired to find the bending moment at point *f* which is 102.5 in. from the wrist-pin center. The distributed load to this point is composed of a downward load which extends from point *f* almost to the wrist-pin center, and a small double-triangular upward load extending from the end of the downward load to the rod end at point *a*. The downward load amounts to 9380 lb, and its center of pressure is $33^1/_2$ in. to the right of section or point *f*. The small upward load amounts to 160 lb, and its center of pressure is 104.8 in. to the right of section *f*. From Fig. 11 the cumulative angular-inertia torques of the 1-in. sections total to point *f* 1783 lb-in., and these act to augment the moment resulting from the external reaction force of 3264 lb. Then the bending moment at section *f* will be represented by the following equation

$$M_f = 3264 \times 102.5 + 1783 + 160 \times 104.8 - 9380 \times 33.5 = 39{,}133 \text{ lb-in.}$$

After the bending moments at the various sections along the body of the rod for each of the six double-angular positions were found in this manner, the flexural or whip unit fiber stresses were obtained in the usual manner by multiplying each moment by the reciprocal of the corresponding section modulus. These values are plotted as ordinates for the six curves of Fig. 12. The maximum fiber stress and its position in the rod was then noted

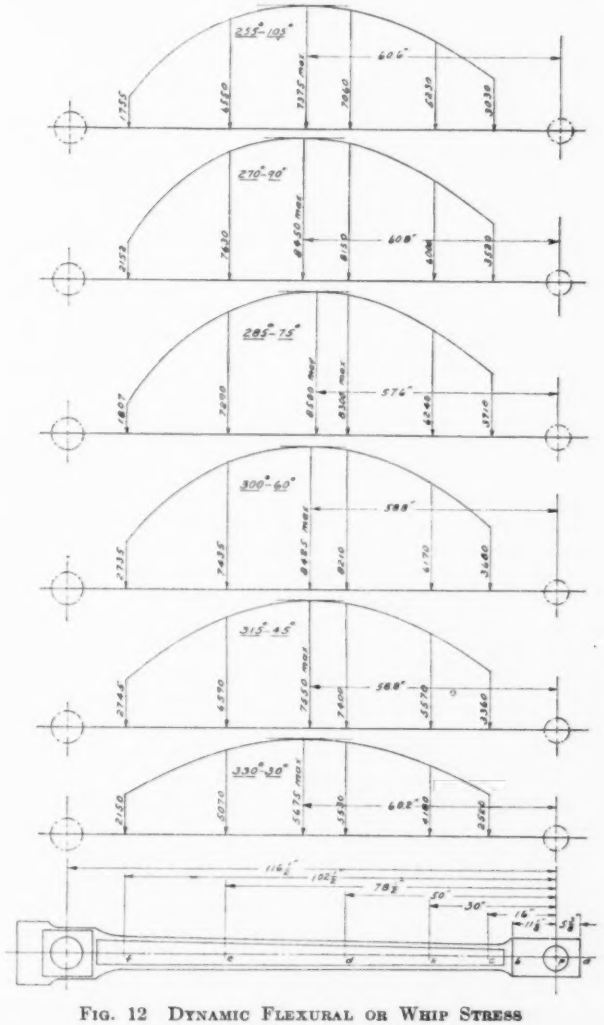

FIG. 12 DYNAMIC FLEXURAL OR WHIP STRESS
(Pounds per square inch.)

for each of the angular positions by carefully drawing tangents to the tops of the curves. These maximum values were then plotted as the ordinates of the curve shown in Fig. 13. The maximum ordinate of Fig. 13 should represent the maximum unit flexural fiber stress developed in the rod and with some accuracy give the precise crank angle of its occurrence.

It will be noted that the maximum flexural stress due to inertia for every angular position is to be found at about 60 in. from the wrist-pin center, that the maximum stress determined is 8500

psi at the 285- and 75-deg positions, and that this is very close to the maximum value as shown by the maximum curve of Fig. 13. Also with the exception of the slight difference due to the weight of the rod which has already been mentioned, it is seen that with the engine running forward the fiber stress on the under side of the rod varies from a maximum compressive flexural unit stress of 8500 psi at the 75-deg position to a maximum

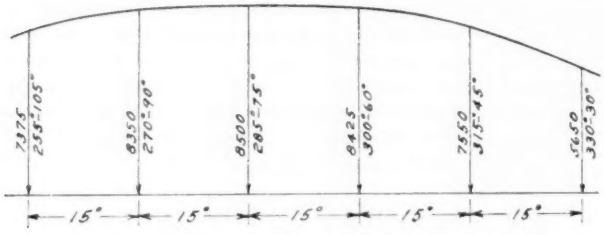

FIG. 13 CURVE OF MAXIMUM UNIT WHIP STRESS
(Pounds per square inch.)

tensile flexural unit stress of like value at the 285-deg position, thus giving a movement of 150 deg as the least space for the reversal.

THE COMBINED TENSILE STRESS

To determine the total tensile stress in the connecting rod, the tensile effect of the inertia of the fraction of the rod on the wrist-pin side of the stressed section, the tensile effect of the inertia of the reciprocating parts, the tensile effect of the steam force, and the tensile component of the normal guide reaction which is due to the inertia of the rod, all must be combined with that due to whip.

A study of these elements seemed to show that the combined stress reaches a maximum within the angular space between 300 and 360 deg. Therefore the rod-fraction axial-inertia diagrams of Fig. 10 for the angular positions 300, 315, 330, and 360 deg were constructed from the axial-inertia-force components of the 1-in. sections previously described. This element of the total force at any section is represented by the diagram area extending to that section. The tensile effect due to the inertia of the reciprocating mass was found by the use of the values of Fig. 5, the tensile effect of the steam force was obtained from Fig. 6, and the tensile effect of the rod-inertia reaction at the guides from the values as illustrated in Fig. 7. The tensile stress due to these forces was then combined with that due to whip for the four angles given, and the unit stresses resulting from the combination are shown by the curves of Fig. 14.

Examination of Fig. 14 shows that the combined stress reaches a maximum of about 13,650 psi at the crank positions of 45 and 315 deg, and at a distance approximately 61 in. from the wrist-pin center. However, for this value to hold for the 315-deg position, the engine would have to be in reverse, since for forward running the steam force would act to place the rod in compression. But though the position of the steam force with respect to the sides of the piston varies with the direction of rotation for any specified angular movement of the crank, thus causing either tension or compression in the connecting rod, the inertia forces do not thus vary. Irrespective of the direction of rotation, the horizontal-inertia effect of the connecting rod and reciprocating masses during the major part of the cylinder-side half of the revolution of the crank is to subject the connecting rod to tensile stress. For during the completion of most of the half of the stroke which ends at the forward dead center these masses are being decelerated, and throughout the first part of the succeeding stroke they are being accelerated. The force for this alternating acceleration and deceleration must be supplied at the crank pin, when not supplied by the fluid pressure.

In Fig. 15, the maximum values of the combined stress for the four angular positions are plotted as ordinates for a curve of maximum combined unit stress. And here again it appears that at about the 45- and 315-deg positions the combined stress is a maximum. Also it should be noted that the combined stress occurs not far from the point in the rod where the whip stress is maximum.

For the 360-deg position the combined stress was determined for the conditions "steam on" and "steam off with no compression" as shown for that position in Fig. 15. The values obtained

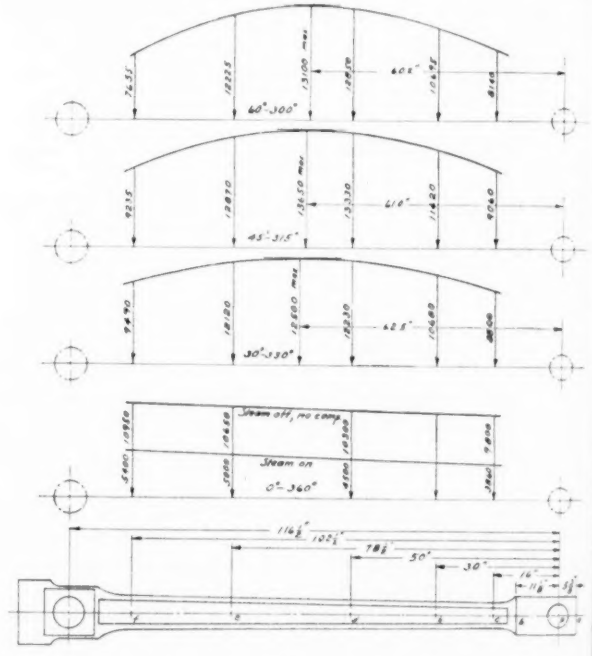

FIG. 14 DIAGRAMS OF COMBINED UNIT TENSILE STRESS

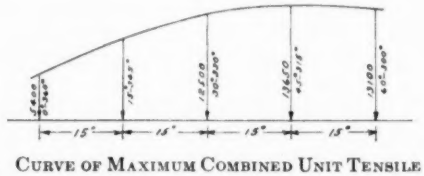

FIG. 15 CURVE OF MAXIMUM COMBINED UNIT TENSILE STRESS

are 5400 psi when operating with steam on, and 10,950 psi with steam off. The latter condition occurs when the locomotive is drifting with cylinder cocks open.

CONCLUSION

The results of the study seem to show that for 100 mph the maximum whip stress that can be expected in a conventional I-section locomotive main rod is of the order of 8500 psi, and that the maximum combined tensile stress will be of the order of 14,000 psi.

As the elastic limit of the usual carbon steel of which these rods are made is about 48,000 psi, the factor of safety with this as base is about 3.5. If $3\frac{1}{2}$ per cent nickel steel of the same carbon content were used for the rod material, the elastic limit would be about 60,000 psi and the factor of safety with this as base would be 4.38.

Appendix

Derivation of the Equations for Forces and Torques Given in the Paper

In addition to the notation given in Fig. 1*b* and the paper the following symbols are used:

Subscripts h and v refer to components in the plane of motion parallel and perpendicular, respectively, to the line of reciprocation

s = displacement of any point n of the connecting-rod axis from its dead-center position, ft

v = linear velocity of any point n, ft

ω = angular velocity of the crank, radians per sec

a = linear acceleration of any point n, ft/sec²

α = angular displacement of connecting rod from dead center, radians

ω_R = angular velocity of connecting rod, radians per sec

ϕ = angular acceleration of connecting rod, radians/sec²

The horizontal displacement of any point n of the connecting-rod axis from its dead-center position is

$$s_h = C + b - C\cos\theta - b\cos\alpha = C + b - (b/R)A - C\cos\theta$$

where $A = (R^2 - C^2\sin^2\theta)^{1/2}$

$$\therefore\ s_h = C + b - C\cos\theta - (b/R)(R^2 - C^2\sin^2\theta)^{1/2} \ldots [6]$$

The horizontal component of the linear velocity of n is

$$v_h = \frac{ds_h}{dt} = C\sin\theta\frac{d\theta}{dt} + \frac{b}{R}\frac{C^2\sin\theta\cos\theta}{(R^2 - C^2\sin^2\theta)^{1/2}}\frac{d\theta}{dt}$$

Since $d\theta/dt = \omega = V/C$ where V is the linear velocity of the crank-pin center

$$v_h = V\left\{\sin\theta + \frac{Cb}{R}\left[\frac{\sin\theta\cos\theta}{(R^2 - C^2\sin^2\theta)^{1/2}}\right]\right\} \ldots\ldots [7]$$

The horizontal component of linear acceleration of n is

$$a_h = \frac{dv_h}{dt} = V\left\{\cos\theta\frac{d\theta}{dt} + \frac{Cb}{R}\left[\frac{(R^2 - C^2\sin^2\theta)^{1/2}(\cos^2\theta - \sin^2\theta)(d\theta/dt)}{R^2 - C^2\sin^2\theta} + \frac{(\sin\theta\cos\theta)(R^2 - C^2\sin^2\theta)^{-1/2}(C^2\sin\theta\cos\theta)(d\theta/dt)}{R^2 - C^2\sin^2\theta}\right]\right\}$$

$$a_h = \frac{V^2}{C}\left\{\cos\theta + \frac{Cb}{R}\left[\frac{\cos^2\theta - \sin^2\theta}{(R^2 - C^2\sin^2\theta)^{1/2}} + \frac{C^2\sin^2\theta\cos^2\theta}{(R^2 - C^2\sin^2\theta)^{3/2}}\right]\right\}$$

Multiplying the expression in braces by C, dividing the term outside by C, and substituting from Fig. 1*b* gives

$$a_h = \frac{V^2}{C^2}\left[B + \frac{b}{R}\left(\frac{B^2 + H^2}{A} + \frac{H^2B^2}{A^3}\right)\right]$$

$$= \frac{V^2}{C^2}\left[B + \frac{b}{R}\left(\frac{B^2(A^2 + H^2) - A^2H^2}{A^3}\right)\right]$$

$$= \frac{V^2}{C^2}\left[B + \frac{b}{R}\left(\frac{R^2B^2}{A^3} - \frac{H^2}{A}\right)\right] \ldots\ldots [8]$$

The horizontal force necessary for the acceleration of a mass at n is

$$F_h = \frac{W}{g}a_h = \frac{WV^2}{gC^2}\left[B + \frac{b}{R}\left(\frac{R^2B^2}{A^3} - \frac{H^2}{A}\right)\right] \ldots\ldots [2]$$

The vertical displacement of any point n is

$$s_v = C\sin\theta - b\sin\alpha$$

$$\sin\alpha = (C/R)\sin\theta$$

$$s_v = C\sin\theta - (bC/R)\sin\theta \ldots\ldots [9]$$

The vertical component of linear velocity of n is

$$v_v = \frac{ds_v}{dt} = \left(1 - \frac{b}{R}\right)C\cos\theta\frac{d\theta}{dt} = \left(1 - \frac{b}{R}\right)V\cos\theta \ldots [10]$$

The vertical component of linear acceleration of n is

$$a_v = \frac{dv_v}{dt} = V\left(1 - \frac{b}{R}\right)\left(-\sin\theta\frac{d\theta}{dt}\right)$$

$$= -\frac{V^2}{C}\left(1 - \frac{b}{R}\right)\sin\theta = -\frac{V^2}{C^2}H\left(1 - \frac{b}{R}\right) \ldots [11]$$

The vertical component of the force necessary for the acceleration of a mass at n is

$$F_v = \frac{W}{g}a_v = -\frac{WV^2}{gC^2}\left[H\left(1 - \frac{b}{R}\right)\right]^* \ldots\ldots [3]$$

The angular velocity of the connecting rod is

$$\omega_R = \frac{d\alpha}{dt} = \frac{d\{\sin^{-1}[(C/R)\sin\theta]\}}{dt}$$

$$= \frac{C}{R}\left[\frac{\cos\theta}{\left\{1 - \left(\frac{C}{R}\sin\theta\right)^2\right\}^{1/2}}\frac{d\theta}{dt}\right]$$

$$\omega_R = \frac{\omega C}{R}\left[\frac{\cos\theta}{\left\{1 - \left(\frac{C}{R}\sin\theta\right)^2\right\}^{1/2}}\right] \ldots [12]$$

The angular acceleration of the connecting rod is

$$\phi = \frac{d\omega_R}{dt} = \frac{\omega C}{R}\left(\frac{\left\{\left[1 - \left(\frac{C}{R}\sin\theta\right)^2\right]^{1/2}(-\sin\theta)\right\}\frac{d\theta}{dt}}{1 - (C^2/R^2)\sin^2\theta} - \frac{+\cos\theta\left[1 - \left(\frac{C}{R}\sin\theta\right)^2\right]^{-1/2}\left(\frac{C^2}{R^2}\sin\theta\cos\theta\right)\frac{d\theta}{dt}}{1 - (C^2/R^2)\sin^2\theta}\right)$$

$$\phi = \frac{\omega^2 C}{R}\left[\frac{-\sin\theta}{\left(1 - \frac{C^2}{R^2}\sin^2\theta\right)^{1/2}} + \frac{C^2(\sin\theta\cos^2\theta)}{R^2\left(1 - \frac{C^2}{R^2}\sin^2\theta\right)^{3/2}}\right]$$

$$= \omega^2\left[\frac{-H}{(R^2 - H^2)^{1/2}} + \frac{B^2H}{(R^2 - H^2)^{3/2}}\right] = \omega^2\left[\frac{H}{A} - \frac{B^2H}{A^3}\right]$$

$$= -\omega^2(A^2H - B^2H)/A^3 = -\omega^2(H/A^3)(A^2 - B^2)$$

$$\phi = -\omega^2(H/A^3)(R^2 - C^2) \ldots\ldots [13]$$

The torque for the angular acceleration of a mass with a moment of inertia I about its axis of rotation is

$$T = I\phi = -I\omega^2(H/A^3)(R^2 - C^2)$$

$$T = -4\pi^2N^2I(H/A^3)(R^2 - C^2)^* \ldots\ldots [5]$$

* The minus sign indicates that the acceleration is in a direction opposite to that chosen for displacement.

Viscosity of Coal-Ash Slags[1]

By P. NICHOLLS,[2] and W. T. REID,[3] PITTSBURGH, PA.

This paper describes a viscometer for measuring the viscosity of coal-ash slag up to temperatures of 2900 F. The investigations disclose that slags in only a relatively small portion of the field of compositions of coal ash have the melting characteristics of glasses and that, for most compositions, there is a distinct liquidus point. From the limited data available for this progress report, plots for viscosity are given for 2800, 2600, 2400, and 2200 F, as well as showing the liquidus lines for each temperature. The relation between "flow temperature," as determined in earlier investigations for use with slag-tap furnaces, and viscosity and liquidus temperature is derived.

When complete trilinear diagrams are available, accurate predictions can be made on the effect of mixing the ash of two coals or of the addition of the main constituents. The authors emphasize that predictions of the relative fusion and clinkering characteristics of coals from the softening temperatures of their ashes may give erroneous comparisons, but that the initial and fluid temperatures can be some additional guide.

Introduction

THIS REPORT is a continuation of those previously presented to the Society on results of investigations on coal-ash slags and their properties. The last three reports were based on work done in cooperation with an A.S.M.E. Special Research Committee on Removal of Ash as Molten Slag From Powdered-Coal Furnaces and, although the committee has been disbanded, this may be considered as a final report for it. The previous reports covered three phases of the general investigations: (1) Studies[4] at one of the first plants using a wet-bottom furnace, the object being to determine the factors involved in this then new method; (2) studies[5] to determine the possibility of adding materials to the slag in a furnace, or to the coal itself, which would flux the slag and permit of its being tapped if it were too refractory to be molten at the temperature of the bed; (3) studies[5,6] to determine the relation between the temperature at which slags would tap with equal ease and their chemical composition under oxidizing and under reducing conditions.

These investigations necessitated some method of measuring the fluidity of the slags and, in particular, of determining the temperatures at which they could be tapped with a relatively similar degree of ease. The straightforward procedure would have been to adopt some method for determining absolute viscosities against temperature. However, at that time no method was developed to study slag associated with other processes, such as steelmaking or glassmaking, that could be used safely for coal ashes with assurance of its suitability, nor were existing methods appropriate for control of the atmosphere from oxidizing to reducing. Thus, it appeared that the development of some new or modified method would be necessary if absolute viscosities were to be determined. It was predictable that such a development would require a long time and the output of determinations would be slow. Therefore, it was not allowable to follow this procedure, because some general information on the properties of slags as related to slag-tap furnaces was required in the shortest possible time.

The solution adopted was to obtain relative measures of the fluidity of the slags by a method of "feel;" the slag being melted in a crucible and using a platinum rod. Three degrees of melting were standardized and indicated by the temperatures at which they occur:

1 The sticky temperature, which is the lowest at which slag on the end of the rod will stick to the slag in the crucible.

2 The penetration temperature, which is the lowest temperature at which the rod will penetrate the slag with a pressure of approximately 6 oz.

3 The flow temperature, which is that at which the rod can be moved through the molten slag and give indications of the same degree of fluidity.

Although such measurements would not be expected to be exact to a high degree, experience showed that different observers could duplicate each other; great exactness not being necessary, because the composition of the slag that occurs at any one station from day to day and the temperature conditions are not accurately predictable.

By this method, the entire field of compositions of coal ashes was covered and the data for relationship of flow temperature to composition were shown in previous studies[7] for melts in an atmosphere of air and[8] for melts under furnace conditions.

Although these results sufficed for immediate requirements, it was realized that the data had only limited application and that a knowledge of the absolute viscosities of coal-ash slags was required. For many years much has been imagined and written as to the meaning of standard cone-fusion temperatures, but the only way to settle the matter is by knowing the viscosities. The same applies to clinkering and to slagging of surfaces. Also, the flow temperature only indicates the temperature required for a certain ease of tapping and of itself does not show the change in fluidity of the slag above and below the flow temperature.

It was therefore decided to extend the investigation to the determination of viscosities of slags as related to their chemical compositions. The difficulties and time required were understood, but the experience and the knowledge of the behavior of the slags, acquired in the earlier work, would be of great help. Preliminary studies of methods were begun in October, 1937, but the development and construction of the furnace and viscometer were not completed until May, 1938.

[8] Reference (6), Figs. 2 and 3.

The preparation for and completion of a test requires a minimum of 2 days, so relatively few have been made to date, as compared with those required to cover the five main constituents of coal ash. However, the tests have been spread over the field and throw enough light on relationship, upon which knowledge is required, to justify a progress report.

The main object of this paper is to suggest and discuss general conclusions. Many more tests will be required to obtain a complete set of numerical values of viscosity against chemical composition.

Choice of Method

The type of viscometer and design of furnace to be used were considered carefully and some experiments were made. The requirements were (1) that the maximum temperature at which the slag could be held should be not less than 2900 F; (2) that it should be possible to control the atmosphere to which the slag is exposed; (3) that the quantity of slag required for a test should not be excessive, because of the time required to prepare it and to melt it in the crucible; (4) crucibles of suitable size and cost. Coal-ash slags high in fluxes are very corrosive. They destroy and are contaminated by ceramic crucibles, which can be used with safety with other slags; also, when the iron is highly reduced or metallic iron is present, they are destructive to platinum. Consequently, the size of crucibles necessary and their cost were important factors.

An argument on methods and a discussion of the literature on viscosity measurement are not included; most work on viscosity at high temperatures has related to glasses and is well summarized by Morey.[9] The method adopted was that of the oscillating bob. Its principle is that a bob suspended in the slag by a torsion wire is made to oscillate and the damping of this oscillation by the slag is measured. Viscosity is a function of damping, of the dimensions of the bob and the containing vessel, of the inertia of the rotating system, and of the torsion of the suspension. This method was adopted because it could cover a large range of viscosities from 1 to 10^6 poises and would allow the furnace to be sealed at the bottom, which is necessary for the control of the atmosphere. It has the disadvantage that the friction factor, as dependent upon the shape of the bob, cannot be computed accurately enough and, therefore, must be determined by calibration with liquids of known viscosity.

Recent researchers who have used the oscillating-bob method are Dantuma[10] and Endell[11,12] and his co-workers. Dantuma did not require a temperature higher than 1000 F and he developed very exact methods, including a photographic record of the oscillations. Acknowledgment is made of the suggestions obtained from these publications.

A description of the apparatus as constructed, its calibration, and some troubles encountered are given as an Appendix. Accurate determinations of viscosity over the entire range are made possible by (*a*) the use of two suspensions, one above the other, so that the change from one to a combination of both can be made by a clamping arrangement; (*b*) by two additive weights, whereby the moment of inertia of the system can be controlled; and (*c*) by changing from damped harmonic motion to damped aperiodic motion for viscosities higher than 100 poises.

Results of Tests

Values for viscosity will be given in the absolute measure of cgs units, or poises. Some idea of the fluidities corresponding to a range of values in poises is shown by:

Water at 68 F	0.01 poise
S.A.E. 10 motor oil at 68 F	1.00 poise
Castor oil at 68 F	10.00 poises

There is no commonly used liquid having a viscosity of 100 poises at normal temperature.

Most of the data will be shown as plots of viscosity against temperature and, because the range of values of viscosities is so large, the scale of log viscosity will be used.

Most of the tests to date have been of melts in air, but enough have been under reducing conditions to show the effect of reduction of the iron oxides. The term "ferric percentage" was introduced in the previous reports as a numerical value to express the state of oxidation of the iron in the slags; it is the ratio of the ferric iron to the total iron expressed as a percentage, and is given by

$$\text{Ferric percentage} = \frac{Fe_2O_3}{Fe_2O_3 + 1.11\,FeO + 1.43\,Fe} \times 100$$

Melting of Typical Coal-Ash Slags

All these tests are concerned with the melting and properties of slags, as distinct from the first melting of the heterogeneous mixture of materials of which a coal ash is composed. Therefore, in all tests, the first procedure is to obtain a complete melting of the charge before any readings are taken. Thus, all readings begin at what is usually the highest temperature that will be used.

A short discussion at this point of the melting of slags will facilitate understanding the data for those who are not familiar with the subject. Slags in general are of two types: (1) Those that, as they are cooled slowly, maintain their glassy, uniform state and do not form any crystalline particles, and (2) those in which crystals of some definite composition begin to form at some temperature during cooling. The temperature at which crystals begin to form is called the liquidus temperature. This temperature has a definite value if cooling is slow enough, but it may require maintenance at each temperature for many hours to obtain a definite value, because the initial formation of crystals may be slow. However, as the temperature is lowered below the true liquidus value, the speed of crystallization increases. Similarly, it requires time for the crystals to redissolve in the slag, if the temperature is raised only slightly above that of the liquidus; solution is more rapid as the increase in temperature above that of the liquidus becomes greater. This action is simple when a melt has only two components but is complex when there are many, as in a coal-ash slag; one kind of crystal may begin to form at one temperature and, at lower temperatures, other types of crystals may appear. The term "solid phase" is more general in its meaning than is crystals.

If no solid phase exists, the melt will be a true fluid and will give true values for viscosity. If solid particles are present, they will increase the internal friction materially and the substance will not act as a true fluid. Its properties will tend to be more those of a plastic substance as the quantity of solid phase increases. It requires time for solid phase to form, and it may take longer for it to redissolve. For example, in a high-alumina slag, crystals of corundum were formed that did not redissolve. Thus, measures of "apparent viscosity," obtained at a temperature below the liquidus, will vary with time; this variation being greater if the crystals tend to interlock or to fuse together.

Fig. 1 shows the test data of a typical slag having a silica-to-flux ratio of 1.36, and a total flux content (iron oxides, lime, and magnesia) of 32.3 per cent. The slag was melted and the first measurement of viscosity was 2765 F, the value being 10 poises. The slag was then cooled in steps by setting the temperature controller to the lower temperature required; sufficient time, usually 15 min, being allowed to elapse to insure constancy before the viscosity determination is made. The points are plotted as the test proceeds and the round dots are those of this cooling cycle. When the temperature of 2225 F of point *A* was reached, it was found that, if the slag was maintained at that temperature, the viscosity increased with time. The actual procedure now used to determine point *A* more exactly is that, after cooling 100 deg, for example, and determining the viscosity, the slag is then heated 50 deg and another determination made. If the liquidus range had been reached, this last viscosity would lie above the plot of the values previously determined.

The slag was kept at the temperature of point *A*, gradually becoming more viscous. After 40 min, the bob was immovable. The temperature was then increased to 2280 F, but the bob still remained immovable. At 2310 F an apparent viscosity of 350 poises was obtained and, at 2325 F, the viscosity was nearly down

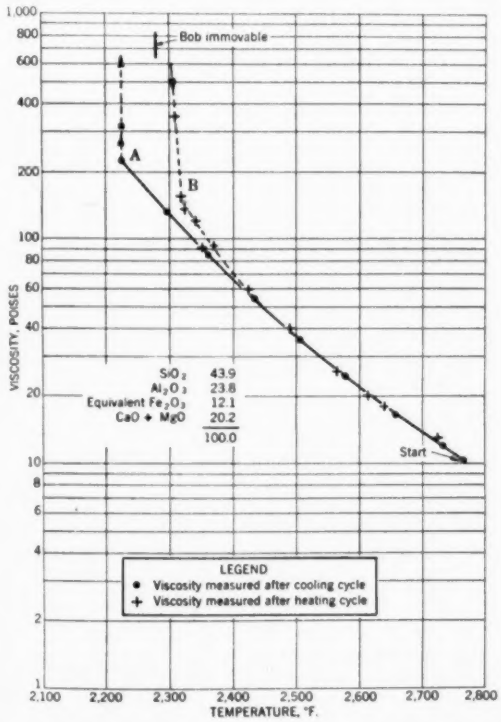

Fig. 1 Viscosity-Temperature Plot of a Typical Slag Having an Indefinite Liquidus Temperature

to that of the cooling curve. If enough time had been allowed, it would probably have given the value of the curve.

In this test the liquidus region was in evidence in a range *A* to *B*, or 100 deg; there is some question as to what temperature should be designated as the liquidus. That of point *A* is too high, because the viscosity changed from that of *A* to the point above it in 5 min; it is probable that the slag was supercooled and that the movement of the bob started crystallization. In many tests a retrial is made to determine a new temperature for point *A* by reheating the slag; the reheating must be thorough to insure that all the crystals are recombined in the slag, or they will act as "seeding" and raise the temperature of the liquidus.

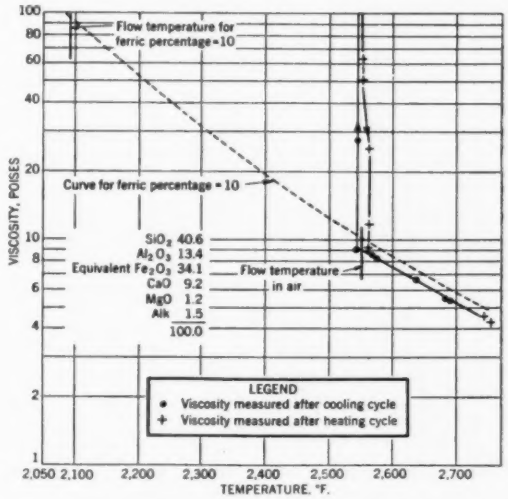

Fig. 2 Viscosity-Temperature Plot of a Typical Slag Having a Definite Liquidus Temperature

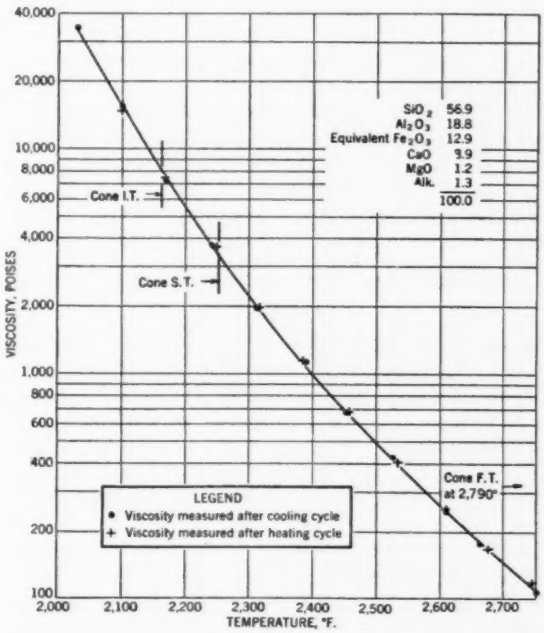

Fig. 3 Viscosity-Temperature Plot of a Typical Glassy Coal-Ash Slag

In this type of test there must be some question as to the true value of the liquidus temperature. For this slag it was recorded as 2300 F.

The solid lines of Fig. 2 show the test data of a melt in air of a slag having a silica-to-flux ratio of 0.91, 34.1 per cent equivalent ferric oxide and 10.4 per cent lime plus magnesia. This represents a slag from the Illinois field and is an example of a narrow liquidus range; that is, a sharp melting point. The liquidus temperature was 2550 F, and its viscosity just above the liquidus temperature was 9 poises, as compared with 100 poises of the slag of Fig. 1.

Fig. 3 is a melt in air of a glassy slag having a silica-to-flux ratio of 2.47; equivalent ferric oxide, 12.9 per cent; and lime plus magnesia, 10.1 per cent. Its viscosities are higher than the previous slags, being about 100 poises at 2760 F and 40,000 at 2020 F.

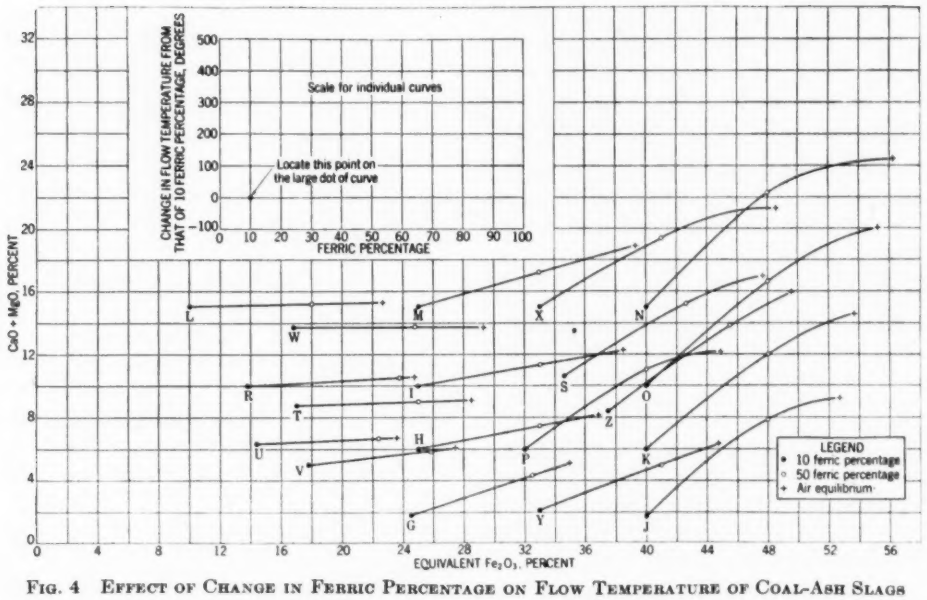

FIG. 4 EFFECT OF CHANGE IN FERRIC PERCENTAGE ON FLOW TEMPERATURE OF COAL-ASH SLAGS

The agreement of the points of the cooling and heating cycles shows the absence of solid phase. Having reached 40,000 poises at 2020 F, no solid phase would be expected to form at lower temperatures, but such a statement is limited to the conditions of this test with the relatively rapid cooling, because there might be crystallization if the cooling were slow enough. However, such a possibility has no importance because the cooling of slags and clinker in practice is always relatively rapid.

EFFECT OF FERRIC PERCENTAGE ON VISCOSITY AND LIQUIDUS TEMPERATURE

Although most of the tests were made in air, with a resulting high ferric percentage, enough were made in nitrogen, using previously reduced slags, to show the effect of a low ferric percentage (that is, high percentage of ferrous iron) on the viscosity and the liquidus temperature. The object of using the neutral atmosphere of nitrogen is to prevent a slag that already has been reduced to a low ferric percentage from being oxidized during the test.

The effect of ferric percentage on the flow temperature was determined in the earlier investigations. Further tests were made after the last report, and Fig. 4 includes all results; the relationships it shows are important.

The heavy dots give the compositions of the slags tested. The curve beginning at a heavy dot gives the change in flow temperature with increase of ferric percentage. The coordinates and scales for these curves are shown in the inset; a tracing can be made of this inset and it can be placed over a curve so that the heavy dots coincide, but this is not necessary.

The ferric percentage for melts in air are shown by crosses and, because no melts were made in oxygen, they are the highest ferric percentages obtained.

Fig. 4 shows that changes in the flow temperature are dependent upon the iron content and that changes in the lime content have little effect. Up to 12 per cent equivalent Fe_2O_3, the ferric percentage has little effect on the flow temperature. With higher ferric percentages, the flow temperature increases with increase in ferric percentage. The order of these increases for about 10 per cent lime are:

Equivalent Fe_2O_3, per cent	15	25	35	40
Increase of flow temperature from 10 ferric percentage to that of air, F	20	100	300	500

Fig. 5 shows the viscosity and liquidus temperatures in air and in nitrogen of a low-iron slag with 13.3 per cent equivalent Fe_2O_3; the ferric percentage in air was 32 and in nitrogen 18. The curve for the melt in nitrogen lies above the other, but parallel to it. From the test data, as shown on the plot, the liquidus temperature for the melt in air is 30 deg lower than that for the melt in nitrogen. The percentage difference in viscosity between the two curves is greater than in other tests.

Fig. 6 shows the data for a slag having a medium iron content of 19.8 per cent equivalent Fe_2O_3. The figure is rather crowded because it shows three tests. The test for the melt in air is shown by the short curve; the ferric percentage was 56. The liquidus range of *A* is not wide and the liquidus temperature is about 2530 F.

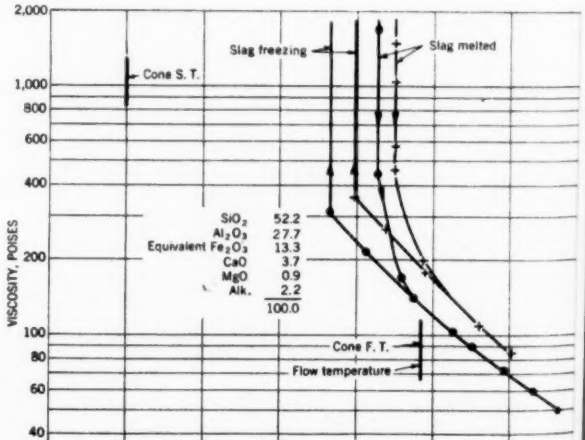

FIG. 5 EFFECT OF CHANGE IN FERRIC PERCENTAGE ON VISCOSITY AND LIQUIDUS TEMPERATURE OF A SLAG HAVING A LOW EQUIVALENT Fe_2O_3 CONTENT

There were two tests in nitrogen and the test points of both fall on the upper curve. With one the slag had a ferric percentage of 30; the test points are shown by circles. The liquidus range is short and the liquidus temperature is about 2410 F, a decrease of 120 deg from that of air.

In the second test in nitrogen the ferric percentage was 13. The test points are shown by crosses and range the full length of the curve. The liquidus range is not shown in the same manner as for the other tests; in this test the solid phase did not begin to separate until the viscosity was over 1000 poises, probably at 1600 poises, at a temperature of 2150 F. The time required for

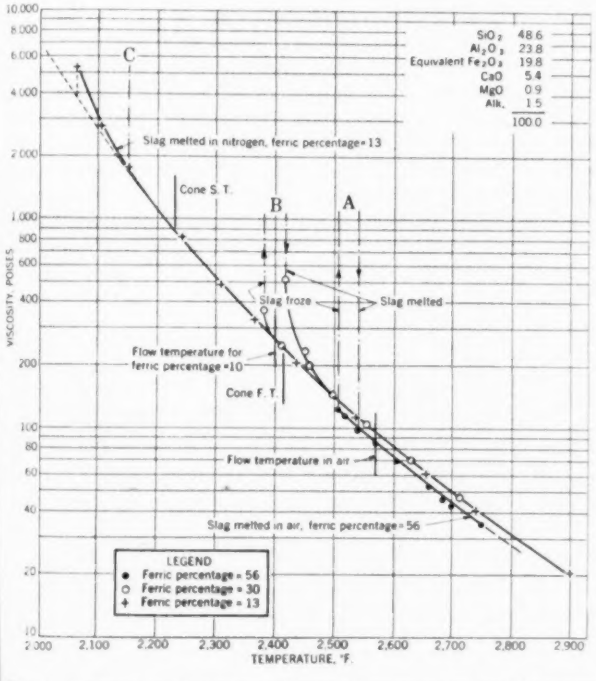

FIG. 6 EFFECT OF CHANGE IN FERRIC PERCENTAGE ON VISCOSITY AND LIQUIDUS TEMPERATURE OF A COAL-ASH SLAG HAVING MEDIUM EQUIVALENT Fe_2O_3 CONTENT

crystals to form will be greater as the slag is more viscous, and the weight of crystals formed in a given time will be less than if the slag is more fluid. Therefore, there was not the abrupt increase in viscosity that occurred in the other tests at *A* and *B*.

Fig. 6 also illustrates the effects of decrease in the ferric percentage. The viscosity is changed only a little, and the shape of the viscosity curve for the reduced slag is similar to that for the oxidized. As the ferric percentage was decreased from 56 in air, the liquidus region was moved to a lower temperature—to *B* for a ferric percentage of 30 and to *C* for a ferric percentage of 13.

The positions of flow temperature in air and for 10 ferric percentage are shown but will be discussed later.

From Figs. 5 and 6 and from other tests, the effects of lowering the ferric percentage from that of air are shown to be relatively simple and are summarized as follows:

1 The shape of the viscosity curve is not changed by a decrease in ferric percentage, but the entire curve is raised about 20 per cent (on the viscosity basis) above that for the melt in air.

2 The main effect of lowering the ferric percentage is that it decreases the liquidus temperature.

3 There is little change in the liquidus temperature with change in ferric percentage for slags having an equivalent Fe_2O_3 content of 12 per cent and lower. As the iron content increases, the change in the liquidus also increases, but the exact amounts have not yet been determined for the entire range of coal ashes.

At this time no tests in nitrogen have been made of high-iron slags because of difficulty in obtaining a crucible that will withstand their erosion, but the nature of the results can be predicted closely. This has been done in Fig. 2 for a slag with 34 per cent equivalent Fe_2O_3. The predicted form for a slag having a ferric percentage of 10 is shown by dotted lines. With this slag, the flow temperature in air is 2550 F, and for 10 ferric percentage it is 2090 F. The dotted curve has a viscosity of 90 poises at 2090 F; from Fig. 4 it can be deduced that the liquidus temperature of this slag would be about 2050 F.

GENERAL RELATIONSHIP OF VISCOSITY TO CHEMICAL COMPOSITION

The major components of coal-ash slags that may affect the viscosity are silica, alumina, iron oxide and its ferric percentage, lime, and magnesia. The effect of ferric percentage is now known. Previous reports have shown that lime and magnesia can be taken as one factor for the flow temperature when the percentage of magnesia is small, which it generally is.

Plots were made to determine whether there were other relationships by which the number of factors could be reduced further. They showed for slags entirely in the liquid phase (*a*) that if (equivalent Fe_2O_3 + CaO + MgO) were taken as one factor, the plots were little affected by the ratio of Fe_2O_3 to (CaO + MgO), but only by their sum; (*b*) that if the alumina were eliminated and the composition reduced to SiO_2 + equivalent Fe_2O_3 + (CaO + MgO) = 100, the plots were closely independent of the ratio of silica to alumina within the limits of 1.5 to 3.

Fig. 7 shows that these assumptions are justified as a first approximation. It is a plot for 2600 F of log viscosity against silica when the composition is expressed in the form just given, which omits the alumina from the plot. A few points are marked

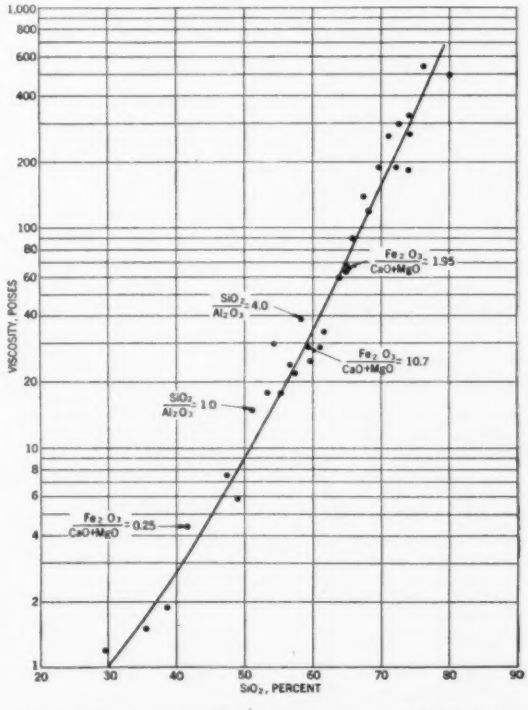

FIG. 7 VISCOSITY OF COAL-ASH SLAGS AT 2600 F IN AIR
(Plotted against SiO_2 content on the basis of omitting Al_2O_3 and making SiO_2 + equiv Fe_2O_3 + CaO + MgO = 100.)

to show that the plot includes points having a silica-alumina ratio of 1 and 4, and iron-lime ratios of 0.25 to 10.7, and yet the points are within a relatively narrow band. The plot shows that log viscosity tends to be proportional to the silica percentage when the alumina is eliminated from the method of plotting, although it is present in the slag.

The reasons for the departure of some of the points from the mean curve have not been determined; no investigation has been made as yet on the separate effects on viscosity of magnesia or the alkalies. However, the points conform nearly enough to a common line to justify making plots on the silica-iron-lime-plus-magnesia basis, because then the first order of relationship of viscosity to composition can be shown by a few diagrams, whereas many would be required if another variable were included.

Fig. 8 shows trilinear plots of viscosity against composition on the basis that SiO_2 + equivalent Fe_2O_3 + (CaO + MgO) = 100. There are four diagrams for temperatures of 2800, 2600, 2400, and 2200 F; the areas for 0 to 20 per cent silica are omitted. The diagram for 2800 F shows an area within the dotted lines that can be taken as the field of composition of normal coal-ash slags, although some may be found to fall outside this area.

Each plot shows the lines of equal viscosity for the range of compositions that are liquids without solid phase at the specified temperature.

Plottings showed that the liquidus temperature is not independent either of the silica-alumina or the iron-oxide-lime-plus-magnesia ratios; consequently, a separate set of trilinear diagrams is required for each of several narrow ranges of silica-alumina ratios. A large number of tests will be required to obtain sufficient data. From the limited number of tests already made, the liquidus values for a silica-alumina ratio of 2.0 to 2.3 were determined, and lines *A-B* follow the compositions of such slags, the liquidus temperature of which melted in air is that of the diagram, 2600 F, for example.

Lines *A-C* are for slags of 10 ferric percentage and are deduced from other data, but if the plots are to represent such reduced slags the isoviscosity lines should be extended to *A-C*.

No liquidus line is shown in the 2800-deg plot because the liquidus temperature of all slags tested was below 2800 F, although it is probable that there would be a separation of solid phase for compositions very high in silica or lime.

As the temperature decreases, the area inclosed by the liquidus lines decreases; that is, the slags that will be liquid at that temperature are reduced to a smaller range of compositions.

There is no claim that these diagrams have a high order of accuracy, especially for the position of the liquidus lines for the 10 ferric percentage. The effects of the minor chemical constituents are not known, nor have there been enough tests of the main constituents. On the other hand, it is safe to use the plots for general information to determine whether a slag of a stated composition will be liquid at one of the temperatures and what will be its approximate viscosity. The procedure is first to eliminate the alumina, thus:

Composition of slag per cent				
SiO_2	47	47 + 0.77	=	61.0
Al_2O_3	23	...		...
Equiv Fe_2O_3	25	25	=	31.5
CaO + MgO	5	5	=	7.5
		77		100.0

The point on the 2400-F diagram that corresponds to the com-

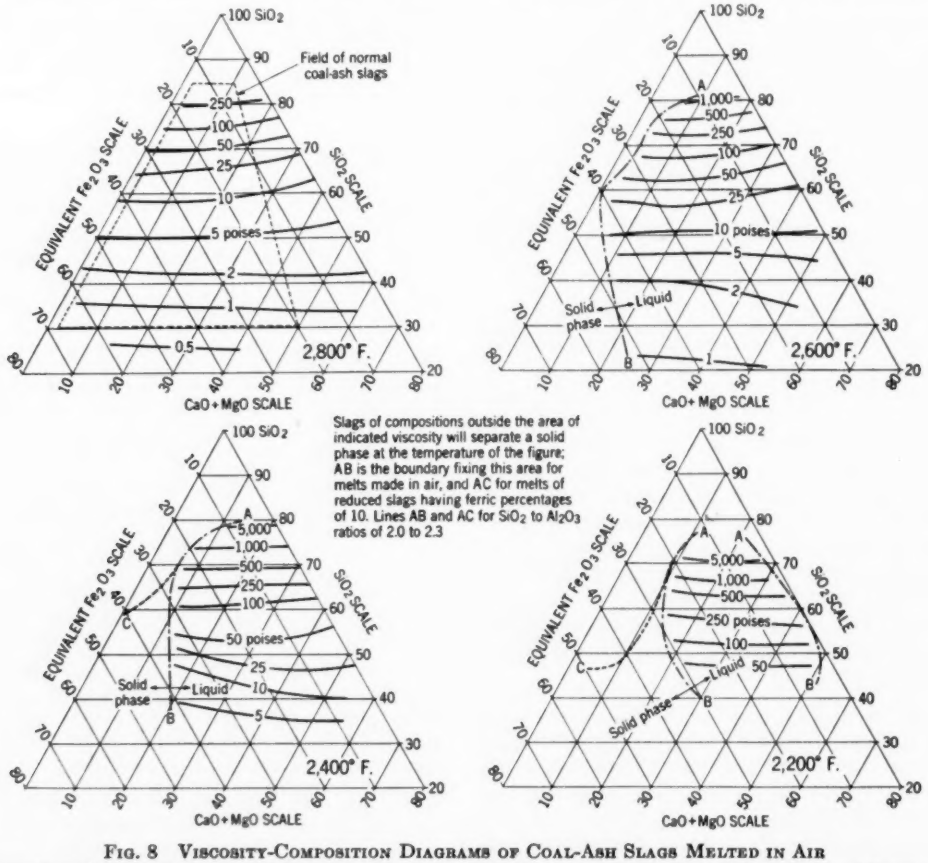

FIG. 8 VISCOSITY-COMPOSITION DIAGRAMS OF COAL-ASH SLAGS MELTED IN AIR

(Plots give the composition of the slags with the Al_2O_3 omitted and on the basis of SiO_2 + equiv Fe_2O_3 + CaO + MgO = 100 per cent; tests indicate that the viscosity of slags is approximately independent of the Al_2O_3 content for SiO_2-Al_2O_3 ratios of 1.5 to 3.0; alkalies not more than 2.5 per cent of original slag.)

position of the last column in the foregoing table is at the intersection of the 100-poise line with the line *A-B*. A slag will tap easily at 100 poises, but if this slag had a high ferric percentage, corresponding to the melt in air, it would give trouble in tapping because it is on the liquidus line. However, slags from furnaces have a low ferric percentage, and because the point is not near the line *A-C*, this slag would tap at 2400 F.

Mean-Viscosity Curve

The plot of Fig. 9 has been made by superimposing the individual curves of a number of tests. The principle used was that each curve must keep its correct position on the viscosity scale but can be moved parallel to the temperature scale, so that separate curves make the best matching. The arrowed lines distinguish the different curves by test number. The temperature scale represents temperature differences and not actual temperatures. Assuming that a mean curve were drawn, then tangents to that curve would be rate of change of log viscosity with temperature. The values for the slopes are the chief interest of this plot and the deductions from them are:

(*a*) The rate of change of viscosity with temperature of coal-ash slags depends mainly upon the viscosity and not upon the temperature.

(*b*) The rate of change of viscosity increases with increase in viscosity.

The object of including this figure is that it fixes a mental picture of relationships. Expressed numerically, the increase of the rate of change of viscosity with increase in viscosity is very large, as is shown by the following approximate values:

at	1 poise,	rate of change of viscosity per 100 F =	0.28 poise
at	10 poises,	rate of change of viscosity per 100 F =	4 poises
at	100 poises,	rate of change of viscosity per 100 F =	58 poises
at	1000 poises,	rate of change of viscosity per 100 F =	850 poises

Relation of Flow Temperature to Viscosity

Some of the slags used for viscosity determinations were identical with those used in the earlier investigation and, for those slags, the flow temperature is shown on the diagrams. Data on other slags were as follows:

Flow temperature, F	Viscosity at flow temperature, poises	Liquidus temperature, F
2550	9	2550
2350	16	2300
2580	20	2550
2685	78	2280
2730	80	2700
2390	80	2150
2570	85	2500
2560	90	2200
2500	120	2400
+2730	(100)	2760

The deductions on the relation of the flow temperature, determined by the feel method, to viscosity and the liquidus limitations are:

(*a*) Normally the flow temperature corresponds to a viscosity of about 80 poises (see values for air in Fig. 6).

(*b*) The flow temperature cannot be less than the liquidus temperature. Thus, if the viscosity at the liquidus is less than 80 poises, the viscosity at the flow temperature will also be below 80 poises. In Fig. 2, the viscosity at the flow temperature for melts in air was 9 poises. The observer could get very close values for flow temperature in a slag like this, because the melting range of slags high in iron is very short and the slag changes from plastic to liquid in the range of a few degrees.

(*c*) If the slag acted like a glass and had no liquidus point, or if the liquidus occurred at a viscosity much above 80 poises, the reaction of the observer was to decide on a value for the flow temperature when the slag had a viscosity greater than 80 poises.

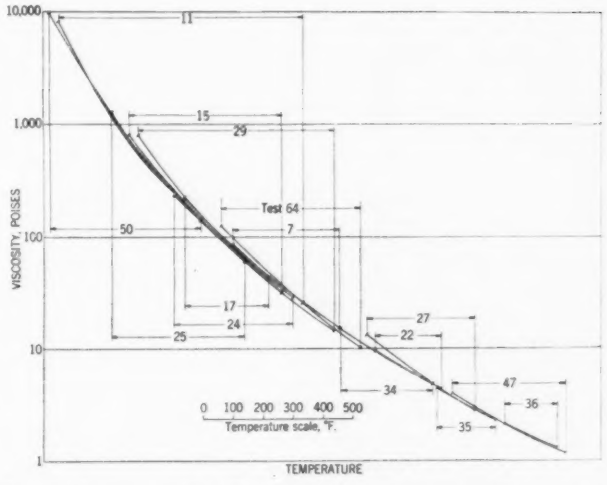

Fig. 9 Curves of Log-Viscosity Superimposed by Shifting of the Temperature Scale

The flow temperature for a ferric percentage of 10 in Fig. 6 is an illustration.

In the investigation on flow temperatures, the aim was to fix its values so that different slags would tap with the same relative ease. This aim was fulfilled, even though the viscosities at the flow temperature are not all alike. Types of slags covered by item (*b*) will flow faster because of their low viscosities; to offset this advantage, they will solidify with a small decrease in temperature and thus form "pipes" of slag, which clog the holes and decrease the flow. Slags covered by item (*c*) will flow more slowly because of higher viscosity but will be less hampered by rapid solidification and the clogging of the hole.

Ash-Cone Temperatures and Viscosity

In the A.S.T.M. cone test for the fusibility of coal ash, the measure of the fusibility of the finely pulverized ash is the temperature at which the cone deforms to specified shapes when the temperature is raised at a specified rate, these shapes being approximately spherical for the softening temperature and spreading to a flat layer for the fluid temperature. The factors that fix the shape the cone will take are:

1 The time-temperature history which, by specification, is that the rate of rise of temperature be a definite and constant value.

2 The states of fluidity of the ash, which are the properties that the cone temperatures are intended to measure.

3 Density of the slag, which will be approximately the same for all slags.

4 The surface tension of the slag. There are no published data on coal-ash slag. The surface tensions of molten glasses[13] range from 250 to 350 dynes per cm at 2200 F; they decrease slowly with increase in temperature. For comparison, at 68 F and against air, the surface tension of water is 72.7 and mercury 465 dynes per cm.

5 As applying more to the fluid temperature, the absorption of the slag by or its reaction with the base. These can be important factors.

The shaping of the cone at different temperatures is a complex function of these factors. The procedure of recording the height of the cone is more definite than is shaping, as is also the Bunte-Baum method[14] used for obtaining a graphical record of height

[13] Reference (9), chapter 7 (footnote 7).

[14] "The Significance of the Inorganic Constituents of Coal on Combustion," by K. Baum, *Glückauf*, vol. 64, 1928, pp. 1733–1741.

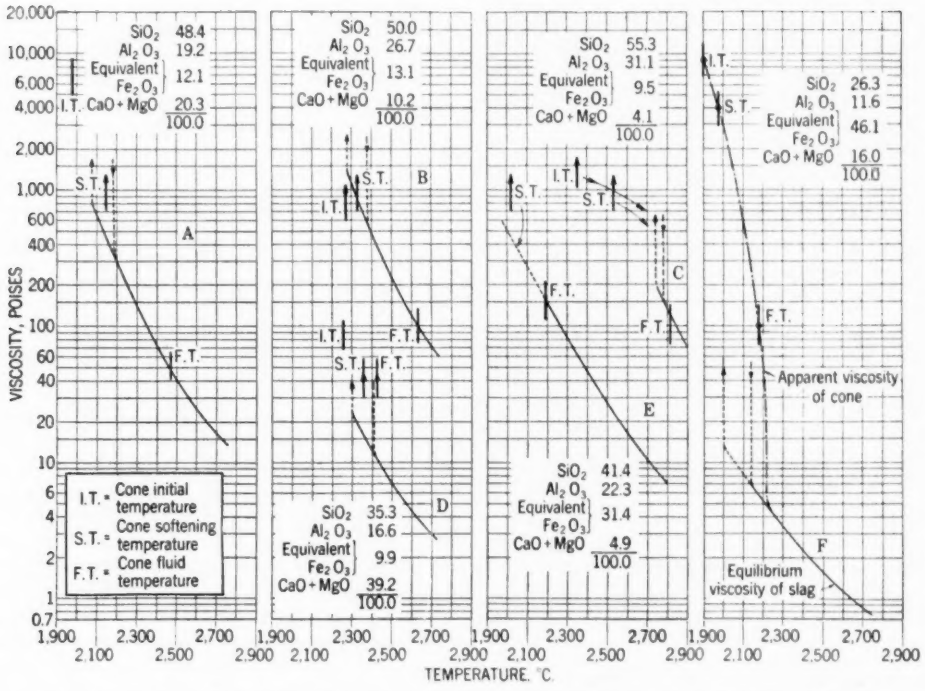

FIG. 10 COMPARISON OF CONE-FUSION TEMPERATURES WITH VISCOSITY-TEMPERATURE CURVES OF SIX COAL-ASH SLAGS

against temperature of a cylinder of ash of 1 in. diam and height.

There are two types of slags:

1 That in which the particles of the original cone are homogeneous and melt to form a true liquid without solid phase. For viscosities below that of the annealing range ($+10^{12}$ poises), there is no measurable time delay for the viscosity of a glass to change to its correct value for a new temperature. With such a true liquid, if held long enough at one temperature, the molten slag would take a final shape fixed only by the factors other than the viscosity; that is, independent of it. The time required to reach the equilibrium shape at a constant temperature will decrease as the viscosity decreases.

2 The type of ash in which some of the particles of the original cone melt to a true glass and others remain solid or fuse to a lesser degree; that is, the slag is not a true liquid. With such a slag, the solid present will affect the shape, and time has the additional importance that the solution of the solid increases with time.

It is not suggested that the shape of the cone against time could be predicted even if numerical values for the factors listed were known, but the principles of what the cone temperatures measure should be recognized when an attempt is made to interpret their meaning.

All standard cone tests are made under reducing conditions and the slag will have a low ferric percentage; therefore, the viscosity tests with which they are compared must also be for slags with low ferric percentage. Only a few such tests are available.

Fig. 3 is for a test in air but, as the slag melted as a true glass and showed no liquidus region down to 2000 F, it can be used for comparison, because the curve of a melt for a low ferric percentage would be parallel to it and about 20 per cent above, and also would have no liquidus. From this figure the cone-fusion temperatures and their viscosities at their intersections with the low ferric percentage curve are:

Initial temperature,	2160 F, 9000 poises
Softening temperature,	2250 F, 4000 poises
Fluid temperature,	2790 F, 100 poises

Because the slag had been premelted and was a glass, all the particles of the cone would be of the same composition; therefore, the first deformation, recorded as the initial temperature, would be due to an equal degree of melting of each particle of the whole cone, which is not so when an unmelted coal ash is tested.

The three viscosities listed for this glassy slag are a reference of comparison for other slags. The range of compositions will be very small for coal ashes, the slags of which are not true glass and yet, at the liquidus temperature, have a viscosity greater than 4000 poises, that is, for most slags the softening temperature is fixed by the liquidus temperature.

Fig. 10 gives the viscosity plots for six slags of widely different compositions and shows their cone-fusion temperatures. The plots illustrate the statement just made that the softening temperature is usually lower than the liquidus temperature, as judged from the heating cycle. The plots show that the softening temperatures are close to the liquidus temperature, as fixed by the line for the heating cycle, except for *F* and *C*, for which they are considerably below. The relationships shown by *C* are confirmed by another refractory slag (Fig. 5); these low-flux premelted slags have glassy characteristics but are not true glasses because an extension of curve *C* to higher viscosities would not pass near 4000 poises at the softening temperature. Slag *F* evidently has a wide liquidus range.

If the liquidus occurs at a viscosity of 500 or more poises, it would be expected that all the solid phase in the cone will have been absorbed by the time the viscosity is 100. Thus, the slag of the cone will act as a true liquid and the fluid temperature will be observed as at about 100 poises, unless reaction with the base affects the flattening of the slag. The viscosity at the fluid temperature of slag *B* was exactly 100 poises, and of *C* and *E* about that much. That of *A* is low, possibly because the slag did not wet the base as well; special tests and technique would be required to prove such explanations, because the base must be quenched at once or deformation will continue.

For slags for which the liquidus occurs at less than 100 poises, the fluid temperature will occur at a temperature a little higher than the liquidus temperature; slags *D* and *F* are examples. On

the plot of F, a dotted curve has been added to show what may be the apparent viscosity of the cone as its temperature increases.

The viscosity plot could be approximated if the liquidus temperature and the viscosity at one temperature were known. Table 1 lists values taken from the plots arranged in the order of the viscosities at 2600 F.

TABLE 1 COMPARISON OF VISCOSITIES WITH CONE-FUSION TEMPERATURES

Slag of Fig. 10	Viscosity at 2600 F, poises	Liquidus temperature F	Liquidus temperature Order	Cone-fusion temperatures Initial, F	Cone-fusion temperatures Softening F	Cone-fusion temperatures Softening Order	Cone-fusion temperatures Fluid, F
F	1.2	2120	3	1900	1970	1	2180
D	4.4	2400	6	2260	2360	6	2430
E	17.0	(2100)	2	1880	2015	2	2195
A	25.0	2185	4	2085	2150	3	2470
B	140.0	2380	5	2270	2335	5	2635
Fig. 3	260.0	Glass	1	2170	2250	4	2790
C	600.0[a]	2780	7	2350	2530	7	2815

[a] From extension of curve below liquidus temperature.

With the exception of slag D, the fluid temperature increases in the same order as the viscosities; slag D is an uncommon slag with very high lime. One point of the viscosity curve would be known if it were assumed that the viscosity at the cone-fluid temperature is 100 poises; but this does not hold for slags like D and E. It is possible that the plot of fluid temperatures against viscosities at 2600 F may give points within a band narrow enough so that the plot could be used for predicting viscosities at 2600 F, when the fluid temperature is known. However, indications from these data are that such predictions could be much in error.

The liquidus temperatures fall somewhat in the same order as the softening temperatures and have higher values. Low-flux slags would be an exception to this approximate rule. A glassy slag with no liquidus can be predicted from the cone temperature because it will have an interval of about 500 F between the softening and fluid temperatures.

As a summary, curves and rules could be derived from experimental data from which the liquidus temperature and one point on the viscosity-temperature curve could be predicted from the cone-fusion temperatures, but there will be the possibility that some predictions may be much in error.

No definite rules for the interpretation of the cone temperatures are given at this time, because data are too few and these cone fusions are for premelted ash; conversion factors are required to convert the values for unmelted ash into those for melted ash. The difference in the cone values is only large for the low-flux ashes; for example, the softening temperature of the unmelted ash of slag C was 2795 F, against 2530 F, for the melted slag.

In addition to such rules, a mean curve of viscosity such as that of Fig. 9 is required as a guide in drawing the viscosity curve through the one known point.

One must not expect that very close interpretations of the cone-fusion values will ever be possible. The criterion of change of shape and the several factors which produce those changes are too indefinite, but it should be possible to get better information than when only the softening temperature is used. For example, the softening temperatures of slags B and D of Fig. 10 differ by only 25 deg, and by that criterion their clinkering would be expected to be similar. However, although both are fluid at 2400 F, the viscosity of B is 470 poises and that of D is 12 poises; that is, D is 40 times more fluid than C. Under most conditions, such difference should certainly make D a worse clinkering coal than C.

The first step toward a better understanding of the cone temperatures was stated to be the ability to translate them into viscosity curves. That will not mean that the viscosity curves will be of greater practical help in prediction or explanation of clinkering or other ash actions, except as far as we can learn to use these tools with skill. They will be of direct help and application in relation to slags in a fluid state, such as slag-tap furnaces. They are needed, and should be helpful, in connection with clinkering, and more so if the analysis of the complicated actions in the fuel bed follows the life history of the coal from the time of firing.

Mixing of Ashes or Slags

The properties of a slag obtained by mixing the ashes of two coals can be determined from the trilinear diagrams of Fig. 8 by drawing a straight line between the two points representing their compositions and reading the values of viscosity, or of the crossing of the liquidus line, for percentage positions between the points. Thus, it is possible to predict the effects of mixing ashes or of fluxing by the addition of iron oxide or lime. Note, however, that these plots do not give any information on slags in the area of solid phase.

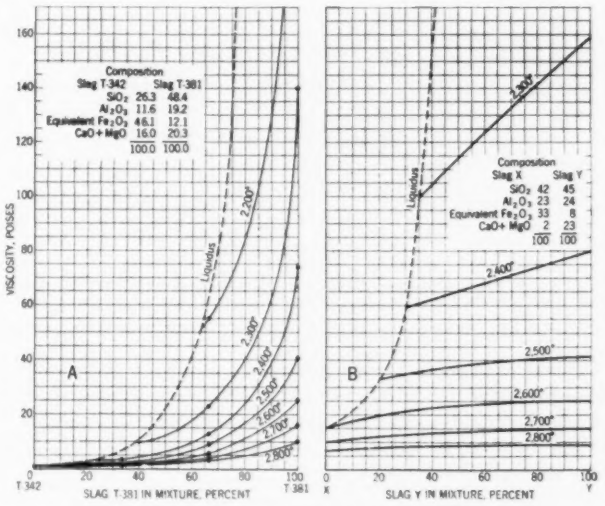

FIG. 11 EFFECT ON VISCOSITY AND LIQUIDUS TEMPERATURE OF MIXING TWO SLAGS

(*A*, having widely different viscosities; *B*, having similar viscosities.)

Such plots are valuable in that by inspection they show which of the three components, silica, iron oxide, or lime, should be increased to produce a desired change. Considering the 2600-F plot, for any composition in the liquid phase inclosed by the boundary *A-B*, the addition of lime will decrease the viscosity and move the composition farther from the liquidus line; both changes will make tapping easier.

To add iron only will decrease the viscosity by about the same amount as will the addition of lime, but now the tendency will be to approach the liquidus line, which is undesirable.

In general, the addition of silica will increase the viscosity, but for a low-silica, high-iron slag it may be beneficial in that it can move the slag toward an area of the field of composition where the liquidus temperature is lower.

Fig. 11 shows the results of mixing slags. Plot *A* is from experimental data. Slag T-342 had a viscosity of 1 at 2700 F and had its liquidus at 2600 F; slag T-381 had a viscosity of 16 at 2700 F and acted as a glass. The data for plot *B* were obtained from the trilinear diagrams of Fig. 8; the slags have somewhat similar viscosities and the same differences in liquidus temperature as those of plot *A*. These plots are self-explanatory.

Effect of Heating on Ferric Percentage

It is important to understand the effect of heat and temperature on the state of oxidation of the iron content of ashes and

slags. The method used in the chemical analysis evaluates the iron oxides as ferric (Fe_2O_3) or ferrous oxide (FeO). Metallic iron is not included, because it will not result from the heating of a slag in the absence of carbon or a reducing gas.

Certain tests were made to determine the factors influencing oxidation and reduction. The primary purpose of these tests was to obtain information required for the conduct of tests of this investigation and not to determine phase-equilibrium data.

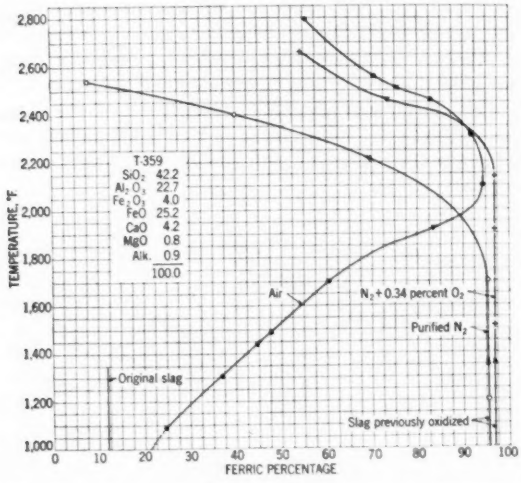

FIG. 12 OXIDATION AND THERMAL DISSOCIATION CURVES FOR A COAL-ASH SLAG
(Original slag ground to pass 60 mesh; 1-hr exposure at each point.)

The slags used had been premelted and were well reduced. They were ground to 60 mesh, and some were oxidized in the same manner as is a coal ash. The tests were made in a platinum-wound furnace, in which the atmosphere could be controlled; they were of three types:

1 Heating the reduced slag in air, stirring until prevented by eventual sintering of slag.

2 Heating the oxidized slag in an atmosphere of unpurified nitrogen containing 0.34 per cent O_2 and traces of water vapor.

3 Heating the oxidized slag in an atmosphere of nitrogen, purified by slow passage over hot copper gauze and drying with calcium chloride, and admitted to the furnace through a carbon tube.

Fig. 12 shows the tests on one slag. The method in all tests was to raise the temperature by steps and maintain it at each temperature for 1 hr. At the end of the hour a sample was taken, immediately quenched in water, and used for the determination of ferric percentage. Samples can only be taken before the pulverized material sinters and after it is at least partly liquid; the larger temperature intervals show when a sample could not be taken.

In the test in air, the slag began with a ferric percentage of 12. The percentage increased at a uniform rate until it reached a maximum of 94 per cent at 2100 F. Further increase in temperature caused dissociation, oxygen being driven off; at 2800 F the ferric percentage was reduced to 56.

In the test in unpurified nitrogen, the original ferric percentage was 97. There was no change in ferric percentage below 2130 F. The final ferric percentage differed little from that in air.

In the test in purified nitrogen, reduction began at 1700 F and at 2540 F the ferric percentage was 8. There is a possibility that this low value may be partly due to carbon particles from the tube being deposited on the slag.

Other slags gave the same type of result, except that the final ferric percentage of slags heated in air was smaller for slags with low iron-oxide content.

Time is required for oxidation, but reduction occurs quickly with the evolution of gas. Rate of oxidation depends upon area of surface, whereas reduction is independent of surface. Thus, when in practice, the ferric percentage of a bed of slag has been lowered by raising its temperature, the slag will retain that lower value after the temperature has been decreased, because oxidation is limited to action at the surface of the bed, where, over most of the area, the atmosphere will not be oxidizing.

GENERAL DISCUSSION

The authors believe that these tests and the deductions from them clear up some of the fog that has surrounded conceptions of the fusion characteristics of coal-ash slags, but the results have included no definite numerical values for the state of fluidity of slags cooled below the liquidus temperature.

The oscillating-bob viscometer is good in that it can cover a range of from 1 to even 10^8 poises, provided the slag remains a true liquid, but its action is extremely sensitive to the presence of solid phase.

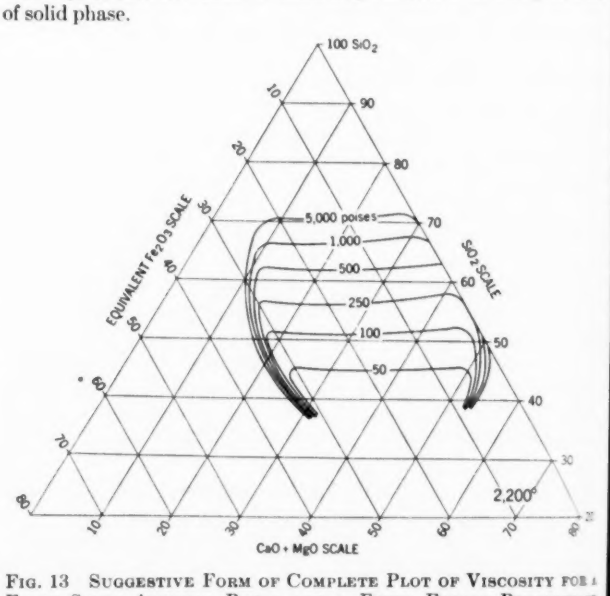

FIG. 13 SUGGESTIVE FORM OF COMPLETE PLOT OF VISCOSITY FOR A FIXED SILICA-ALUMINA RATIO AND A FIXED FERRIC PERCENTAGE

There is a great distinction between measurements of the state of fluidity at temperatures above and below the liquidus. Above the liquidus temperature, the slag is a true liquid and the same value for its viscosity will be obtained independent of the method used. Below the liquidus, the problem is entirely different. The numerical results obtained will depend upon the method and apparatus, the procedure and the time-temperature history of the thermal procedure. For example, the oscillating method would give higher values for equivalent viscosity than would the method of a bob rotating at a constant speed. In the procedure, the numerical value depends upon whether the slag is agitated to break up crystal formations. In these tests, measures of apparent viscosity at constant temperature have increased 100 per cent during a 15-min interval.

Thus, any method of measurement when solid phase is present in the slag will be arbitrary; for results to be duplicated there must be a rigid specification for procedure and for its relation to time.

The method of test to be used for temperatures below the liquidus has not been fixed because the correct choice is still in doubt. Three main possible principles are (1) rate or quantity of

flow under specified conditions, (2) force or work required to produce shear in the slag under specified conditions, and (3) deformation under specified conditions.

If the initial and softening temperatures are added to the viscosity-temperature plots, they show whether the initial melting is slow or fast and enhance the value of the plot.

Numerical values by any method could be expressed as apparent viscosity, under the definition that the apparatus and method are calibrated against a true glassy slag for which the viscosity-temperature plot has been determined.

Fig. 13 suggests the type of plot that would give complete data on the fusibility of coal-ash slags. The isoviscosity lines, approximately horizontal for the true liquid area are the same as those of the 2200 F plot in Fig. 8. The extensions of those lines begin from the liquidus line of Fig. 8 and are the apparent viscosity values. Their shapes would be as shown, but the distance between them is not based upon data, except that it is known they will be crowded closer together at the lower part than at the upper part of the plot. One plot would be restricted to one temperature, one ferric percentage, and a restricted range of silica-alumina ratios.

Acknowledgments

This investigation has been carried out under the authorization of A. C. Fieldner, chief engineer, Coal Division, United States Bureau of Mines. Paul Cohen, junior fuel engineer, assisted from the inception of this phase of the general investigation. The many chemical analyses required were made in the Chemical Section by F. H. Gibson under the direction of W. A. Selvig.

Acknowledgment is made to H. R. Lillie of the Corning Glass Works, Corning, N. Y., for supplying samples of glasses and slags with their viscosity curves; also to the Gulf Research Laboratory, Pittsburgh, Pa., for supplying samples of oils with their viscosity data.

Appendix

Description of Apparatus

Fig. 14 is a cross section through the furnace and viscometer; all the essential parts are labeled. Fig. 15 shows the complete apparatus; the switchboard in the background is for control of heating, and a multiple-tap transformer is below it; the apparatus beneath the table is for the purification and control of nitrogen for the atmosphere of the furnace.

Furnace

Experience in this investigation had shown that the operating temperature of a platinum-wound furnace should not be higher than 2750 F or its life would be short, as the temperature of the winding would be at least 2850 F. As the maximum operating temperature required was 2900 F or more, the upkeep of a platinum-wound furnace would be excessive.

The design adopted for the heater was a silicon-carbide tube 2 × 3 in. diam and 12 in. long. The end terminals are water-cooled copper plates, the spring pressure being on the upper plate. Turned lightweight refractory blocks surround the tube and are enclosed in a shell of high temperature sheet iron; the space between this and the furnace casing is filled with sil-o-cel powder. The casing is of welded construction, and the assembly is gas tight except for the opening at the top around the tubular element.

The regulation of the current is by means of a multiple-tap transformer of 3-v steps with variable resistors for adjustment between steps. The maximum load is about 3 kw.

The control and operation of the furnace has been satisfactory,

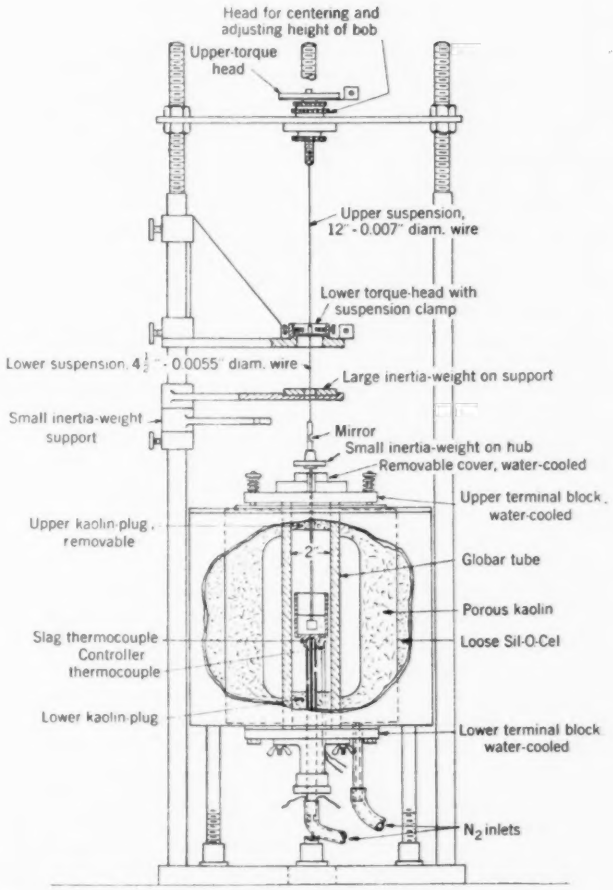

Fig. 14 Furnace and Viscometer for Determination of Viscosity of Coal-Ash Slags

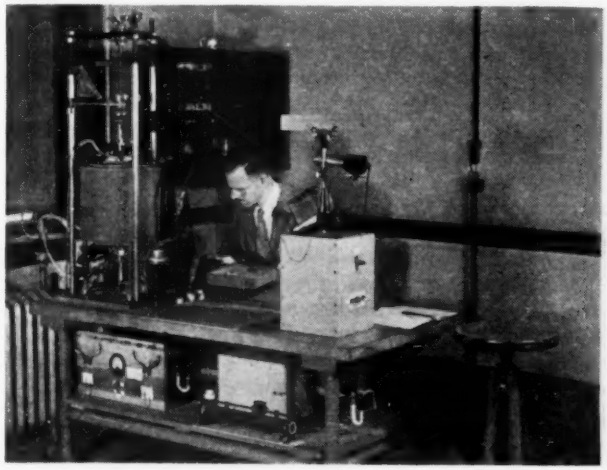

Fig. 15 General View of the Viscometer Setup

but the average life of the heating element has been only about 200 hr, or 15 to 20 heats, in not more than 5 of which a maximum temperature of 2930 F would occur. Failure has been caused by development of hot spots or cracks. Such local high temperature involves the additional risk that silicon vapor may be evolved and damage any platinum in the furnace.

Crucibles—Temperature Control

The crucibles have an inside diam of $1^1/_2$ in. and a depth of $2^1/_4$ in. Porcelain crucibles of special design are satisfactory for slags of total flux content of 15 per cent and a maximum temperature of 2900 F, or for a flux content of 25 per cent and a maximum temperature of 2800 F. Platinum crucibles are used for higher-flux slags or long exposure to high temperature.

A platinum 10 per cent rhodium thermocouple is used for temperature control, the hot junction being exposed to direct radiation of the furnace tube. Thus, with its small heat capacity, the thermocouple rapidly follows changing temperature of the tube and, through a potentiometer-activated temperature controller, maintains the slag at any fixed temperature within a maximum variation of 2 F. Thus it was possible to bring the slag to a given temperature and to hold it at that temperature indefinitely, without the furnace requiring constant supervision. At temperatures near the liquidus, this was of great value because momentary unobserved cooling of 10 F is sufficient, with some slags, to cause abrupt freezing of the melt.

Viscometer

The bob of the viscometer is $^1/_2$ in. in diam $\times$ $^1/_2$ in. long and has a $^3/_{32}$-in. spindle, both of platinum 20 per cent rhodium. The spindle extends outside the furnace and passes through a removable water-cooled cap which closes the furnace at the top and prevents heating of the upper part of the viscometer.

The viscometer has several ranges; two suspensions are connected in series such that both can be used as a unit, or the lower suspension only by clamping the junction of the suspensions at the lower torque head. The two inertia weights provided are of such moment of inertia that the smaller weight, in conjunction with the two suspensions, or both weights with the short suspension, form systems having a period of approximately 10 sec when oscillating in simple harmonic motion. This period of 10 sec was fixed as the shortest for which an observer could determine accurately the amplitude of an oscillation by the scale reading at the point where the oscillation reversed direction. For viscosities of less than 1 poise, both weights are removed and the period is about $2^1/_2$ sec.

When the damping effect of the viscous slag is so great that readings are not possible with harmonic motion, the inertia of the system is made its minimum and aperiodic motion is utilized, the time for the bob to rotate over a given angle being measured. The torque heads are equipped with magnets, so that a given twist of the suspension from the 0 position can be maintained until the bob has rotated to a preassigned position. A key switch is then operated, releasing the magnet so that the bob is free to rotate under a definite torque and, simultaneously, the electric timing clock is started. When the bob has rotated to the second preassigned position, the key switch is again operated, stopping the clock and reenergizing the magnet for the next timing cycle.

Viscometer Calibration

The original calibration was made with castor oil, the viscosity of which was checked in a modified Ostwald viscometer. Later, calibrations were made against a polymerized mineral oil having a much higher viscosity and also were measured in an Ostwald viscometer. These calibrations, made between 40 F and 180 F, could be compared directly and showed differences of about 5 per cent. Two calibrations were made at high temperatures with a synthetic iron-free slag and a glass, both of which had been measured previously in a Margules-type viscometer by H. R. Lillie, of the Corning Glass Works, who furnished the samples. Fig. 16 shows the comparison between the viscosity computed from the constants originally determined

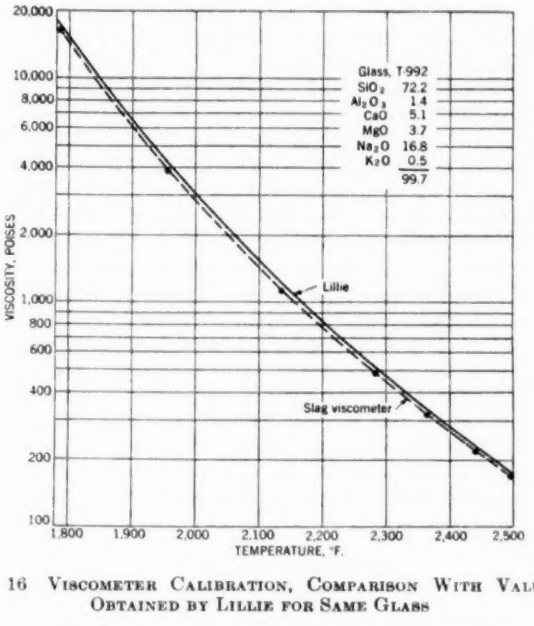

Fig. 16 Viscometer Calibration, Comparison With Values Obtained by Lillie for Same Glass

with castor oil and the viscosity for the same glass as reported by Lillie; the slag viscometer curve is approximately 5 per cent low. The constancy of deviation indicates that calibrations with castor oil are a sufficient check on the continued operation of the viscometer. The synthetic slag, which was of lower viscosity, has a similar agreement. The indicated accuracy of the instrument itself is approximately ± 5 per cent.

Two series of 50 consecutive determinations of the viscosity of two oils in this viscometer indicate that, for identical conditions of temperature and viscometer arrangement, with harmonic motion, the standard deviation from the true average will not exceed 1 per cent 99.9 per cent of the time, nor, for aperiodic motion, will the standard deviation exceed 3 per cent.

Discussion

R. M. Hardgrove.[15] The characteristics of slag are very important in the design and operation of large boiler furnaces fired by pulverized coal and stokers.

At the time the authors started this work, it was thought that the ability to tap the molten slag was the important feature. It still is necessary to tap the slag, but, as furnace designs have advanced, resulting in higher furnace liberations and the more general use of two-stage furnaces which have higher temperatures in the primary furnace, the difficulties in tapping slag have been reduced to a point where it is not of major importance.

The coating by slag of secondary-furnace walls, slag screens and superheater tubes is, however, a problem of major importance in both stoker-fired and pulverized-coal installations, and the determination of the characteristics of slag under these conditions is a subject worthy of intensive investigation.

The primary purpose of a boiler is to absorb heat. Slag coatings on the water-cooled walls reduce heat absorption and require operating labor to maintain the units in satisfactory working condition.

In boiler furnaces, there usually exist a reducing atmosphere in the primary furnace and an oxidizing atmosphere in the secondary furnace, in varying degrees. It is very essential that more

[15] Engineer in Charge, Design Department, The Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

research be carried on covering the full range from reduced to fully oxidized atmospheres. The writer would like to suggest that further work should approach the problem from that angle. The curves, such as Fig. 8, if completed to cover the possible degrees of oxidation, would be in a very useful form. Fig. 7 is a very interesting plot. In order to obtain smooth curves of constant temperature, it is not necessary to omit the Al_2O_3 as it can be added to the SiO_2 and the sum of SiO_2 and Al_2O_3 used as abscissa just as satisfactorily.

Viscosity and liquidus point may have some relation to the tendency to stick to furnace walls and tubes, but it is not clear just how it can be used. Perhaps the sticky characteristics at some temperature below the liquidus would be more analogous.

The authors have conducted a very thorough research and we surely hope they will find ways of continuing the program.

Authors' Closure

This opportunity is taken to add a figure which simplifies comparison of the properties of the slags indicated in Fig. 10 of the paper. Fig. 17 shows the viscosity curves and the cone-fusion temperatures of 8 coal-ash slags. The viscosity curves are for reduced slags of low ferric percentage, and the fusion temperatures are for the premelted slags and not for the original coal ash. Table 2 gives the chemical composition of the slags which are lettered in order of decreasing flux content; this designation is not the same as for the same slags in Fig. 10.

TABLE 2 COMPOSITION OF SLAGS OF FIG. 17

	A	*B*	*C*	*D*	*E*	*F*	*G*	*H*
SiO_2	26.3	35.3	41.4	48.4	50.0	57.5	53.3	55.3
Al_2O_3	11.6	16.6	22.3	19.2	26.7	19.1	28.3	31.1
Equiv Fe_2O_3	46.1	9.9	31.4	12.1	13.1	13.2	13.7	9.5
CaO + MgO	16.0	38.2	4.9	20.3	10.2	10.2	4.7	4.1
	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0
Fe_2O_3 + CaO + MgO	62.1	48.1	36.3	32.4	23.3	23.4	18.4	13.6

Fig. 17 shows clearly the relationships between cone temperatures and viscosity for each slag, as well as those between the properties of slags having a wide range of composition.

Since the completion of the paper, viscosity and cone-fusion tests have been made on two glasses so that the results might be compared with those obtained for the glassy coal-ash slag. The values for the two glasses and for the glassy slag *F* of Fig. 17, are given in Table 3.

TABLE 3 VALUES FOR SLAG AND TWO TYPES OF GLASS

	Slag *F*		Pyrex		Soft glass	
	Deg F	Poises	Deg F	Poises	Deg F	Poises
Initial temperature	2160	9000	2020	60000	1480	100000
Softening temperature	2250	4000	2220	7000	1600	50000
Fluid temperature	2790	100	2900	600	2220	700

Table 3 shows that these three widely different types of glasses do not have the same viscosities at the initial, softening, and fluid temperatures, respectively. Thus the cone-fusion test is not a consistent measure for viscosity even for glassy slags. However, the relative positions of the I.T., S.T., and F.T. points of slags *F*, *G*, and *H* of Fig. 17, indicate that the corresponding viscosities of glassy slags of the coal-ash type may not differ so widely as do the glasses.

The authors take issue with some of the points raised by Mr. Hardgrove. Although tapping of slagging furnaces is not the problem that it was in the earlier days, yet he will agree that, even in recent installations, considerable trouble and expense could have been avoided if knowledge of the properties of the slags, such as that given by Fig. 17, had been available when the equipments were designed.

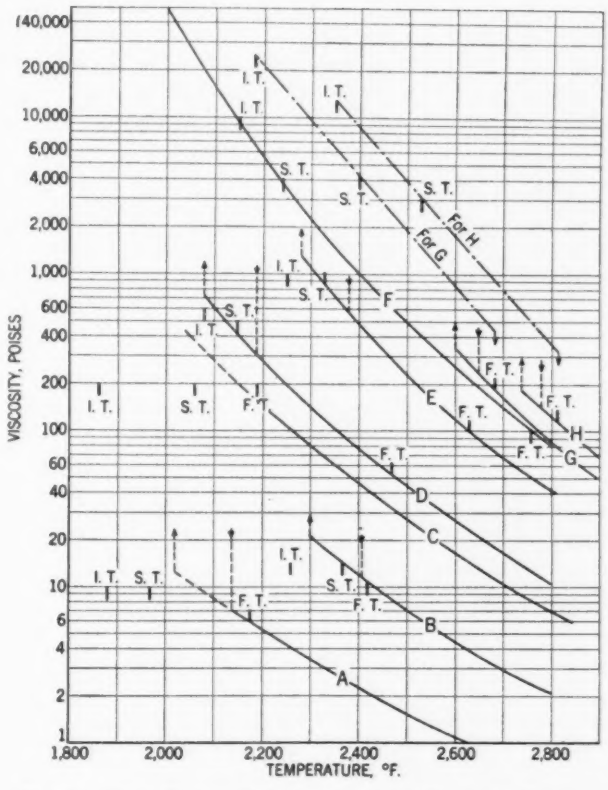

Fig. 17 Cone-Fusion Temperatures and Viscosity Curves for 8 Coal-Ash Slags

Again, data on viscosity and cone fusions, similar to those of Fig. 17, for any slag give primary characteristics for slagging properties much in advance of any previously available. As stated in the paper, more exact measures than those given by the cone, initial, and softening temperatures are required to express the properties of the slag below the liquidus temperature but, until such data are available, the cone-fusion temperatures give some indication of the mobility or plasticity of the slags.

Fig. 4 is a complete indication of the effect of ferric percentage over its entire range. These data were published in 1934,[6] and that paper should be consulted for the full application of Fig. 4. In addition, the authors have available similar data, as yet unpublished, on the effect of the ferric percentage on the "penetration" and the "sticky" temperature for the entire range of coal-ash slags.

Methods other than those omitting the Al_2O_3 can be used to reduce to three components for the plots of Fig. 8. The omission of the Al_2O_3 was found to be most satisfactory because the plot then shows the effect of silica content on viscosity, but silica plus alumina can be used for plots limited to a narrow range of ratio of silica to alumina.

Discussion

Cavitation Characteristics of Centrifugal Pumps Described by Similarity Considerations[1]

J. W. Macmeeken.[2] The authors prove in this paper the importance of the Thoma-Moody parameter $\sigma = \frac{H_{sv}}{H}$, for determining the safe lower limits of the absolute suction pressure above the vapor pressure of the fluid. Their discussion of this parameter as part of the general laws of similarity of machines of the same hydraulic type proves that no other criterion is necessary for determining the absolute pressure and suction-lift characteristic, provided consideration is limited to particular models and to series multiplications of these models.

However the whole field of centrifugal-pump applications would require an infinite number of models to cover the entire range of specific speeds. Often several different types of models for each specific speed are required to cover the variations of characteristic that are called for in centrifugal pumps in commercial use. Therefore it is necessary to have a knowledge of the variation of values of σ with specific speed and also to have a knowledge of the variation of σ in models of different hydraulic characteristics of the same specific speed.

The writer would like to emphasize that specific speed is only one of several type determinants in centrifugal pumps. This is true very particularly with reference to suction-lift or absolute-pressure parameters.

The curve shown in Fig. 8 of the paper represents a different value of σ for each specific speed throughout the range shown and the variation of σ value is continuous.

The importance of different values of σ for the same specific speed is illustrated in Figs. 1 and 2 herewith. Fig. 1 shows the characteristic curve of an 8-in. centrifugal pump, which delivers 2600 gpm against a total head of 180 ft at a speed of 1750 rpm. A breakdown occurs when the suction lift is 16.6 ft. Fig. 2 shows another impeller in the same pump, which delivers the same capacity and head but in which a breakdown does not occur until the suction lift is 26.1 ft. In Fig. 1, the value of σ is

$$\frac{32.7 - 16.6}{180} = \frac{16.1}{180} = 0.0895$$

but in Fig. 2 the value of σ is

$$\frac{32.7 - 26.1}{180} = \frac{6.6}{180} = 0.0368$$

These figures, taken from a popular size of commercial pump, show that a very great difference in the value of σ can exist in the same pump with two different impellers, both of which have the same specific speed.

Fig. 3 shows the characteristic of a centrifugal pump for the same capacity and head as before but with a speed of 3500 rpm instead of 1750 rpm. This shows a breakdown when the suction lift is 1.7 ft, which is equivalent to a σ value of $\frac{32.7 - 1.7}{180} = \frac{31}{180} = 0.172$. This shows that the value of σ is higher for higher specific speeds.

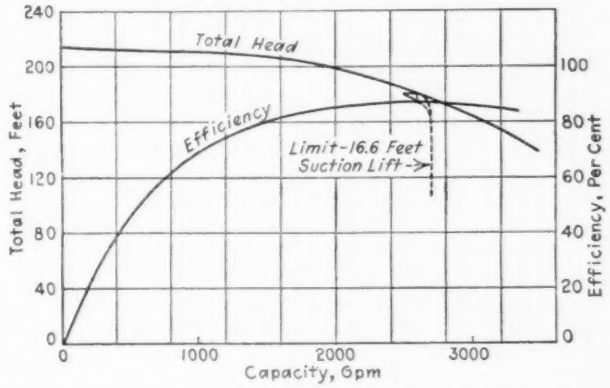

Fig. 1 Performance Curve, 8-In. Double-Suction Pump; 1750 Rpm Impeller—A

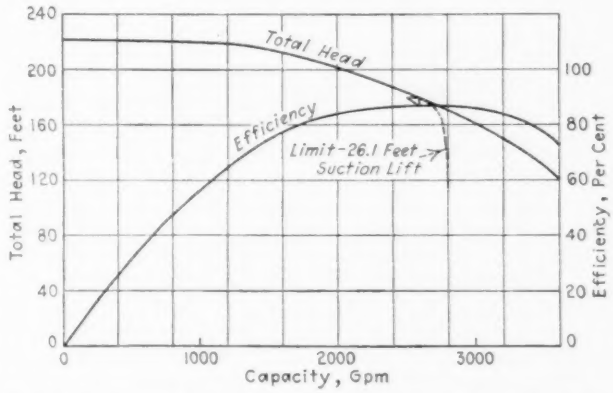

Fig. 2 Performance Curve, 8-In. Double-Suction Pump; 1750 Rpm Impeller—E

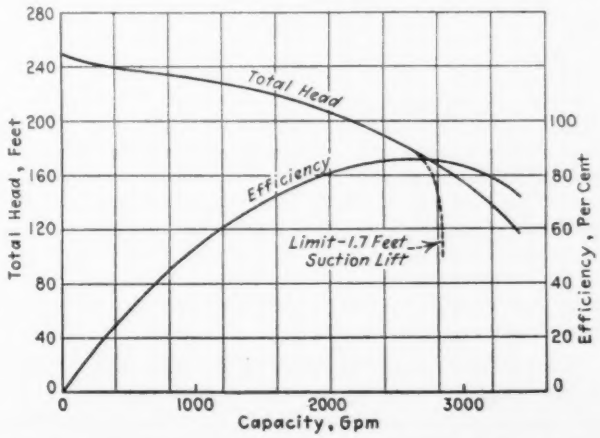

Fig. 3 Performance Curve, 8-In. Double-Suction Pump; 3500 Rpm

[1] Paper by G. F. Wislicenus, R. M. Watson, and I. J. Karassik, published in the January, 1939, issue of the A.S.M.E. Transactions, vol. 61, no. 1, pp. 17–24.

[2] Cameron Pump Department, Ingersoll-Rand Co., Phillipsburg, N. J. Mem. A.S.M.E.

It has been common practice among pump designers to calculate the absolute pressure required on the suction of centrifugal pumps by the use of dimensionless coefficients. The use of such coefficients and their limiting values permits the designer to lower the limits of suction pressure required with a fair degree of accuracy below average commercial practice, when suction lift is of great importance. The lowest possible suction pressures are required in condensate-removal pumps for surface condensers, for chemical-process pumps in conjunction with evaporators, and in well pumping, where submerged pumps are not required.

The parameter $S = \dfrac{N \times \sqrt{Q}}{H_{sv}^{3/4}}$ (Equation [6] of the paper), combined with the provision S = const and N_s = const (Equation [7]), appears on analysis to be inconsistent with observed tests.

Starting with Equation [6]

$$S = \frac{N \times \sqrt{Q}}{H_{sv}^{3/4}} = \text{const when } N_s = \text{const}$$

$$\therefore H_{sv}^{3/4} = N\sqrt{Q} \times \text{const, for a particular } N_s$$

$$\therefore H_{sv} = (N\sqrt{Q})^{4/3}$$

Now let

$$N = n\sqrt{H} \quad \text{and} \quad Q = q\sqrt{H}$$

n and q are sometimes called unit speed and unit capacity, respectively.

$$\begin{aligned} \therefore H_{sv} &= (N\sqrt{Q})^{4/3} \times \text{const} \\ &= (n\sqrt{H} \times \sqrt{q \times \sqrt{H}})^{4/3} \times \text{const} \\ &= (nH^{1/2} \times q^{1/2} \times H^{1/4})^{4/3} \times \text{const} \\ &= n^{4/3}q^{2/3} \times H \times \text{const} \qquad [1] \end{aligned}$$

$$\therefore \frac{H_{sv}}{H} = n^{4/3}q^{2/3} \times \text{const}$$

now let U_1 = peripheral velocity of D_s in ft per sec

and $K_{u1} = \dfrac{U_1}{\sqrt{2gH}}$

also let V_{su} = velocity of entrance at D_s in ft per sec

and $K_{su} = \dfrac{V_{su}}{\sqrt{2gH}}$

$$\begin{aligned} \text{Then } \frac{H_{sv}}{H} &= \left(\frac{K_{u1} \times 1840}{D_1}\right)^{4/3} \times \left(\frac{\pi}{4} D_1^2 \times K_{su}\right)^{2/3} \times \text{const} \\ &= K_{u1}^{4/3} \times C_1 \times K_{su}^{2/3} \times C_2 \times \text{const} \\ &= K_{u1}^{4/3} \times K_{su}^{2/3} \times C \qquad [2] \end{aligned}$$

which is the form of the equation in terms of dimensionless coefficients.

$$\begin{aligned} \therefore \text{Also } \frac{H_{su}}{H} &= \frac{U_1^{4/3}}{H^{1/2 \times 4/3}} \times \frac{V_{su}^{2/3}}{H^{1/2 \times 2/3}} \times C \\ &= \frac{U_1^{4/3} \times V_{su}^{2/3}}{H} \times C \qquad [3] \end{aligned}$$

Now two impellers of the same D_2 but with slightly different D_s may have the same N_s and the same capacity and head. The two impellers, the characteristics of which are shown in Figs. 1 and 2, are examples. Now consider the effect on the writer's Equation [3] of a slight change in D_s, as illustrated in Fig. 4. It is known from tests that a slight change in D_s results in a change in σ and S.

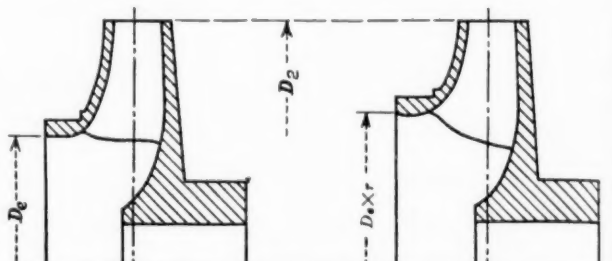

FIG. 4 EFFECT OF CHANGES IN INLET DIAMETERS OF IMPELLERS

Referring to Fig. 4, let D_2 be the diameter of both impellers and let the entrance diameter of impeller No. 1 be D_s, and let the entrance diameter of impeller No. 2 be $D_s \times r$, where r is a linear ratio, say, slightly greater than unity. By Equation [3]

$$H_{sv} = U_1^{4/3} \times V_{su}^{4/3} \times C \qquad [4]$$

where U_1 is the peripheral velocity of D_s in impeller No. 1 and V_{su} is the entrance velocity of flow at the eye of impeller No. 1. Then for impeller No. 2

$$\begin{aligned} H_{sv} &= (rU_1)^{4/3} \times \left(\frac{1}{r^2} V_{su}\right)^{2/3} \times C \qquad [5] \\ &= r^{4/3}U_1^{4/3} \times \frac{1}{r^{4/3}} V_{su}^{2/3} \times C \\ &= U_1^{4/3} \times V_{su}^{2/3} \times C \end{aligned}$$

the same as H_{sv} for impeller No. 1 (see Equation [4]).

That is, Equation [4], which is the equivalent of Equation [6] of the paper is such that, in impellers of the same capacity and specific speed, a slight change in D_s only, makes no change in H_{sv} or in the parameters σ and S.

If this were true and in agreement with actual tests, S would indeed be a valuable parameter and the calculation of σ would always be very simple, because it would be independent of the value of D_s. But unfortunately tests show that a change in D_s only, changes the value of σ. Hence the writer believes that the parameter $S = \dfrac{N\sqrt{Q}}{H^{3/4}}$ is proved to be of incorrect form by the method of reductio ad absurdum.

Instead of the Equation [6] of the paper and its derivatives such as the writer's Equation [2], it may be proved that

$$\frac{H_{sv}}{H} = K_{u1} \times K_{su} \times C_1 \qquad [6]$$

and then instead of [5], we would have

$$\begin{aligned} H_{sv} \text{ (for impeller No. 2)} &= rU_1 \times \frac{1}{r^2} V_{su} \times C_1 \\ &= \frac{U_1 V_{su}}{r} \times C_1 \end{aligned}$$

Now H_{sv} (for impeller No. 1) $= U_1 V_{su} \times C_1$

Therefore σ for impeller No. 2 is smaller than σ for impeller No. 1 in the ratio $\dfrac{1}{r}$: 1, or the impeller with the larger D_s has the lower value of σ. This is in agreement with a large number of

tests of many different impellers. The few impellers which are not in agreement have some feature of design which causes an interference such as too high entrance ratio, or too many vanes.

The writer has found that the variation of σ with N_s is best expressed by the following equation

$$\sigma = K \times C \times N_s^{4/3} \quad [7]$$

where K is a performance coefficient and is dependent on hydraulic efficiency, type of suction approach, length of suction pipe, degree of saturation of the fluid with air or gas, and on the inlet ratio of impeller vanes.

On the other hand C is a constant which is a measure of the relative size of inlet and has well-defined limits. For example, large C represents a relatively small D_s and low value of C represents a relatively large D_s, where D_s is the entrance diameter of the impeller. The value of C therefore determines, if it is within certain limits, whether the efficiency may be affected.

Values of K may be placed in three classifications: (1) When absolute suction pressure is sufficiently high that the pump efficiency is not affected; (2) a certain lower value of K means that the pump efficiency is slightly affected; (3) a still lower value of K is obtainable only with deaerated water, such as is obtainable in condensate-removal pumps, in evaporators, and in process pumps, where there is no quantity of gas dissolved in the fluid.

The derivation of the writer's Equation [7], with theoretical and practical values of K and C, is too lengthy to be given in detail in this discussion.

The development of Equation [7], however, differs from that of Equation [6] of the paper in that Equation [6] of the paper is a function of rotational head, whereas the writer's Equation [7] is derived from the rotational head, modified by the conditions of velocity of approach in the suction element of the pump. The velocity of approach is a function of capacity and not of rotation.

The writer would emphasize that the use of parameter S, given by the authors, is capable of serious error in the determination of limits for σ throughout the whole range of specific speed, because it merely represents a hydraulic condition and not the ability of any particular model to cope with the hydraulic condition.

In particular the authors' parameter S is, from its form, not influenced by change of impeller D_s which is contrary to test experience.

If the use of the authors' parameter S is restricted to machines of true similarity, it is totally unnecessary because then the Thoma-Moody parameter σ is all that is required.

The writer appreciates fully the very consistent mathematical discussion of the authors on this subject, which contributes to a better understanding of the subject; and he offers his criticism of the parameter S, merely because he finds it is not in agreement with test results and, because its use may result in serious confusion and possible errors in determining the best size and most economic speed of a centrifugal pump for the absolute suction pressure available.

L. F. Moody.[3] The occurrence and causes of cavitation in hydraulic machinery seem to have been first studied in the fields of marine propellers and hydraulic turbines. But little published material has appeared concerning cavitation in pumps. This cannot be explained by the absence of cavitation from centrifugal pumps, because no such happy state exists. While its occurrence in pumps is usually of somewhat less consequence than it is in great modern turbine units, its presence even in small pumps is far from welcome.

The authors have investigated the cavitation characteristics of centrifugal pumps as related to specific speed, as has previously been done empirically for turbines.[4] In so doing they have introduced a new cavitation coefficient, having the same dimensions as specific speed, and have deduced, by somewhat intuitive reasoning, an approximate functional relationship between the Thoma cavitation coefficient σ and specific speed. The relationship amounts to the proposition that, at least in low-specific-speed pumps, σ should vary as the four-thirds power of the specific speed, very nearly; or σ = (a constant) $N_s^{4/3}$. For this constant they have used their new cavitation coefficient S, putting $\sigma = (1/S^{4/3})N_s^{4/3}$.

They recognize that with material changes in design characteristics, as with widely different specific speeds, S may not be strictly constant, but they justly argue that S should change very slowly, and perhaps inappreciably, over wide ranges of N_s.

The writer has for several years been attempting to collect results of pump cavitation tests and to plot σ values vs. N_s. The data so far obtained seem to bear out in a general way the authors' thesis; a curve drawn through the centers of gravity of the mass of plotted points agrees well with the functional relationship they present. The writer also recalls arriving very nearly at the same conclusion in a theoretic analysis in which he showed that, for turbines and pumps of similar design characteristics, part of the cavitation factor, represented by velocity head at the runner throat, varies as $N_s^{4/3}$. Curves were plotted on this basis.[5] This is merely mentioned in partial confirmation of the authors' conclusion. The writer considers that the authors in their analysis have made a useful step in advance.

The practical difficulty in applying the results of such an analysis seems to be greater for pumps than for turbines. While limiting safe values of σ for Francis turbines have been found to vary rather consistently with specific speed, so that a fairly definite envelope could be drawn and usefully applied in practice, the spread of points in the field of propeller turbines is so great that such a curve can be used in that field only as a rough preliminary guide. It has been recognized that thorough cavitation tests for each individual design are the only dependable index to safeguard a new propeller-turbine installation.

In the pump field, however, the points, collected from various sources and from pumps by different builders, show so great a scattering throughout the entire field that it becomes a matter of judgment where to draw an envelope that will give reasonable safety in general practice.

The writer has come to believe that a general chart for pumps of any and every make cannot be a safe (and at the same time economical) guide. Only for a particular line of pumps of consistent design characteristics can a general curve or chart be practically applied as a safe and useful index. For example, a curve forming an envelope of the zone of reasonably safe practice for the general run of commercial pumps is widely different from one representing pumps of special design, such as the class of highly efficient pumps furnished by several American builders for the Metropolitan Water District of Southern California and tested with great accuracy at the Pasadena Laboratory. The σ for certain pumps plotted in the chart are as much as double those of other pumps of the same specific speed. The writer feels that the Utopia to be sought is the happy day when each individual pump will be tested not only for capacity and efficiency but for its cavitation coefficients as well.

[5] "The Present Trend of Turbine Development," by L. F. Moody, Trans. A.S.M.E., vol. 43, 1921, p. 1134.

It is far more calamitous to a customer to secure a pump which is found to operate in the cavitating region than to lose a per cent or two in efficiency. When it is considered that many a pump might have been installed at a slightly lower elevation, often at no extra cost, and thereby freed from serious operating difficulties such as noisy and unstable operation and, still worse, frequent shutdowns and impeller replacements, it should be realized that it is at least as important to know the safe value of σ as to know the efficiency. According to a chart, a pump may figure out as safely applicable to a given case, but the pump itself may be unaware of the fact and refuse to conform.

It is also felt that many tests which are thought to determine the cavitation factor do not really do so. For example, the practice sometimes employed of depending on the value of ultimate capacity or "breakdown point" for a given suction head is not a proper criterion, as shown in Fig. 2 of this paper. Its use probably results in many pumps operating in the cavitating range.

A. J. Stepanoff.[6] The fact that similarity of suction conditions as to cavitation for pumps of different specific speeds can be expressed by a parameter, similar in appearance to the expression for specific speed, is interesting but, the writer feels, its practical usefulness is very limited.

For the development of the connection between the cavitation parameters S or σ and specific speed, the authors make an assumption that the suction conditions, or the suction absolute pressure above the vapor pressure when cavitation starts, remain the same for the same capacity, if the impeller diameter is cut and the speed is constant. This means that the absolute pressure at which cavitation starts will depend on capacity only or, since the suction passages are fixed, it will be a function of the velocity through the impeller eye. Furthermore, when the pump speed is changed, the variation of the head, capacity, and power is the same as when the impeller diameter is cut at constant speed. Therefore, with equal reason it can be stated that in this case also the absolute pressure at cavitation conditions is a function of the capacity or radical velocity through the impeller eye only. This is confirmed very closely by actual tests on pumps of low specific speed, and only approximately on pumps of medium specific speed.

For correlating the experimental data on cavitation of centrifugal pumps of different specific speeds, accumulated in the course of several years, the writer has plotted the velocity heads, calculated for average radial velocities at the impeller inlet against the total suction lift, measured at the suction nozzle, and referred to the pump-shaft center line. These curves were published[7] and discussed in February, 1933. The writer has used these curves for several years since and has found them to be satisfactory for predetermination of pump cutoff capacity for given suction conditions for commercial pumps of low specific speed of about 1200 or less (single-suction pumps) when pumping water. It was found that, with pumps of low specific speed, the head-capacity curve dropped so suddenly under cavitation conditions that no decrease in efficiency or head was observed before the pump actually cut off. For slightly higher specific speeds, 1200 to 1500, a slight drop in head and efficiency was observed considerably before the maximum capacity was reached. For small commercial pumps this was disregarded as unimportant. This method of plotting the test data on cavitation was suggested by the observation that, for pumps of low specific speed, the maximum capacity, at constant suction conditions, does not change when the impeller diameter is cut. Also, it was found that the cutoff capacity changes very little, or not at all, when the speed of the pump is changed and the total suction lift kept constant.

This method of plotting cavitation-test data was used by Defeld in his book,[8] published in 1930. Later the writer prepared similar curves, based on the limited number of observations for boiling water and petroleum oils, which he has found to be useful in his work.

The writer does not share the authors' enthusiasm about the usefulness of the cavitation parameter S.

$$S = \frac{NQ^{1/2}}{H_{sv}^{3/4}} \qquad [8]$$

because it is possible to establish a much simpler relationship between the cavitation parameter σ and the specific speed N_s. Von Widdern[9] developed such a relationship over three years ago. He made essentially the same assumptions as the authors, that two impellers of different diameters and different total heads for the same capacity and at the same speed produce the same dynamic depression, or require the same suction head to suppress cavitation

$$\Delta h = \frac{c_1^2}{2g} + \lambda \frac{w_1^2}{2g} \qquad [9]$$

where $c_1^2/2g$ is the absolute velocity head at the impeller entrance and $\lambda w_1^2/2g$ is the drop of pressure below average on the back side of the vane, due to the power applied to water by the vane; w_1 is relative velocity at the impeller entrance; λ is an experimental coefficient similar to the lift coefficient of an airfoil. By definition

$$\sigma = \frac{\Delta h}{H} \qquad [10]$$

For two impellers of different outside diameters otherwise identical, operating under the same suction conditions, the following equation can be written

$$\frac{\sigma_2}{\sigma_1} = \frac{H_1}{H_2} \qquad [11]$$

In the expressions for the specific speed of the two impellers the speed N and capacity Q are the same. Therefore

$$\frac{N_{s1}}{N_{s2}} = \left(\frac{H_2}{H_1}\right)^{3/4} \qquad [12]$$

Combining Equations [11] and [12] we obtain

$$\frac{\sigma_2}{\sigma_1} = \left(\frac{N_{s2}}{N_{s1}}\right)^{4/3} \qquad [13]$$

which is the desired relationship between the cavitation parameters for two impellers defined above in terms of specific speed. Von Widdern has also published experimental data on cavitation, based on a large number of observations, showing the validity of the relationship as given by the writer's Equation [13], if the difference in specific speed of the two pumps being compared is not too great.

The advantages of using parameter σ over the authors' parameter S is that σ has a definite physical meaning, well known to hydraulic engineers. Calculations when using σ are simpler.

[9] "On Cavitation in Centrifugal Pumps," by H. Cardinal von Widdern, *Escher-Wyss News*, January–March, 1936, p. 14.

Besides, there are considerable experimental data on cavitation expressed in terms of σ already accumulated by the pump and turbine designers.

The relationship given by Equation [13] is only implied by the authors' Equation [4]. By combining Equation [13] of this discussion and [4] of the authors', it can be shown that the parameter S is a constant for impellers of different specific speed, obtained by variation of the outside diameter only.

Both the authors and von Widdern have established the relationship between the cavitation parameter and specific speed of pumps referred to the operating point. However, when specific speed is used as a pump-type number, this is referred to the best efficiency point on the head-capacity curve. When the impeller diameter is cut, the normal capacity for the best efficiency point decreases in direct ratio of impeller diameter or square root of the normal head.

$$\frac{Q_{1n}}{Q_{2n}} = \left(\frac{H_{1n}}{H_{2n}}\right)^{1/2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

Following Bischoff and Thoma[10] the cavitation parameter σ for all points on the constant-speed head-capacity curve for convenience can be referred to the normal head H_n.

$$\sigma = \frac{\Delta h}{H_n}$$

and for the same dynamic depression Δh, the ratio of the cavitation parameters for two impellers at the same capacity and speed but referred to the normal head will become

$$\frac{\sigma_2}{\sigma_1} = \frac{H_{n1}}{H_{n2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [15]$$

The ratio of the specific speeds for the normal conditions will be

$$\frac{N_{s1}}{N_{s2}} = \left(\frac{Q_{n1}}{Q_{n2}}\right)^{1/2} \left(\frac{H_{n2}}{H_{n1}}\right)^{3/4} = \left(\frac{H_{n2}}{H_{n1}}\right)^{1/2} \quad \ldots\ldots\ldots [16]$$

and the ratio of the cavitation parameters in terms of the specific speed at the point of best efficiency will become

$$\frac{\sigma_2}{\sigma_1} = \left(\frac{N_{s2}}{N_{s1}}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [17]$$

It is interesting to note that, if the relationship as given by the writer's Equation [17] is plotted on log scales, the curve will have a slope intermediate between that of the border lines on the Pasadena Laboratory tests reproduced in Fig. 7 of the paper and the curve based on the Hydraulic Institute Standards chart.

In their attempt to demonstrate the usefulness of the parameter S, the authors go so far as to suggest "factoring" of the impeller suction passages from one specific speed to another. This evidently is not acceptable to anybody familiar with pump design. There is already a well-established experimental relationship between all of the controlling impeller proportions including suction area, number of vanes, and entrance angles, for different specific speeds. This is so rigid in consistent designs that the ratio D_1/D_2 of the impeller eye and outside diameters was used as a type number in the past in the same manner as specific speed is universally adopted now. To destroy these proportions will immediately impair the best possible pump peak efficiency. Besides, it is well known that the points of minimum pressure under cavitation conditions are located in back of the impeller vane, some distance from the vane inlet tips. This low-pressure zone in pumps of medium and high specific speed may extend as far as half of the vane length. Thus, if the portion of the impeller vanes affecting cavitation is factored, it would be impossible to design the outer half of the impeller to match the impeller suction and obtain the desired head capacity with good efficiency. Apparently water pumps are, and will be, designed for the best possible efficiency, but the selection of pumps and the layout of pumping plants will be made with due regard to cavitation conditions.

It should be noted that the relation between the cavitation parameter σ and specific speed, established by von Widdern, applies equally to hydraulic turbines.

The authors' paper contains a number of authoritative statements which are either contrary to the facts, or are generalizations not justified in the light of the present state of knowledge of centrifugal pumps. For instance, the statement is made: "The combined influence of the changes in Reynolds' number and in the relative roughness is reasonably well known through test results with geometrically similar pumps of different sizes and for different speeds, and it is to be expected that the influence of these factors on the cavitation behavior of a pump will be of the same order of magnitude as their influence on capacity, head, or efficiency." Is it meant here that the effect of viscosity on the head, capacity, and efficiency is "reasonably well known" when pumping viscous liquids, such as petroleum oils? If not, why mention viscosity, Reynolds' number, "fluid," "machine," and not confine the discussion to water centrifugal pumps?

With water pumps and turbines, the question of determination of full-size pump efficiency from model tests, or efficiency of the same pump at different speeds, even when the suction conditions are properly adjusted, is still debatable. The difficulty lies in the fact that the change in efficiency with pump size and speed are of the same order as the accuracy of commercial testing instruments.

At another point, the general statement is made that "for most practical cases we need not include the temperature, vapor pressure, or nature of the fluid in cavitation formulas or charts, except in so far as these factors have an effect on the type of pump used." If we take petroleum oils, liquids next to water in importance in the pump business, the behavior of pumps under cavitation conditions is entirely different from when pumping water. Any formulas, charts, or test data obtained on water cannot be directly applied to oil-pumping problems.

On the other hand, the writer does not see why the established parameter σ or S, and formulas giving their connection with specific speed, cannot be applied with equal reason to hydraulic turbines, as the authors claim; or, why "the total turbine head and the net suction head are more intimately related, so that a separate consideration of suction and discharge flow conditions may not offer a useful approximation?"

The fact that the lines of constant parameter S in Fig. 7 happen to be in "excellent agreement" as to slope of the shaded area, the writer considers as a plain coincidence and not a "startling verification" of the practical usefulness of the cavitation parameter S, because the shaded area includes a limited number of points obtained with pumps of different specific speeds and of different makes. The actual slope of the lines drawn through two or more points corresponding to pumps of different specific speeds but of the same design and make may be different from the slope of the bordering line enclosing the whole shaded area.

W. M. White.[11] The cavitation characteristics of centrifugal pumps have been rather neglected in the development of the

[10] "Untersuchungen über das Verhalten Einer Kreiselpumpe bei Betrieb im *Kavitationsbereich*," by Armin Bischoff and D. Thoma, *Mitteilungen des Hydraulischen Instituts de Technischen Hochschule*, Munich, vol. 8, 1936, p. 56.

[11] Manager and Chief Engineer, Hydraulic Department, Allis-Chalmers Manufacturing Company, Milwaukee, Wis. Mem. A.S.M.E.

industry. The first real step in their study was that undertaken by the Hydraulic Institute in order to establish recommendations for limiting specific speeds to eliminate troubles from vibration and pitting.

The original work on this study was done without the use of the Thoma-Moody parameter σ, the data being assembled by plotting specific speed against total head and drawing lines of constant suction conditions through the critical points. The use of the σ-values would have aided this work materially. The authors have added considerably to this by their new cavitation parameter S. It is believed that, for low-specific-speed pumps, the relations set forth should be reliable. However, it should be emphasized particularly that at higher specific speeds the use of this method is apt to be in error.

There is no assurance that the limiting value of S should be constant, regardless of the specific speed. The writer has plotted numerous pumps on the specific speed-S basis and can find no definite limiting value of S. On the other hand, when these same values are plotted on a specific speed-σ basis, the curves show a very definite trend from specific speeds of 500 up to 10,000 rpm, which covers the range of centrifugal, mixed-flow, and propeller-type pumps.

Fig. 10 of the paper is a good way to present the limiting capacities of various suction heads. There is danger, however, that it would be used for pumps in the higher specific-speed range and, therefore, would give misleading results.

M. SEDILLE.[12] The coefficient S introduced by the authors appears to mark considerable progress in the presentation of test results of cavitation in pumps. It is particularly important for the similitude calculations of pumps having similar inlet waterways and different outside dimensions, in other words, different values of N_s.

As the authors have shown, the advantage which this coefficient offers of being independent of what happens at exit from the impeller holds good only for impellers where this independence is clearly assured, i.e., for pumps having a low or moderate specific speed.

It is, therefore, not surprising that the authors of the paper have found by tests that S is practically independent of N_s in the region of corresponding specific speeds.

There exists another method of presentation which has the same properties as the coefficient S, as far as independence from the phenomena at impeller exit is concerned, but which starts out from an entirely different order of ideas. It is derived directly from the coefficients introduced by Rateau in the theory of turbomachines.

Referring to Fig. 5, it is well known that Rateau's characteristic coefficients have the form

$$\mu = gH/u_1^2 = \text{manometric coefficient} \quad [18]$$

$$\delta = Q/u_1 r_1^2 = \text{capacity coefficient} \quad [19]$$

H signifies the pump head and Q its capacity. There exist other coefficients which will, however, be ignored at this time.

Concerning the inlet waterways of the pump, the introduction of a supplementary variable, the suction head, requires a new dimensionless coefficient to follow this variation. It is natural to select as the new variable the analog of the manometric coefficient referred this time to the pump inlet

$$\mu_0 = gh_0/u_0^2 \quad [20]$$

where h_0 is the pressure necessary to make the water penetrate into the pump.

[12] Ingenieure AM et ECP. Ingénieur à la Société Rateau, Paris, France.

It is now possible to express the variations of μ_0, as for example, those of μ as functions of δ. In this study it is advisable to replace the variable δ by the analogous variable δ_0 referred to the inlet diameter of the impeller

$$\delta_0 = Q/u_0 r_0^2 \quad [21]$$

The pressure required to make the water penetrate into the pump may be defined as the difference between the dynamic pressure at the pump inlet and the minimum static pressure in the impeller, in other words

$$h_0 = \frac{V_0^2}{2g} + \left(\frac{w^2 - u^2}{2g}\right)_{\max} - \frac{w_0^2 - u_0^2}{2g} \quad [22]$$

This head is thus independent of atmospheric pressure and of the temperature of the water.

It is impossible to measure h_0 directly. It can be determined

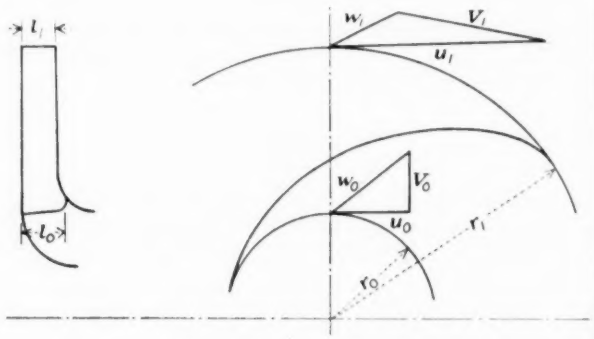

FIG. 5 NOTATION DIAGRAM

FIG. 6 CURVES OF μ VERSUS δ FOR DIFFERENT VALUES OF μ_0

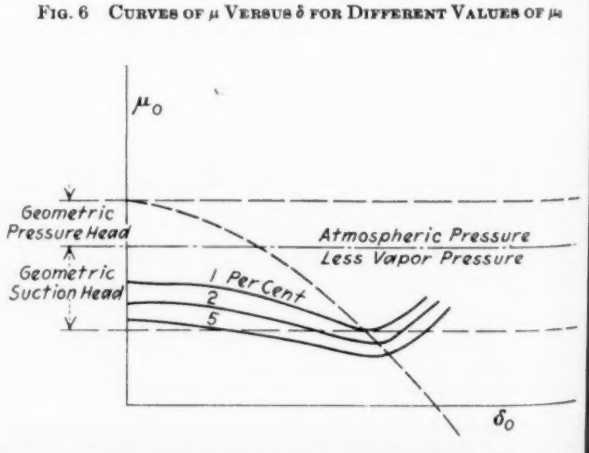

FIG. 7 CURVES OF μ_0 VERSUS δ_0 FOR DIFFERENT CAPACITY REDUCTIONS WITH CONSTANT INLET OPENING

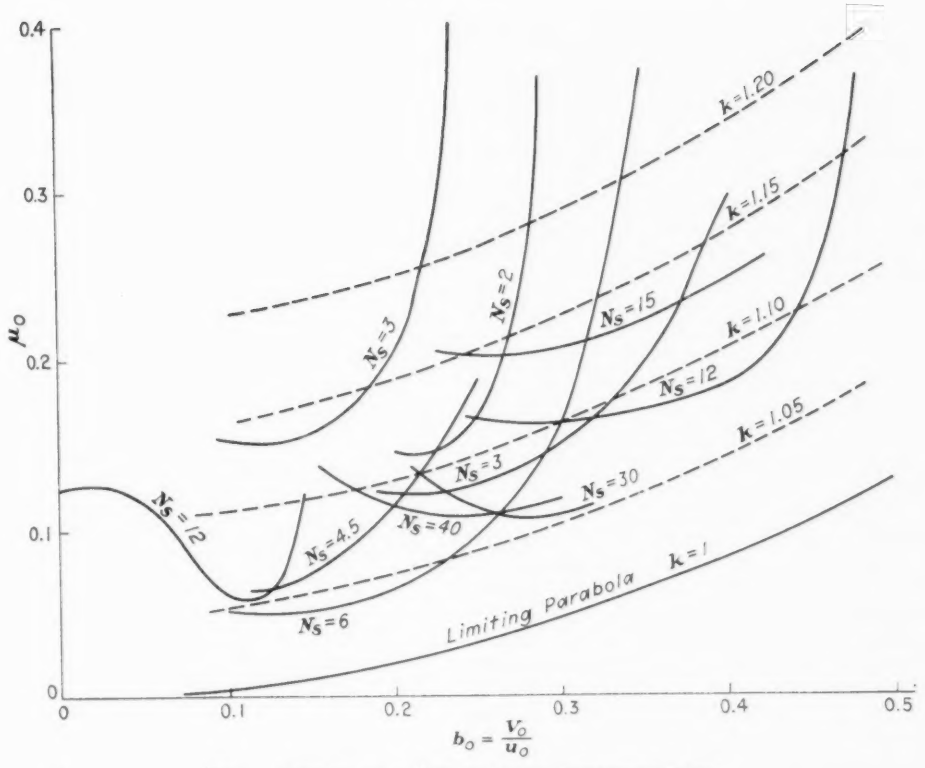

FIG. 8 CURVES OF μ_0 VERSUS b_0 FOR DIFFERENT PUMPS

only as a difference by measuring the suction head of the pump. There remains, however, the difficulty of establishing accurately the beginning of cavitation.

It is known that the curve (μ, δ) of a pump is strongly affected by cavitation as soon as the latter appears. If the suction lift is increased, the curves are noticeably deformed in the region of large capacities which is the most affected. This is due to the well-known drop in pump head and to the fact that the capacity rapidly approaches a limiting maximum value. Some pumps are also affected in the region of low capacities.

If a curve of capacity as a function of suction head is plotted for an opening of known properties, it is difficult to determine the point where cavitation starts to cause a reduction of capacity. For this reason the practice has been adopted of defining the suction head as the head for which the capacity is reduced by a certain percentage, 5 per cent for instance. There is no difficulty in establishing by tests the corresponding suction head and possible arguments can be easily avoided.

The performance of a given pump can then be completely defined by the family of curves (μ, δ) as a function of the parametric value μ_0, Fig. 6, and by the different curves of μ_0 as a function of δ_0 for the desired percentage reduction of capacity for constant opening. The latter curves can be easily derived from points of the former, Fig. 7.

The curves μ_0 make it possible to follow suction performance under different conditions. If the suction circuit has only a geometric static suction head (mine pumps) the characteristic of the circuit is horizontal, Fig. 7, and if the curve μ_0 of a pump has the form shown in the figure, an interruption of the flow may take place, either by increase, or decrease of the capacity. In the more general case the pump circuit has a suction head corresponding to the flow in suction pipe. The characteristic of the circuit will, in this case, be a parabola with its concavity turned downward.

The comparison of curves (μ_0, δ_0) of different pumps gives interesting data concerning the forms of the inlet openings and of the impeller near the inlet.

In order to eliminate entirely the influence of the impeller width at the inlet one can plot cavitation curves by referring μ_0 not to the variable δ_0, but to a variable $b_0 = V_0/u_0$ which is a direct function of the vane angle at the inlet.

The resulting curves, the general character of which is shown in Fig. 8 and which have been used for a long time by the Rateau Company, make it possible to obtain directly interesting data concerning the part played in the total head by the two partial heads

$$h_{01} = V^2/2g$$

$$h_{02} = \left(\frac{w^2 - u^2}{2g}\right) \max - \frac{w_0^2 - u_0^2}{2g} \quad \ldots\ldots\ldots [23]$$

which is, in fact $\mu_{01} = b^2/2$

$$\mu_{02} = \mu_0 - (b^2/2) \quad \ldots\ldots\ldots\ldots\ldots [24]$$

The simple form of the chart giving S as function of N, does not permit this separation. It is, further, necessary to know the relative dimensions of the impeller inlet of the tested pump.

In particular, for axial-flow pump

$$h_{02} = \frac{w^2}{2g} \max - \frac{w_0^2}{2g} = \frac{w_0^2}{2g}(k^2 - 1) \quad \ldots\ldots\ldots [25]$$

where k is a coefficient greater than one, which measures the ratio between the maximum velocity along the blades and the inlet velocity.

This separation makes it possible to obtain directly the value of the velocity coefficient k. The latter is influenced by the profile of the waterways, the wall thickness of the inlet opening, the radii of curvature near the edge of the inlet, and so on. It is possible to plot directly on the cavitation chart lines k = const.

As the coefficient b_0, as abscissa, depends only upon the shape of the inlet opening, the cavitation curves of pumps of different specific speeds are located in various regions of the chart. It is worth noting that in the same region of the chart are located the cavitation curves of entirely different pumps. At the same time, pumps with the same N_s can be treated in the same way though they may be situated in different regions of the chart.

To sum up it might be stated that the μ_0-b_0 chart permits judging directly the properties of the inlets of an impeller and comparing inlets which are otherwise quite different, having, for instance, different values of S and N_s.

The S-N_s chart possesses another inconvenience. The N_s of a pump varies with the location of its operating point. It happens sometimes, despite the precautions taken by the designer, that the location of highest efficiency does not coincide with the location of maximum suction. In such cases it is necessary, to indicate which are the values of capacity and of head used for the calculation of these coefficients, and it would be for instance, illogical to calculate S on the basis of values corresponding to location of maximum suction and N_s on the basis of values corresponding to maximum efficiency.

All this, however, does not detract from the usefulness of the coefficient S recommended by the authors and it is quite possible to use both methods which complement each other. The S-N_s chart will be especially useful for users of pumps and sales departments, while the μ_0-b_0 charts have a greater interest for engineers. On the other hand one might criticize the coefficients S and N_s as not being dimensionless and to changing their value according to location and the system of units used.

It is, however, easy to select instead of S and N_s analogous and proportional coefficients which will remain constant, provided that their different components are expressed in a coherent system of units.

In the writer's opinion, the value simplest to define is

$$N_s = \frac{N(t/\text{min})Q^{1/2}}{(gH)^{3/4}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [26]$$

which can be expressed immediately by means of the Rateau coefficients as

$$N_s = \frac{30}{\pi}\,\delta^{1/2}\mu^{-3/4} \sim 10\,\delta^{1/2}\mu^{-3/4} \quad \ldots\ldots\ldots [27]$$

Similarly, a cavitation coefficient can be expressed by

$$s = \frac{N(t/\text{min})Q^{1/2}}{(gh_0)^{3/4}} \sim 10\,\delta_0^{1/2}\mu_0^{-3/4} \quad \ldots\ldots\ldots [28]$$

The coefficient N_s, as defined long ago is still in current usage, especially in the design of hydraulic turbines. It has not yet gained general recognition in centrifugal-pump engineering. The writer hopes that the authors will make efforts to introduce, at least in this field and, if possible, for general use, a dimensionless coefficient of specific speed of the type just described.

PAUL BERGERON.[13] Thanking the authors for mentioning in their paper the application previously made in France of the properties they have developed, the writer wishes to remark that since 1931 he has frequently and satisfactorily used the principle of adapting the impeller of a pump known with regard to cavitation to a pump of different specific speed. The principle is exact and safe if the specific speed of the pump which has to be designed is lower than the specific speed of the pump taken as a starting point, in other words, if the impeller vanes of the new pump have to be made longer than those of the model pump.

[13] Ingenieur École Centrale des Arts et Manufactures, Paris, France.

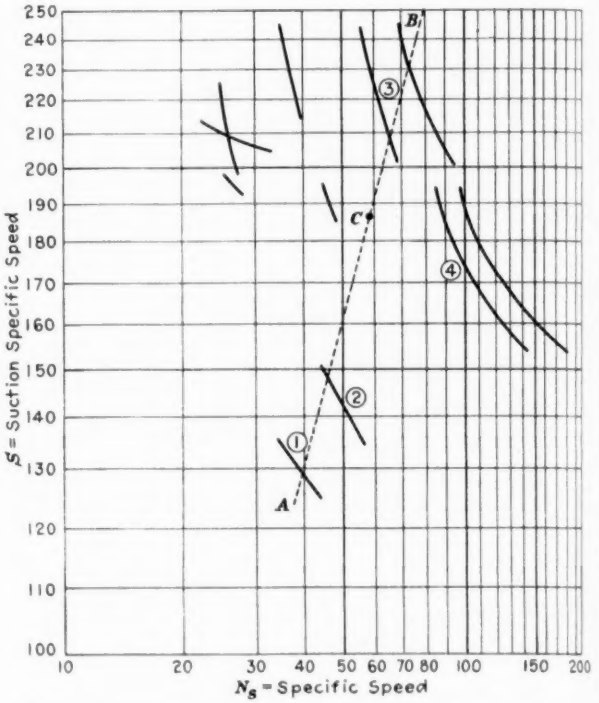

FIG. 9 CURVES OF S VERSUS n_s FOR A PUMP WITH ONE INLET
(Capacities in cubic meters per second, head in meters.)

In the contrary case, the application of the principle is difficult, especially if it has not been preceded by tests of successive cutting down of the impeller of the model pump to determine the zone where the discharge is affected by the suction.

Except for pumps of very low specific speed, the zone affected by the suction is very near the outlet diameter, which latter is determined by the suction possibilities of the pump. In fact, it should be noted that the same head-capacity characteristic may be obtained with two pumps of quite different outside diameter. If these two pumps of identical specific speed are determined, the one which has the greater outside diameter will have a higher suction capacity than the one with the smaller outside diameter, while in general, its efficiency will be less because the friction losses will be higher.

From this it follows that: (1) For a pump designer having sometimes to obtain high efficiency and sometimes to solve problems of high suction lift, pumps of the same specific speed may have quite different suction capacities. (2) Pumps with high specific speed will have a suction capacity (a capacity determined by the coefficient S) lower than that of pumps with low specific speed; in fact, the outside diameter of pumps with high specific speed is necessarily small, which limits the possibilities of developing the suction passages.

As a consequence of the great variety of problems to be solved, the pump designer usually establishes a considerable number of different pumps of which many may have the same specific speeds but different suction capacities. For classifying these different types of pumps, the coefficient S (suction specific speed) becomes important. A pump is, in fact, entirely determined by its specific speed and the coefficient S. If, then, one determines, at each point in the utilizable zone of the head-capacity characteristic of each pump, the value of the specific speed n_s and of S, and if one plots for each pump on a chart the values of S as a function of n_s one can show in a simple diagram all types of pumps available to the designer with all their possible applications.

Fig. 9 shows a partial abstract of a chart which has been used for nine years for the classification of Bergeron pumps. The practical value of such a chart is considerable. Normally, a pump to be designed is determined by the total head H, the capacity Q, and the suction head H_{sv}. From these values one obtains

$$S/n_s = (H/H_{sv})^{3/4} \quad [29]$$

which is represented on a chart by a straight line, for instance, in a specific case, by the straight line AB, Fig. 9. All pumps situated above this line may be taken into consideration: The pumps 1, 2, and 3 cut by this straight line are the extreme pump types which can solve the problem. Each corresponds to a speed obtained from the values of

$$S = nQ^{1/2}/H_{sv}^{3/4} \quad [30]$$

$$\text{or } n_s = nQ^{1/2}/H^{3/4} \quad [31]$$

Questions of speed (in the case of coupling with an electric motor), of efficiency, or manufacturing cost determine the choice between the several admissible types. Let it be assumed that pump 3 is the best suited. If the motor speed nearest to that given for this pump leads to values of S and n_s determining the point C, it will be possible to build a pump strictly similar to 3 which has the same specific speed, but a suction capacity higher than required. If pump 3 did not exist, it would be possible to start out from pump 4 by lengthening the impeller vanes in order to reduce the specific speed, as indicated in the example analyzed in detail by the authors.

In general, it is clear that such a chart makes it possible without further research to utilize all the properties of the pumps which the designer chooses.

In conclusion, without wishing to dwell any longer on this question, it might be said that the idea of combining capacity and suction head with the speed, while disregarding the pump head, is of great practical value because it permits the experienced designer to determine immediately at what maximum speed a pump of given capacity must run to produce a certain suction head.

H. H. Anderson.[14] This paper has been of particular interest and value to the writer. He has not used the parameter S in the form described by the authors but has for some time used the split form, as follows: Instead of

$$S = NQ^{1/2}/H_{sv}^{3/4} \quad [32]$$

plot N^2Q against H_{sv}, Fig. 10.

This gives a curve

$$H_{sv}^{3/2} = N^2Q \quad [33]$$

$$\text{or const} = N^2Q/H_{sv}^{3/2} = S^2 \quad [34]$$

It is convenient to show on the charts of N^2Q the permissible suction conditions of the Hydraulic Institute (American) so that particular test points can always be compared with quoting standards.

The plotting of Hydraulic Institute limits to a basis of N^2Q indicates readily the variation in permissible suction lift due to increase of total head for a given value of N^2Q. This variation is mentioned by the authors: "For the present the additional assumption is that changes in the outer waterways . . . do not affect flow conditions in suction passages. . ."

It will perhaps be useful to see the nature of these variations

[14] Chief Hydraulic Designer, The Harland Engineering Company, Limited, Alloa, Scotland.

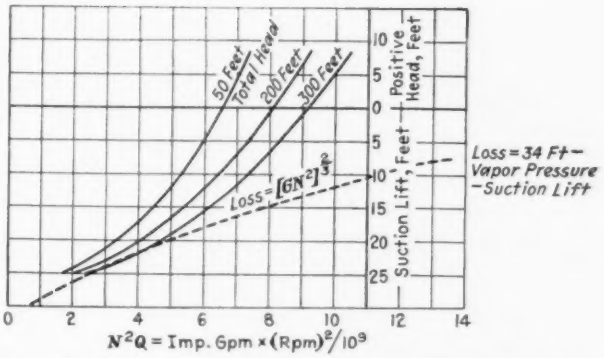

Fig. 10 Maximum Suction Conditions for Single-Entry Impellers
(For double-entry impellers, double gpm.)

from the suction chart based on N^2Q. The writer hopes therefore that his use of $N^2Q = H_{sv}^{3/2}$ will be of interest to the authors in emphasizing the practical value of their paper.

Authors' Closure

Before answering the various discussions the authors wish to call the reader's attention to the fact that the numbers and titles of Figs. 8 and 9 of the paper must be interchanged in order to agree with the illustrations.

The authors wish to thank all those who have given of their time and knowledge in presenting discussions of this paper. There can be no doubt that these contributions from such an outstanding group of engineers form a most valuable addition to the literature on the cavitation problem in general.

Because many of the points brought out in the various discussions have been answered in one or more of the other discussions, the authors will restrict the closure to those important points which remain answered only partially or not at all, and to those points which it will be helpful to reemphasize. In particular the relative merits of the σ- and S-representations and their practical usefulness have been well presented in the discussions by Bergeron, Sedille, and Anderson, and require no amplification.

Mr. Macmeeken in the first part of his discussion analyzed the effect of changes in the impeller inlet diameter on the cavitation performance of the pump. Unfortunately his careful derivations are based on a fundamental misunderstanding of the text. As stated in connection with Equation [8] of the paper the relation S = const must necessarily be true only if the inlet flow conditions are similar. However, if for the same speed of rotation and capacity the inlet diameter is increased, the flow conditions cannot remain similar because the peripheral velocity at the eye of the impeller increases while the flow velocity through the eye decreases. Hence, a discussion of the effect of a change in the inlet diameter based on the equation S = const contains from the beginning a contradiction and must necessarily lead to a contraditcory result.

Neither σ nor S have but one value for a given specific speed. As brought out in the discussion by Bergeron their variations under otherwise constant conditions classify the respective pumps with regard to their cavitation performance in the same way as pumps are classified by their specific speeds with respect to speed, head, and capacity. The classification according to the values of S, however, is approximately independent of the specific speed, while a classification with respect to σ has a meaning only if quoted together with the specific speed. By calculating the S-values for the cavitation points at the conditions given on the curves presented by Mr. Macmeeken, it is found that the second

FIG. 12

example refers to a pump specially designed for high-suction qualities while the other two pumps represent cases of average-suction performance. The comparison on the basis of the respective S-values has the advantage that it shows whether the design of the inlet can or cannot be similar and in which general respects the designs must differ. Had these tests however been made at different instead of the same speeds or on pumps geometrically similar to the ones tested (but of differing physical dimensions), the comparison would not have been so directly obvious but would have been made evident by the simultaneous comparison of the values of σ and N_s, or by the comparison of the S-values alone. It is indeed in the very nature of the parameter S that any changes in the form of inlet design and flow conditions are reflected by corresponding changes in S, while geometrically similar or perfectly equivalent inlet flow conditions are characterized by the same value of S.

The authors have not found that the relation between the net inlet head H_s and the inlet diameter can be expressed generally by Mr. Macmeeken's Equation [6], which equation leads to the conclusion, that, other factors being constant, the inlet head at breakdown is inversely proportional to the first power of the eye diameter. On the other hand it is noted that Mr. Macmeeken independently arrived at Equation [7] which is equivalent to the fundamental relation derived in the paper. It may be of interest to compare Equation [7] of the discussion with Equation [14] of the paper because the latter in connection with Equation [11a] may be written in the form

$$\sigma = \frac{1}{S_N^{4/3}} \times \frac{1}{S_Q^{2/3}} \times N_S^{4/3} \quad \ldots\ldots\ldots\ldots [35]$$

which has the same structure as his Equation [7].

Mr. Macmeeken's caution regarding the use of the parameter S seems to be based largely on the previously discussed misunderstanding regarding the effect of changes in the impeller diameter. Beyond that the authors should like to refer in this respect to Fig. 12 of their closure and to the discussions by Bergeron, Moody, and White.

Regarding the discussion by Professor Moody the authors would like to point out that much of his collection of empirical cavitation-limit points has been included in the accompanying Figs. 11 and 12. It is interesting to note that again the four-thirds-power relation between σ and N_s has been derived previously by somewhat different methods, apparently indicating that this relation is a fundamental one.

The latter fact is once more borne out in the discussion by Stepanoff quoting a publication by von Widdern. Equation [9] of this discussion has been investigated in the past at the Pasadena Laboratory and has also been used by Spannhake in Germany. The subsequent method of deriving the four-thirds-power relation between σ and N_s is interesting but not fundamentally different from that given by the authors.

Referring the σ-values of a pump only to the pump head at best efficiency, H_n, was the procedure originally used at the Pasadena Laboratory, but was dropped for practical reasons. The derived relation of Equation [17] of the discussion is indeed interesting but can be misinterpreted too easily if the underlying definitions are momentarily overlooked.

The authors do not agree with Mr. Stepanoff regarding the fact that all controlling impeller proportions are so well established as to prohibit some changes in the inlet dimensions without corresponding changes in the remaining dimensions. Such changes if carried out by an experienced pump designer have been found to be possible without adverse effects on the efficiency. Naturally, however, if such changes are carried too far they will ultimately reduce the efficiency of the pump, but such sacrifices are made rather frequently in order to obtain exceptional suction performance or a minimum over-all cost.

The authors naturally made sure that the agreement between the shaded area and the lines S = const in Fig. 7 of the paper was not just a coincidence. This was borne out by individual points within the area obtained with pumps furnished by the Worthington Pump and Machinery Corporation. The agreement shown in Figs. 7 and 12 is considerably better than the authors originally expected, and in view of the great simplicity of the underlying principle may well be considered as a startling one.

Mr. Stepanoff's objection to the inclusion of cavitation-performance data on water and *all* oils in one consideration is well founded, inasmuch as the derivation in the paper is based on fluids with well-defined vapor pressures. In other words, the statements made apply principally to one-component liquids, a condition met by but few of the petroleum derivatives. However the discrepancy, with the proper determination of the "head above vapor pressure," is slight and usually well on the side of safety. For highly viscous liquids the failure to hold similar flow conditions between the highly viscous liquid and the nonviscous liquid in geometrically similar inlet passages immediately precludes the possibility of bringing them into one consideration.

Concerning the application of the factor S to turbines, the authors wish to point out that the basic principles apply equally to pumps and turbines, but they are not certain at present whether or not results will be equally valuable.

The discussion by Dr. White must be considered as a particularly valuable one because of the large amount of test data and general experience backing his statements. Figs. 11 and 12 are intended to answer the question as to the relative appearance of a plot of σ- and S-points, respectively, using N_s as a common abscissa. Because of the rigid mathematical relation between σ, N_s, and S expressed by Equation [14] of the paper, both plots (σ-N_s and S-N_s) have to be equally consistent. Regarding the collection of points given, the authors wish to emphasize that this collection intentionally covers a wide variety of designs with greatly differing dates and places of origin. (Only condensate pumps and process pumps for extremely low inlet pressures have not been included because the cavitation limits for such pumps are defined in a different way than for pumps of standard applications and therefore would show misleading extreme values on the diagram.) If only pumps of a consistent series of designs were included the resulting scatter of points doubtlessly would be considerably reduced. On the given diagrams this scatter is further increased by the fact that the points are limits of "safe" operation, which are more difficult to determine than the ultimate-breakdown limits.

It is appropriate to call for caution in the use of any diagram such as shown in Fig. 10 of the paper. In view of the collection of points shown in Fig. 12 such a diagram however, may be used for a quick estimate of cavitation limits over a wide if not the whole range of specific speeds. This fact is illustrated by line A-C in Fig. 11, representing a constant value of S = 7800, on which value the whole diagram of Fig. 10 of the text was based. As pointed out by Professor Moody no diagram or general equation can be expected to give exact cavitation limits for given designs. For such purposes the experimental method doubtlessly will continue to form the only reliable basis for considerable time to come.

The coefficients used in the discussion by Dr. Sedille are physically equivalent to the coefficients S_n and to the ratio S_s/S_n introduced in the paper. The latter ratio was used by the authors when these methods were originally presented before the Hydraulic Institute. It was not included in this paper because the authors wished to maintain a complete analogy between their coefficients and the coefficients already in general use by centrifu-

gal-pump engineers with respect to pump head and capacity. For the same reason the authors did not use the strictly dimensionless form of the new coefficients but they fully agree with Dr. Sedille that such a dimensionless form of all pump coefficients would be highly desirable to use, particularly in international communications.

The form of representation described by Dr. Sedille refers in particular to questions of pump design by including design data of the impeller. On the other hand the authors as well as Dr. Bergeron have focused their attention in this paper primarily on the question of performance characteristics rather than design characteristics. The purpose of this restriction was to make the present paper more concise and easier to understand than would have been possible had a discussion of design characteristics been included. The authors naturally have already extended their investigations into the latter field and find Sedille's contribution in this direction most helpful and appropriate. The authors have been informed that promising work along the lines mentioned in this discussion has already been in progress for considerable time at the Pasadena Laboratory.

Regarding the details of Dr. Sedille's discussion the authors merely wish to point out that the use of Equation [22] seems to require further theoretical investigation with respect to the relative flow conditions in radial-flow impellers. They feel that the rotational character of the relative flow may require some modifications of this equation.

As pointed out in the paper, Dr. Bergeron already has used the parameter S for a considerable number of years. His discussion therefore, presents a mature and elegant interpretation of this parameter. Bergeron points out that the performance of any pump is completely defined by two parameters, N_s and S, so that the performance of all pumps can be represented in a two-dimensional field, i.e., on an S-N_s diagram. By the sample given he indicates that the performance of every pump is described by a curve on this diagram, and he shows how a collection of such curves, corresponding to the points on Fig. 12, can be used for the selection of a pump for given operating conditions. The two parameters N_s and S may not be completely independent of each other, depending on the behavior of S as a function of N_s. Bergeron is of the opinion that, for high and medium specific speeds, S tends to increase only if N_s is reduced. This statement is probably true if, as he assumes, the pump of higher specific speed is developed from the pump of lower specific speed by a reduction in the length of the vanes. However, the specific speed may be increased also in different ways such that the average vane pressure decreases, in which case the change of S as a function of N_s may not follow the trend given in the discussion. The authors therefore feel that this relation between S and N_s depends entirely on the method of design by which the changes in N_s are produced. In addition to a certain freedom of choice on the part of the designer this method will depend largely on the type of pump, i.e., the range of specific speeds in question so that the trend of changes of S as a function of N_s may not be the same for the whole range of specific speeds. Finally it has to be pointed out that Bergeron's conclusions apparently are derived on the basis of cavitation limits directly related to the ultimate cavitation breakdown (ultimate capacity) of the pump. His conclusions might have been different if the considered cavitation limits were based on the conditions under which the influence of cavitation begins to be noticeable. Generally speaking it is therefore necessary to state always the type of cavitation limit considered in order to define completely the physical meaning of subsequent conclusions.

The discussion of Mr. Anderson is very helpful and once more confirms the fundamental four-thirds power relation derived in the paper and so frequently appearing in the discussions.

A Supersensitive Governor for Hydraulic Turbines

By W. M. WHITE,[1] MILWAUKEE, WIS.

A supersensitive governor is defined in this paper as one that will move the gates of a hydraulic turbine in the corrective direction by reason of a change of speed of 0.02 per cent and will then move the gates back by reason of a change of the speed back to the former speed. The author outlines the elements essential to a supersensitive governor in order to accomplish this fine degree of regulation. The application of these principles to governor design is then outlined.

THE essential elements in a supersensitive governor, as defined, to accomplish the fine degree of regulation of the gates of a hydraulic turbine, as well as for governing the turbine under other conditions, are:

1 A frictionless, sensitive, powerful flyball.

2 Means for causing rotation of the flyball in exact ratio to the rotation of the turbine shaft or, as an alternative, in exact ratio to the cycles of the system.

3 Means for translating the minute axial motion of the flyballs, due to a change of speed of 0.02 per cent, to proportionate movement of the turbine gates without causing an opposed force to the axial movement of the flyball sufficient materially to affect the ratio of speed and axial motion of the flyball when free.

4 Means for causing a predetermined droop in speed in proportion to the gate opening of the turbine.

5 Momentary means for increasing greatly the ratio of speed change to gate motion on sudden changes of load, thus making use of the connected flywheel effect for stabilizing the speed during the slowing up of the rate of movement of turbine gates to prevent disastrous pressure changes, caused by the inertia of the water columns to and from the turbine.

The frictionless flyball of the supersensitive governor is a combination of springs and weights so related that movement of the actuating stem of the flyball is caused by the flexure of the springs without any moving joints. The centrifugal force of two revolving flyballs is resisted by coiled springs between the two, and this combination is driven and supported by multiples of flat steel springs between the fixed driving head and the flyball weights. Axial motion to the floating collar is imparted by other multiple flat springs fixed between the flyballs and the axially moving collar which is supported only by, and revolves in, a sleeve bearing. The axially moving collar surrounds but does not touch the supporting shaft between the fixed driving head and a lower bearing. The axial motion of the floating collar is imparted to a pilot-valve stem through a slot and hole in the governor shaft, being held in position at its upper end only by the connection to the axially moving collar and at its lower end by the bearing of this revolving pilot valve in its ported sleeve. By this combination is secured a pilot valve rotating in its sleeve and the actuating collar revolving in its sleeve bearing, thus having no friction to axial motion imparted by flexure of multiple springs rigidly fixed to the flyball.

Therefore, the force produced by the weights of the flyball under minute speed changes are translated to the rotating pilot valve with only the resistance of the molecular friction of the springs and the floating rotating spring support.

The sensitivity of the flyball is secured by driving it at the high speed of 900 rpm. Because of this high speed and terrific power of the flyball weights at this speed, the slightest change of speed provides sufficient power to give immediate movement to the pilot valve. A powerful flyball is secured by making the flyball and particularly the weights of such size that a minute change of speed supplies considerable energy to move the pilot valve.

The curve shown in Fig. 1 gives the ratio of a change of speed

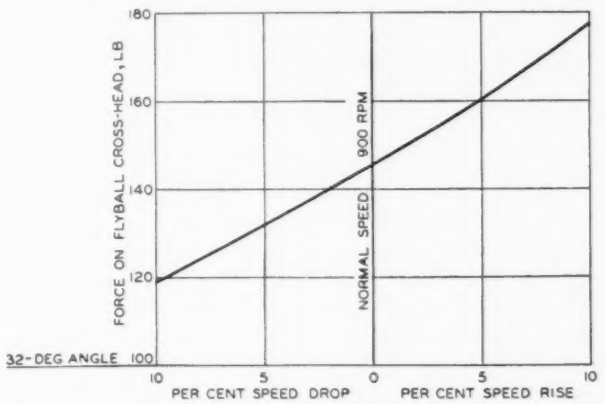

FIG. 1 ENERGY CURVE FOR 900-RPM SUPERSENSITIVE FLYBALL

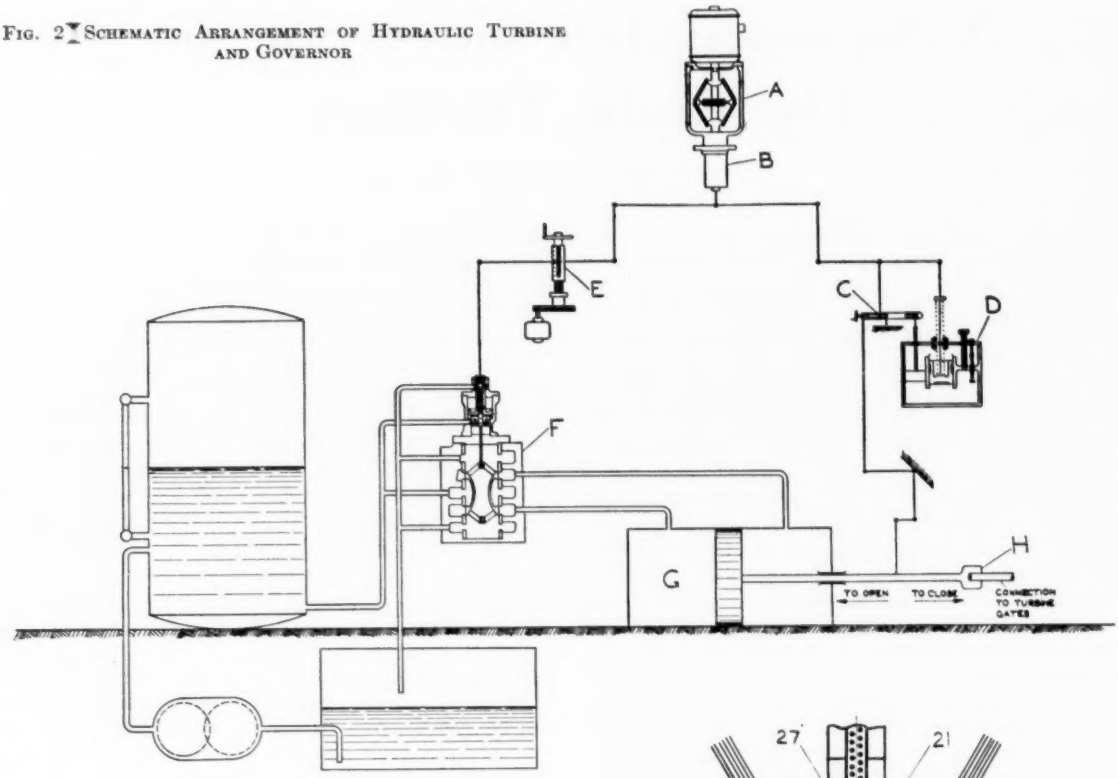
and force at the pilot valve. From this curve, it may be seen that the range of the flyball is through a speed of 10 per cent above normal down to 10 per cent below normal and that the power of the flyball is 35 lb on the stem, when the stem is held in a position of normal speed and the flyball speeded up to 10 per cent above normal speed. When, however, a change of speed of 0.02 per cent takes place, it produces a force of 0.05 lb on the pilot valve. Because of the requirement of action within a very small speed change, the force from the flyballs to move the pilot valves is greatly reduced and means for amplification of this force is shown hereafter. The transverse coil spring provides means for adjusting the flyballs to the desired range of speed change of the flyball for maximum travel of the pilot valve. A more detailed description will now be given so that the action of the flyball may be followed by reference to Fig. 2.

DESCRIPTION OF FLYBALL-GOVERNOR MECHANISM



In Fig. 3, the upper fixed support of the flyball (4) is rigidly doweled to the driving motor shaft and held in position by the bearings of the motor. Between the movable flyball support (21) and the fixed support (4) are supported the flyball weights (13) by flexible springs (14) as indicated. Support (21) revolves in the sleeve bearing (25), also shown in enlarged detail in Fig. 4. The flat springs (14) act only as connecting members between the flyball weights, the fixed support, and the movable support.

FIG. 2 SCHEMATIC ARRANGEMENT OF HYDRAULIC TURBINE AND GOVERNOR

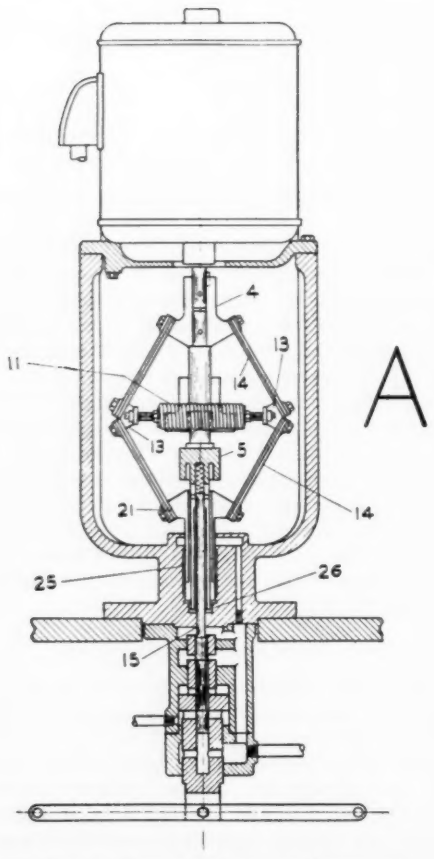

FIG. 3 DETAIL OF FLYBALL GOVERNOR

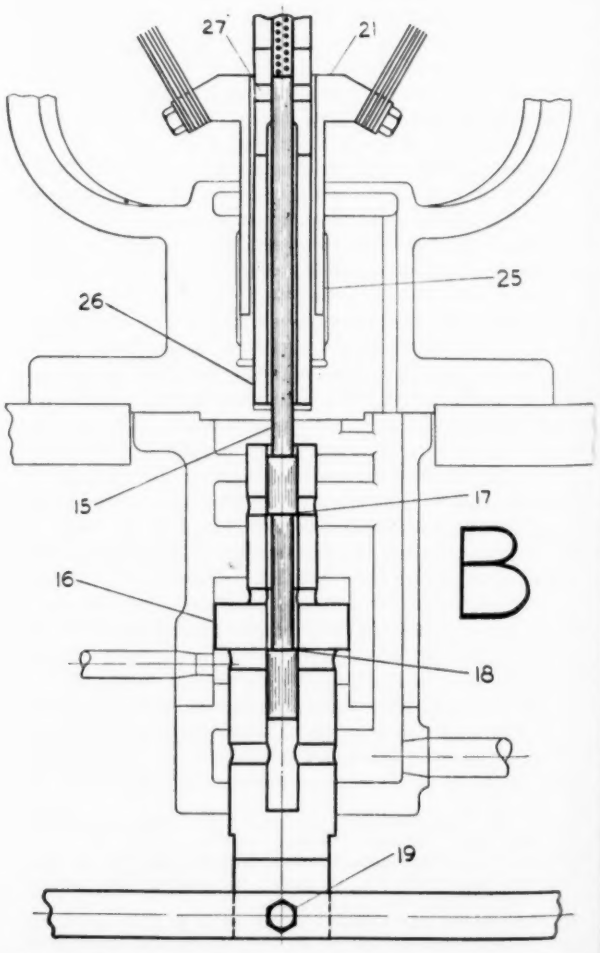

FIG. 4 ENLARGED DETAIL OF FLYBALL-GOVERNOR BEARING

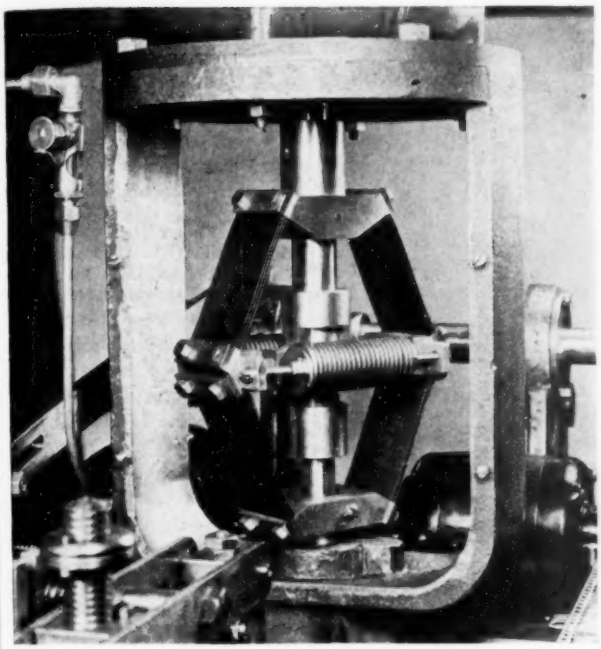

FIG. 5 ASSEMBLY OF NEW SUPERSENSITIVE FLYBALL FOR HYDRAULIC-TURBINE GOVERNOR

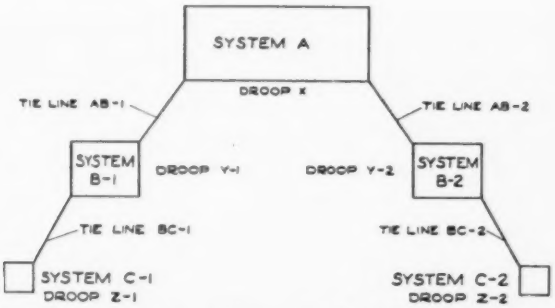

FIG. 7 SCHEMATIC ARRANGEMENT OF FIVE HYDROELECTRIC SYSTEMS INTERCONNECTED BY FOUR TIE LINES

Transverse springs (11) serve to hold the flyballs in fixed position for a given speed. The moving parts are held in the axis of rotation by the shaft (5), one end of which is doweled to the motor shaft, the other end being supported in a lower bearing located centrally of, but not touching, the axially moving support (21). The shaft (5) is bored to carry within but not to touch the pilot-valve stem. It is also slotted, through which a cross pin fixes the axially moving collar (21) to the pilot valve.

By means of the double sleeve bearing (25), shown in Fig. 4, supporting the shaft (5) and support (21) apart from each other, static friction is thus avoided which is one of the essential features of this flyball. It is this double bearing feature which makes the flyball frictionless in respect to the actual motion of the pilot

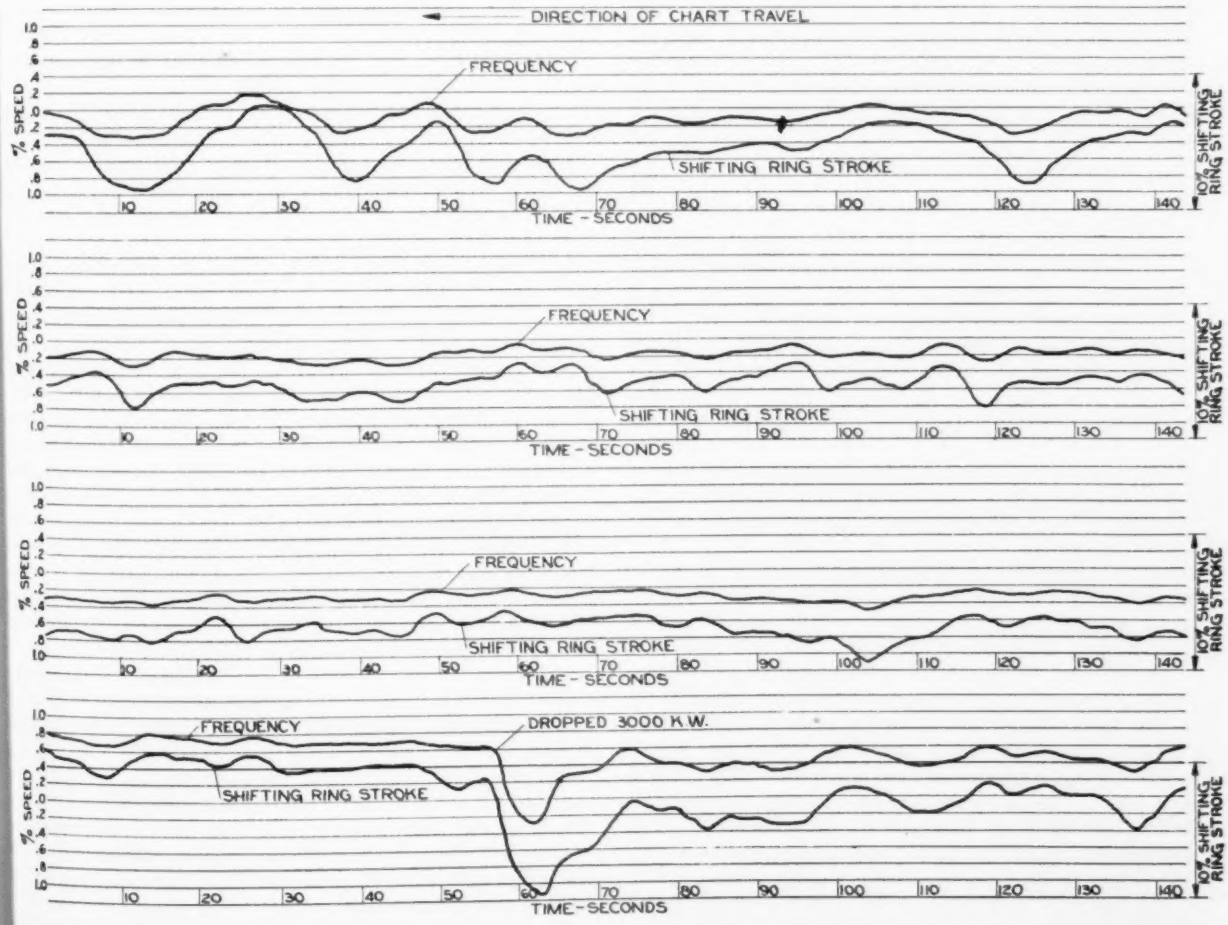

FIG. 6 SIMULTANEOUS RECORDINGS OF FREQUENCY AND SHIFTING STROKE OF A SUPERSENSITIVE-GOVERNOR INSTALLATION

FIG. 8 FRONT VIEW OF CONTROL BOARD USED ON GOVERNOR FOR PICKWICK LANDING DAM, TENNESSEE VALLEY AUTHORITY, APRIL, 1938

valve and enables such fine degree of regulation to be secured.

A properly designed and proportioned belt-driven flyball has heretofore provided a degree of regulation within 0.5 per cent but, as the demands for closer regulation have increased, a more exact ratio of speed of flyball to rotating turbine shaft has been necessitated, or a more exact ratio of the speed of flyball to the cycles of the system.

A separate generator for driving the motor-driven flyball is the best known means at present of maintaining a fixed ratio between the flyballs and turbine shaft. Transformers connected to the system for driving these flyballs is the best known method of providing a fixed ratio between the speed of the flyballs and the cycles of the system. A fine degree of regulation has been attained by both of these methods. The author believes that the latter method will ultimately prove to be preferable for maintaining the exact ratio between cycles of the system and rotation of the flyball essential to the most perfect regulation. As the load changes and, particularly, as the power factor of the generator changes, as it does during the load change and during the power-factor change, a difference occurs between the normally fixed ratio of rotation of turbine shaft and cycles of the system because the pole pieces take up different positions under the foregoing conditions with respect to the rotating field. It is true that this difference is minute but, since we are straining for the most minute regulation possible, it may be that we will have to have that definite relation between rotation of flyball and cycles of the system which is afforded by using transformers for driving the motor-driven flyballs.

Means for translating the minute axial motion of the flyball collar, caused by a change of speed of 0.02 per cent with little resistance to its movement, comprises a pilot valve $^1/_2$ in. in diam, controlling admission of oil pressure to two sides of a $2^1/_4$-in-diam piston. The diameter of the piston is made small so that only a minute volume is displaced by a movement of the pilot valve corresponding to a change of speed of 0.02 per cent. The reaction around the sharp edge of the pilot valve and its corresponding port which causes axial force on the pilot valve is, of course, in proportion to the velocity through the port, the amount of opening of the port, and the diameter of the valve. By making the diameter small, the volume and consequently the velocity is kept so low as to avoid unfavorable reactions.

By this hydraulic multiplication, the axial force is multiplied 1000 times for use in moving the main pilot valve of the governor. The piston follows the pilot valve so closely that measurements made show a difference between the position of the two in normal operation not greater than 0.001 in. The pilot valve (15), Fig. 3, coacts with a combined sleeve and piston (16) having ports (17) and (18). In the old type of governor, the flyball spindle was directly connected to the floating lever at point (19). This hydraulic multiplying device gives the required force at the point (19) to operate the floating lever of the governor with the minute speed change.

Fig. 2 is a diagram of a governor in which the supersensitive flyball is illustrated at A, the multiplying device at B, and the means for causing speed droop at C. The essential elements of the remaining parts of the governor are the same as heretofore used, except that the restoring mechanism is made unusually rigid to provide for an exactness of motion which will permit division of load between the units when the speed droop is of the order of 0.5 per cent.

Fig. 6 gives the plottings of simultaneous recordings of frequency and shifting stroke of a supersensitive-governor installation. From these curves it is readily seen that the gate motion follows a change of frequency of 0.02 per cent.

The supersensitive governor, by reason of its fine degree of regulation, provides for a division of load between such units with much less speed droop than has heretofore been secured in practical operations. It is believed that the supersensitive governor will afford an additional means of operating systems in parallel with one another over tie lines of less kilowatt capacity than either of the interconnected systems.

Reference is made to Fig. 7, in which the five blocks represent five hydroelectric systems which are interconnected by four tie lines as indicated. The supersensitive governor provides means for moving the gates of all of the turbines in all of the stations simultaneously with a speed change of 0.02 per cent. The speed droop of the governors in each of the systems may be made different from that of the others to cause such relative change of gate in each unit in the system as will result in a minimum change of power in the connecting line.

Because of the sensitivity of the governor, the speed droops may be set as low as 0.1 per cent in some groups with fair division of load between units and as high as 6 per cent in another group to provide a large gate movement for a given change of speed in one group with a resulting smaller change of gate opening in another unit of the system.

The possibilities of the supersensitive governor for the regulation of systems of tie lines have not been fully explored.

Power Swings in Hydroelectric Power Plants[1]

By W. J. RHEINGANS,[2] MILWAUKEE, WIS.

Power swings chargeable to hydraulic turbines have been found in hydroelectric plants built as far back as 1912. However, it has only been during the last ten years that much thought has been given to such swings, their characteristics, source, and elimination. The purpose of this paper is to supply technical data on the subject and to start such discussion as may lead to a better understanding of the problem. The paper shows that power swings are due to draft-tube surges. It deals with the characteristics of such surges, their relation to power swings, the elimination of surges and power swings in the field, if necessary, and a consideration of the factors of the design of a hydroelectric unit which will prevent small draft-tube surges from producing excessive power swings. However, the paper does not present a theoretical analysis of the true origin or source of draft-tube surges, which is a matter for further observation and study and for future discussion.

THE power swings referred to in this paper are the fairly regular swings readily apparent in hydroelectric power plants on the switchboard indicating instruments, such as the ammeters indicating generator-armature current and the indicating wattmeters. A distinction is made between power swings and load swings in that the former is defined as being a pulsation in power output of a generating unit, while a load swing is the fluctuation on a transmission and distribution system due to change in load demand.

Power swings may be identified by their regularity and frequency, which is roughly one third of the speed of the unit. Thus they are too fast and too regular to be accounted for by any of the usual normal changes in demand for load. The amplitude of the power swings may be anywhere between 5 per cent to practically 100 per cent of the output of the unit. Such swings are found only in connection with Francis- and propeller-type turbines, which eliminates impulse turbines from consideration.

Although power fluctuations can be produced by governor hunting, those which are to be discussed occur with the turbine guide vanes held in a fixed position, either mechanically or by the governor.

Power swings in hydroelectric power plants are not a new occurrence of recent years, since they are found in plants built as far back as 1912. In those days they attracted but slight attention because they were causing no trouble and were not considered harmful to the operation of a power system. Today, with the development of long transmission lines, power swings, while actually having caused trouble in only a few cases, are sometimes suspected of being the source of increased transmission-line instability.

Sensitive Switchboard Indicating Meters Developed

One factor responsible for centering attention upon power swings recently has been the development of sensitive electrical switchboard indicating meters which have very little damping effect. The meters in the older plants were quite sluggish, thus minimizing any existing fluctuations. The newer meters are built for greater accuracy and greater sensitivity; thereby, the damping effect has been reduced. They will overtravel during a quick power change, the overtravel being particularly pronounced when there are comparatively rapid and regular fluctuations in power output. Units having any tendency toward swings cause the meters to indicate greater power fluctuations than actually exist. Tests at one plant showed that the indicating meters were overtraveling 20 to 30 per cent during power fluctuations.

This is not meant as a criticism of the electrical meters, since they function correctly under ordinary circumstances and do not overtravel for slow changes. It does mean that in many cases the overtravel of sensitive switchboard indicating meters calls attention to power swings which, under other circumstances, would be disregarded.

However, sensitive undamped meters do not account for the several cases during the last ten years where the magnitude of the power swing was so great as to make it impossible to keep the units in parallel with other units on the line. It is therefore only natural that engineers are giving more and more thought to locating the source of power swings and to their elimination or prevention.

A search of the literature on the subject shows practically no mention of power swings as thus defined. During some of the discussions at National Electric Light Association meetings about ten years ago, power swings were mentioned as a probable contributory source of electrical instability, but no effort was made to analyze them in detail. Therefore, it was thought a paper at this time on the characteristics, source, elimination, and prevention of power swings, based on ten years' experience in their observation, study, and analysis, would be a valuable contribution to the art.

Power Swings Closely Related to Draft-Tube Surges

There is now no longer any question but that power swings, such as are chargeable to the hydraulic turbine, are closely related to and dependent upon surges in the draft tube. This is definitely established from the characteristics of the swings and of the draft-tube surges.

Draft-tube surges do not occur in all turbines. Where they are absent, there are no power swings that are chargeable to the turbine.

Power swings are accompanied by surges in the draft-tube vacuum or pressure of exactly the same frequency and by an audible swish in the draft tube of similar frequency, Figs. 1 and 8.

Power swings always occur over a short range of gate openings. They build up quickly to a maximum amplitude and disappear at higher or lower gate openings. Fig. 2 shows a typical curve of amplitude plotted against per cent gate opening. The surges in the draft-tube vacuum or pressure follow this same tendency of building up to a maximum at the same gate opening at which the

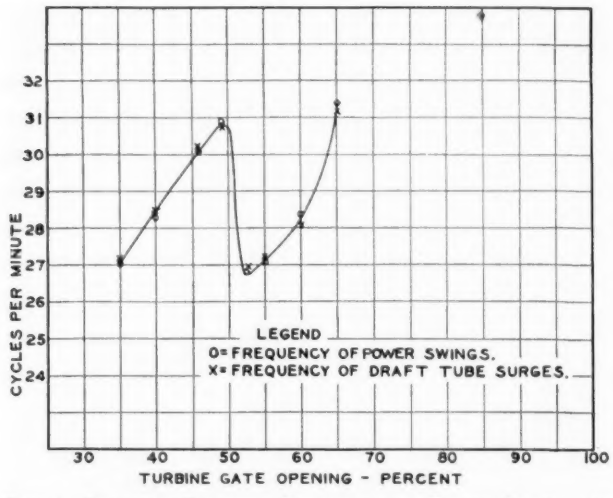

FIG. 1 RELATION BETWEEN FREQUENCY OF POWER SWINGS AND DRAFT-TUBE SURGES FOR VARIOUS GATES ON A TURBINE
(At gates below 35 per cent and above 65 per cent, power swings and draft-tube surges disappeared, therefore, no frequencies could be noted.)

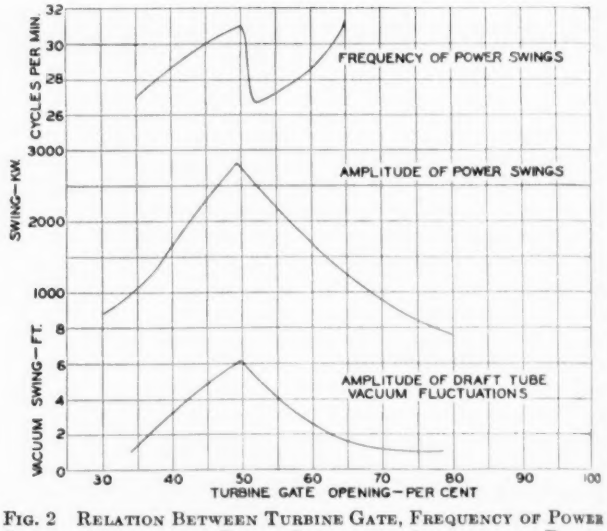

FIG. 2 RELATION BETWEEN TURBINE GATE, FREQUENCY OF POWER SWINGS, AMPLITUDE OF POWER SWINGS, AND AMPLITUDE OF DRAFT-TUBE SURGES
(Below 35 per cent and above 65 per cent gate, power swings, and draft-tube surges were so small and irregular that no frequencies could be determined.)

maximum power swing occurs. The same is true of the audible swish in the draft tube.

The range of frequency of the power swings eliminates the possibility of their being a direct function of the turbine speed in combination with the number of guide vanes or runner vanes.

The deciding factor, however, is that the power swings can be eliminated or greatly reduced by admission of air to the draft tube, or by making physical changes in the draft tube, thereby changing the flow conditions. This would not be possible, however, if the power swings were not dependent upon the draft-tube surges.

The manner in which the draft-tube surges produce the power swings is as follows: The fluctuations in draft-tube vacuum or pressure cause a fluctuation in the effective head on the turbine and thereby cause a fluctuation in the discharge. The fluctuations in discharge then produce a further fluctuation in penstock pressure due to water hammer. This is proved by the fact that draft-tube surges are always accompanied by penstock pressure fluctuations of similar frequency. In short penstocks the amplitude of the penstock fluctuation is small. In long penstocks the amplitude is always an appreciable amount and, under certain conditions of length of penstock as related to frequency of fluctuation, may assume serious proportions, Fig. 3. Since the elimination or change of draft-tube surges always eliminates or changes the penstock pressure fluctuations, it is certain that the draft-tube surges produce the penstock pressure fluctuations and not vice versa.

Observation has shown that the penstock pressure fluctuations are usually in phase with the draft-tube surges. As the vacuum in the draft tube increases, the penstock pressure increases and vice versa. Thus the penstock pressure fluctuations may combine with the draft-tube surges to create a change in head on the turbine, which produces a variation in torque on the runner. Since the turbine is connected to a generator, the electrical connection of which to a transmission system is in the nature of a spring, it is apparent that a regular variation in torque on the turbine runner can produce a corresponding oscillation in the generator output.

MAGNITUDE OF POWER SWINGS

The magnitude of the power swings also depends upon the relation between the frequency of the draft-tube surges and the natural frequency of oscillation of the generator connected to the power-transmission system. By causing a fluctuation in the torque on the turbine runner, the draft-tube surges will impress corresponding variations on the generator output. The generator connected to the transmission system has a natural frequency of its own which should not be confused with the alternating-current frequency of the system. Since the electrical connection between the turbine and the transmission system is in the nature of a spring as noted, the unit, when tied to the transmission system, will follow the laws of vibration. These laws state that a periodic disturbing force will produce forced vibrations in a vibrating body and that the amplitude of the forced vibrations will depend upon the magnitude of the disturbing force and upon a magnification factor. As the name implies, the magnification factor is a multiplier, applied to the amplitude of vibration, which amplitude corresponds to the disturbing force acting upon a vibrating body. The size of the magnification factor depends upon the amount of damping in the vibrating body and upon the relation between the frequency of the disturbing force and the natural frequency of the vibrating body.

When the periodic disturbing force has a low frequency compared with the natural frequency of vibration of the vibrating body, the magnification factor approaches unity. When the disturbing force has a very high frequency compared to the natural frequency of the vibrating body, the magnification factor approaches zero. However, when the frequency of the disturbing force approaches the natural frequency of the vibrating body, the magnification factor becomes very large. This relation is illustrated in Fig. 4, where the magnification factor is represented as a function of the ratio between the disturbing-force frequency and the natural frequency of the vibrating body.

The amount of damping in the vibrating body also affects the value of the magnification factor, especially when the disturbing force approaches resonance with the natural vibrations of the vibrating body. This is illustrated in Fig. 4, where the magnification factor approaches infinity at resonance, when there is zero damping.

In the case of a hydroelectric unit, the draft-tube surge is the periodic disturbing force and the rotating element of the turbine and generator connected to the transmission system is the vibrating body. This presents a problem similar to that of a pulsation

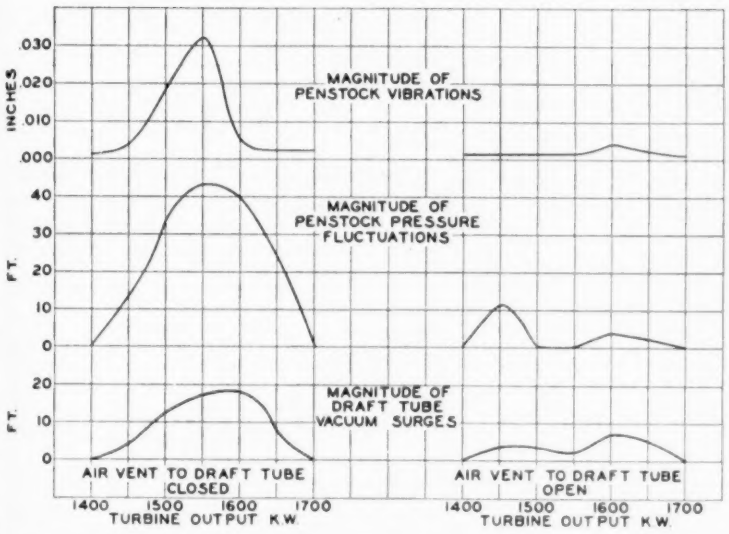

FIG. 3 RELATION BETWEEN MAGNITUDE OF DRAFT-TUBE VACUUM SURGES, PENSTOCK PRESSURE SURGES, AND PENSTOCK VIBRATIONS AT VARIOUS LOADS WITH AIR VENT TO DRAFT TUBE CLOSED AND THEN OPENED

(Turbine, 1700 kw, 260 ft head, 900 rpm. No power swings present; frequency of vibrations, surges, and fluctuations 320 per min.)

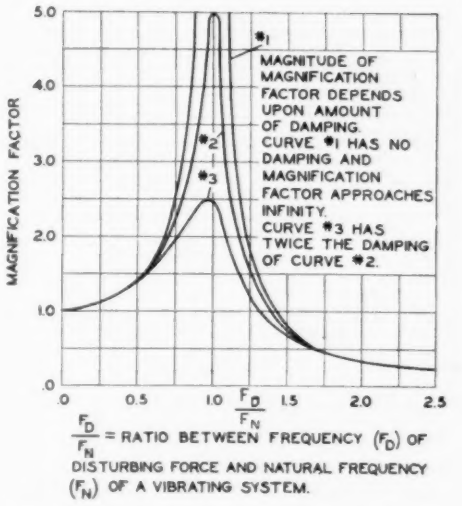

FIG. 4 VARIATION IN MAGNIFICATION FACTOR FOR DIFFERENT VALUES OF RATIO BETWEEN FREQUENCY OF DISTURBING FORCE AND NATURAL FREQUENCY OF A VIBRATING SYSTEM

in power where an internal-combustion engine (reciprocating drive) is used to drive a generator.

At this point, it should be emphasized that, in making this comparison, the vibrations of the rotating element refer to an oscillation in the speed of the rotating parts and do not refer to a mechanical vibration of the unit.

In the hydroelectric unit, when the frequency of the draft-tube surge approaches the natural frequency of oscillation of the generator connected to the transmission system, the magnification factor will be large and a small fluctuation in torque on the runner can produce a very large forced swing in generator output. It is a condition of this sort, combined with low damping in the generator, which produces power swings approaching the full rated output of the turbine.

Damping in a generator may be increased by use of amortisseur windings which would reduce the magnification factor and thus prevent serious power swings. However, it should be noted that damping is effective only when the disturbing force is near resonance with the natural vibrations of the vibrating body. When the frequency of the disturbing force is more than 30 per cent higher or more than 30 per cent lower than the natural frequency of the vibrating body, damping has very little effect on the magnification factor. Therefore, so long as resonance conditions are avoided, it is not practical to increase the damping of the generator for the sole purpose of reducing possible power swings.

The author knows of only one case in which the combined draft-tube surge and penstock-pressure fluctuation was of sufficient magnitude to produce a fluctuation in torque on the runner corresponding to a power fluctuation greater than 10 per cent of the rated turbine output. In this one exceptional case, the fluctuation in torque on the runner was 30 per cent of the rated output, but the frequency of the torque fluctuation was so high compared to the natural frequency of the generator that there were no power swings, Fig. 3. In those cases, where the power swings exceeded 10 per cent of the rated turbine output, the fluctuations in torque were being multiplied due to conditions approaching resonance.

PREVENTING RESONANCE TO ELIMINATE POWER SWINGS

Thus, if it is possible in the design of a hydroelectric unit to prevent resonance conditions, the possibility of obtaining large power swings will be eliminated. In order for the designer to determine whether a condition of resonance will be approached in a proposed hydroelectric unit, he must know the frequency of the draft-tube surges, if present in the proposed turbine, and the natural frequency of the generator as connected to the transmission system. The frequency of the draft-tube surges can be determined approximately from an empirical formula based upon the following observations:

In one case the speed of the turbine was varied while carrying a water-rheostat load and the frequency of the draft-tube surge

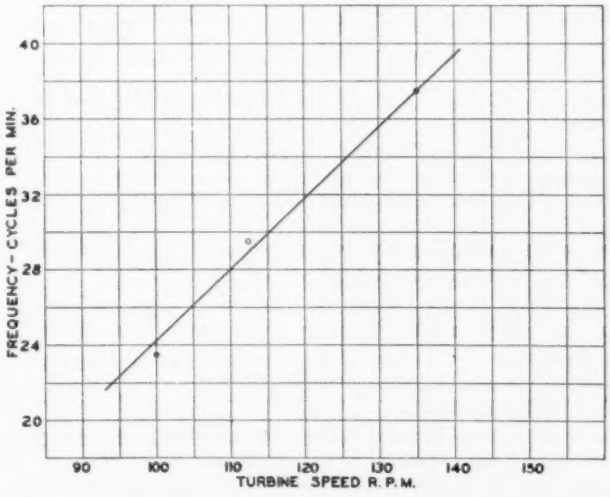

FIG. 5 RELATION BETWEEN SPEED OF A TURBINE AND FREQUENCY OF DRAFT-TUBE SURGES

(Data taken from one turbine by varying its speed while on water-rheostat load.)

was determined for various speeds. The results of this test are shown by the curve Fig. 5, indicating that the frequency of the draft-tube surge varies directly with the speed of the turbine.

Based on extensive data obtained from various sources, it was

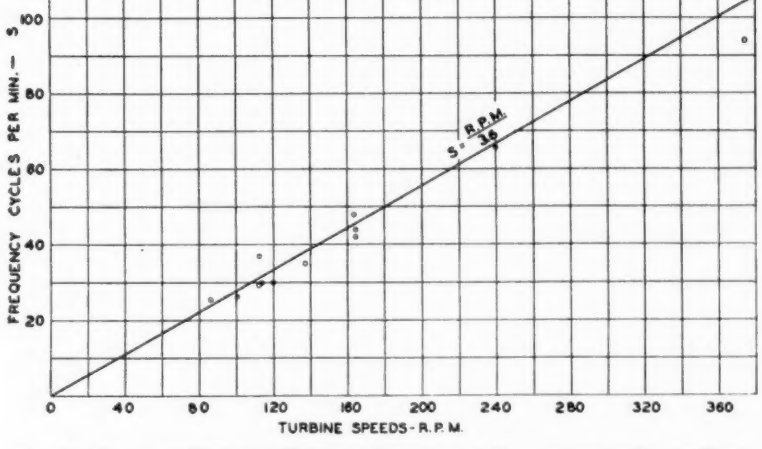

FIG. 6 RELATION BETWEEN TURBINE SPEEDS AND FREQUENCY OF DRAFT-TUBE SURGES AND POWER SWINGS
(Data taken from field observations on turbines in various power plants.)

also found that the frequencies of draft-tube surges and power swings have a rough relationship to the speed of the unit for various types and sizes of turbines, Fig. 6. This relationship can be expressed empirically as

$$S = \frac{\text{rpm}}{3.6} \quad \ldots\ldots [1]$$

where S = approximate frequency of draft-tube surge in cycles per min
rpm = speed of turbine in revolutions per min

The natural frequency of the generator connected to a transmission system depends upon the generator characteristics and transmission-line characteristics. This formula is

$$F = \frac{35200}{\text{rpm}} \sqrt{\frac{Pr'' \times f}{WR^2}} \quad \ldots\ldots [2]$$

where
F = natural frequency in cycles per min
rpm = revolutions of unit per min
f = alternating-current frequency of system in cycles per sec
WR^2 = weight in lb of entire rotating mass of unit times the square of its radius of gyration in ft

$$Pr'' = \frac{Pr\ Pr'}{Pr + Pr'}$$

where
Pr = synchronizing power of generator in kw per electrical radian
Pr' = kw per electrical radian displacement between generator voltage and transmission-line voltage. This displacement is a function of transmission-line characteristics such as line reactance, line resistance, and load carried on line.

It is not within the scope of this paper to explain the various combinations of generators and transmission lines in detail, since the calculations can be made by anyone familiar with the theory and design of synchronous machines. However, Equation [2] may be simplified by assuming the generator to be connected to an infinite system, i.e., a system having constant voltage and constant alternating-current frequency. Equation [2] will then be

$$F = \frac{35200}{\text{rpm}} \sqrt{\frac{Pr \times f}{WR^2}} \quad \ldots\ldots [3]$$

In the design of a hydroelectric unit, a regulation constant is used to give an indication of the degree of stability and the regulating qualities of the unit under consideration. The formula for the regulating constant is

$$C = \frac{WR^2 \times (\text{rpm})^2}{\text{hp}} \quad \ldots\ldots [4]$$

where C = regulating constant
hp = rated output of turbine in horsepower

From Equation [4]

$$WR^2 = \frac{C \times \text{hp}}{(\text{rpm})^2} \quad \ldots\ldots [5]$$

Substituting this value of WR^2 in Equation [3]

$$F = \frac{35200}{\text{rpm}} \sqrt{\frac{Pr \times f \times (\text{rpm})^2}{C \times \text{hp}}}$$

$$F = 35200 \sqrt{\frac{Pr \times f}{C \times \text{hp}}} \quad \ldots\ldots [6]$$

Although Pr, the synchronizing power of the generator, depends upon the load on the generator, the generator voltage, and power factor, as well as upon generator-design characteristics, for rough approximation, it can be assumed that

Pr = 2.3 kw rating of the generator

But the kw rating of the generator corresponds approximately to the output of the turbine.

Therefore

$$Pr = 1.7 \text{ hp (approximately)} \quad \ldots\ldots [7]$$

and Equation [6] becomes

$$F = 35200 \sqrt{\frac{1.7 \text{ hp} \times f}{C \times \text{hp}}}$$

$$F = 46000 \sqrt{\frac{f}{C}} \quad \ldots\ldots [8]$$

This shows that regardless of the size, type, power-output rating, speed of the unit, or head on the turbine, the natural frequency of its generator connected to an infinite transmission system is a function of the system frequency and the regulating constant C. The natural frequency of generators connected to a finite system will also be a function of the system frequency and regulating constant C, but due to factor Pr'', the natural frequency in these cases will be lower than if the generator were connected to an infinite system.

ELIMINATING CONDITIONS OF RESONANCE

Thus, when the designer finds that he will have the unfortunate combination of draft-tube surge frequency and natural frequency of the generator connected to a particular distribution system which gives resonance conditions, he can change the speed of unit without changing the regulating constant, he can change the regulating constant without changing the speed of the unit, or be

can change both, in order to prevent such resonance conditions.

If the designer changes the speed of the unit but finds it desirable to retain the same regulating constant, a change in WR^2 of the unit will have to be made. With the regulating constant unchanged, the natural frequency of the generator will remain the same but the draft-tube surge frequency will change, due to the change in speed of the unit.

If it is found possible to change the regulating constant as well as the speed of the unit, a change in speed would accomplish both, without requiring any change in the WR^2 of the unit. This would be desirable because a change in speed in this case would have opposite effects upon the draft-tube surge frequency and upon the natural frequency of the generator. For example, a decrease in speed of the unit would decrease the draft-tube surge frequency as indicated by Equation [1], and would also decrease the regulating constant C, as indicated by Equation [4], provided the WR^2 remains unchanged.

However, a decrease in the regulating constant would increase the natural frequency of the generator as indicated by Equation [8] and, thereby, the net effect of a change in speed would be away from resonance conditions.

If it is undesirable to change the speed of the unit, the regulating constant would have to be changed by changing the WR^2 of the unit. This would change the natural frequency of the generator but not the frequency of the draft-tube surges.

The regulating constant C used for the various hydroelectric installations has no fixed relation to the turbine size, output, speed, or head on the turbine. It does depend upon the type of turbine, the transmission system, and upon the regulation desired. However, as a general rule, the regulation constant will be between 4,000,000 and 16,000,000. Exceptions to the upper limit are the very large low-speed units, where the generator rotor has a large WR^2 for structural reasons.

Confining this discussion to the smaller units and to a 60-cycle system frequency, the very general statement, based on Equation [8] may be made that natural frequencies of hydroelectric generators fall within the comparatively small range where the highest natural frequency to be expected is about twice the lowest. The natural frequencies of the very large units, with a large regulating constant, and of units on 50- and 25-cycle alternating-current systems would be somewhat below this range.

Accordingly, in low-speed units, i.e., units with low rpm, the draft-tube surge frequency is likely to be low enough to be below the natural frequency of the generator and, while resonance conditions may not be present, the per cent power swing will at least be equal to the per cent torque fluctuation on the runner.

Higher-speed units are likely to be in a critical range where resonance conditions may be set up.

Above this range of speeds, the draft-tube surge frequency will be greater than the natural frequency of the generator, giving a magnification factor approaching zero, Fig. 4, and making high-speed units remarkably free of power swings. This latter condition has been frequently observed in the field.

It should be emphasized that the foregoing are only generalizations and that many individual exceptions can be found. It is for this reason that no attempt has been made to set the actual speeds at which critical conditions are likely to obtain, nor to fix the limits of the natural frequencies of the generators, especially since the latter depend upon transmission-line characteristics as well as upon the generator characteristics.

Variation of Draft-Tube Surge Frequency With Change in Turbine-Gate Opening

A characteristic of the draft-tube surge frequency is its variation with a change in turbine-gate opening, Fig. 1. A change in gate opening will bring the draft-tube surge frequency either closer or farther away from the natural frequency of the generator. This explains in part why the amplitude of power swings sometimes varies so greatly for a small change in gate opening.

The frequency of the draft-tube surges remains practically fixed for a given gate opening and for small changes in head on the turbine. However, the natural frequency of the generator may vary depending upon the generator load, power factor, transmission-line characteristics, number of units in parallel, etc., as previously mentioned.

Thus one combination will bring the natural frequency of oscillation of the generator closer to the frequency of the draft-tube surges and will produce greater power swings than another combination.

The amount of power swing which can be safely allowed in a hydroelectric unit depends largely upon local conditions. In so far as the generator alone is concerned, the A.S.A. rules for rotating electrical machinery allow a current pulsation of 66 per cent of the rated current in motors driving reciprocating machinery. No rule is given for generators but, in the design of generators to be driven by reciprocating engines, it is usually considered that, if the power swings are kept below 50 per cent of the rated output, there will be no serious heating or dangerous increases in generator stresses.

Effect of Power Swings on Transmission System

As to the effect of power swings on a transmission system, it has been demonstrated in actual practice that, if the swings are not too large, they have no serious effect on the system. There are units in operation today which have power swings of 10 per cent of the rated turbine output or 16 per cent of the turbine output at the gate where the swings occur. Although these units are connected to a 200-mile transmission line, exhaustive tests have shown that the swings had so little effect upon the operation or stability of the system it was not thought desirable to go to the slight expense of making the changes which tests had demonstrated would practically eliminate the swings.

Power swings are sometimes transmitted over transmission lines to all parts of the system. In one case, power swings on a unit were transmitted over about 600 miles of transmission line, causing power fluctuations in the output of units at the other end of the line. Even this condition did not affect the stability of the system.

Power swings if sufficiently large can produce voltage swings. This is objectionable because usually there are numerous connections on a system demanding constant voltage. Since the fluctuations in voltage as produced by the power swings are quite rapid, a heavy burden is placed upon the voltage regulator and, although the regulator is constantly trying to correct the voltage fluctuations, it can never quite keep up with them.

Power swings constantly tend to change the transmission-system frequency. However, on extensive systems with a large total WR^2, the power swings are relatively so small that the change in system frequency is infinitesimal. Therefore, it is very seldom that power swings have any effect upon the system frequency. So long as power swings do not affect the system frequency materially, they will not affect the operation of the turbine governor. However, there have been a few instances in which a single unit with power swings was connected to an isolated distribution system and produced a large fluctuation in the system frequency which affected the operation of the governor. As an illustration of this condition, the following case may be cited:

A 250-kw 60-cycle unit was carrying the entire power load in a small city. The turbine had a power swing at 75 per cent gate of about 25 kw. So long as the system was tied in with a larger system, these small power swings could not change the frequency noticeably and therefore did no harm. When the system was cut

loose from all interconnections and operated as an independent system the frequency would vary as much as three cycles in synchronism with the power swings. This change in frequency was reflected in the governor operation. The governor would vary the turbine gates, trying to correct for the frequency fluctuations. However, the system frequency fluctuated 58 times per min and the governor could never catch up with these comparatively rapid fluctuations. The governor varied the turbine gates about 10 per cent at the rate of 10 times per min. This movement of the turbine gates had a tendency to accentuate the power swings and the system-frequency swings.

The relation between the power swings and system-frequency swings in this case was such that, when the power increased, the system frequency increased and, when the power decreased, the system frequency decreased. This immediately indicated that the source of the trouble was in the output of the generating unit and not in a fluctuation of load on the system.

Fins Added to Draft Tube to Reduce Power Swings

After some experimentation, fins were added to the draft tube, Fig. 7, which reduced the power swings and system frequency fluctuations 75 per cent.

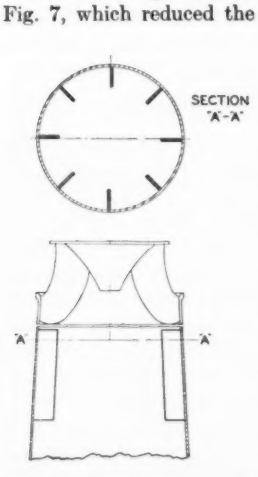

Fig. 7 Fins Installed in Draft Tube to Reduce Draft-Tube Surges and Power Swings

When a unit with draft-tube surges is connected to a water-rheostat load, the generator output remains fairly constant. The fluctuation in torque on the runner manifests itself in a change in the speed of the unit. The change in speed is possible under these conditions because the only WR^2 in the system is that of the generator and turbine.

As explained and illustrated previously, draft-tube surges react upon the penstock pressure in such a manner as to cause fluctuations in the penstock pressure. The increase in penstock pressure is not sufficient to cause excess stresses in the penstock itself. In some cases, however, the continued and regular fluctuation in penstock pressure causes a penstock vibration which may become serious. The following case is cited as an illustration of this condition:

Two 1700-kw, 900-rpm units, operating under a head of 260 ft were both connected to a single penstock 765 ft long. At outputs between 1500 and 1600 kw on either or both units, there was a violent draft-tube vacuum surge of 18 ft, a penstock-pressure surge of 43 ft, and a penstock vibration of $^1/_{32}$ in., all at a frequency of 320 per min. In this particular case, there were no power swings because the frequency of the draft-tube surge was considerably higher than the natural frequency of the generator connected to the transmission system, which gave a magnification factor of practically zero, Fig. 4. This is an excellent example of a high-speed turbine being free of power swings despite large draft-tube surges. It was found possible to eliminate the draft-tube surges, the penstock pressure fluctuations, and the penstock vibrations by admission of air to the draft tube, Fig. 3.

Mechanical vibration and rough operation of the turbine sometimes accompany draft-tube surges. Whether the draft-tube surges cause the rough running and vibration has not been definitely established. There is reason to believe that there is some relation between them because the roughness of operation usually occurs at the same turbine-gate opening at which the draft-tube surges are a maximum and because it has been found possible to reduce vibration and roughness of operation by admission of air to the draft tube, which also reduces the draft-tube surges.

Field Methods for Reducing Draft-Tube Surges and Power Swings

After a unit has been designed, built, installed, and placed in operation and then develops draft-tube surges and power swings, it becomes necessary to use economical methods in the field to eliminate or reduce them. The first criterion of such a method is its effect upon power output and efficiency. One of the most reliable methods is the admission of air to the draft tube, preferably to the center, either as free air or compressed air, Fig. 3. This method invariably reduces the draft-tube surges and thus the power swings, but sometimes it affects the power or efficiency of the turbine, especially on low-head installations.

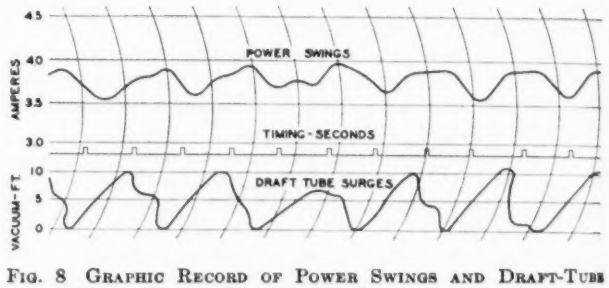

Fig. 8 Graphic Record of Power Swings and Draft-Tube Surges Before Making Any Changes in Turbine

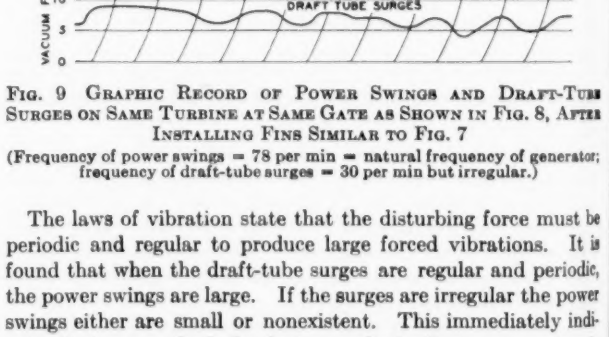

Fig. 9 Graphic Record of Power Swings and Draft-Tube Surges on Same Turbine at Same Gate as Shown in Fig. 8, After Installing Fins Similar to Fig. 7

(Frequency of power swings = 78 per min = natural frequency of generator; frequency of draft-tube surges = 30 per min but irregular.)

The laws of vibration state that the disturbing force must be periodic and regular to produce large forced vibrations. It is found that when the draft-tube surges are regular and periodic, the power swings are large. If the surges are irregular the power swings either are small or nonexistent. This immediately indicates that one method of reducing or eliminating power swings is to break up the regularity of the draft-tube surges.

Admission of air, besides reducing the draft-tube surges, always tends to break up their regularity. It thus serves a dual function in reducing power swings. Another advantage of the admission of air is that it can be controlled by the gate movement and admitted only at such gates as required.

The disadvantages are that the admission of free air is affected by large variations in the tailrace levels. In some cases, where the level of the tailrace is above the turbine runner, it becomes necessary to force compressed air into the draft tube. It may not always be convenient to supply compressed air for this purpose.

Certain changes in draft tubes have also reduced the surges and power swings considerably in many cases. Among these, the most successful method has been the installation of fairly short fins on the walls of the draft tube directly below the runner, Fig. 7. The fins break up the swirl in the discharge, change the flow condi-

tions, and cause the draft-tube surges to become irregular, in addition to reducing their amplitude, thereby reducing the magnitude of the load swings, Figs. 8 and 9.

A low cone in the draft tube, if it is of the concentric type similar to W. M. White's hydraucone, has also been successful in many cases.

In conclusion, the following facts may be stated as having been definitely established:

1 That the power swings chargeable to the hydraulic turbine are always accompanied by draft-tube surges and penstock pressure fluctuations, but that draft-tube surges and penstock pressure surges are not always accompanied by power swings.

2 That the power swings are produced by fluctuations in torque on the runner, which in turn are caused by the draft-tube surges and penstock pressure fluctuations.

3 That the magnitude of the power swings depends upon the magnitude of the change in torque on the runner and upon the relation between the frequency of the draft-tube surges and the natural frequency of the generator connected to the distribution system.

4 That by avoiding resonance of draft-tube surges and natural vibrations in the generator during design of a proposed hydroelectric unit, serious power swings can be avoided.

5 That power swings as much as 10 per cent of the rated output of the generating unit can be tolerated without harm to the operation of the unit or stability of the transmission system.

6 That the power swings can be greatly reduced or eliminated in the field by admission of air to the draft tube or by making physical changes in the draft tube.

Discussion

A. F. Darland.[3] The writer believes that the author was present at the Cushman No. 2 hydroelectric plant of the City of Tacoma at the time difficulties were encountered because of power swings. On that occasion the difficulty was entirely overcome by venting the turbine cover plates through small air valves, about $1^1/_2$ or 2 in. in diam. Not only were the power swings eliminated but a small increase in output of the generators was realized due to the smoother flow in the draft tubes, resulting from the opening of the air vent. The power swing occurred at about 0.6 or 0.7 gate opening and the air valve was arranged to open automatically at these values of gate openings.

McNeely DuBose. Hydroelectric operators have seemed to accept that a water-wheel unit should have a "rough spot" or a "jumping point" somewhere in its range of operation. At that particular point there might be an uncomfortable vibration, an alarming heaving of the penstock, or an occasional step-bearing failure, but the point could be quickly passed over. Operators learned so well to keep their machines away from it that a year or so after installation, this condition was practically forgotten by the engineers.

But with passing years, these unstable points have become less easily overlooked, for larger generators with longer transmission lines seem to be more susceptible to recurrent hydraulic surges than were the smaller units with shorter lines of 30 years ago.

Nor is the problem of power swings necessarily restricted to some particular gate openings which can be avoided. There have been cases where swings originated at comparatively small gate openings and continued in greater magnitude up to full gate, if the machines could be kept on load up to that point.

Mr. Rheingans points out that little or nothing on this subject has appeared in technical literature. That might be amended by saying "public" technical literature, for reams of paper have been used in correspondence on this subject. Probably this reticence is natural. A hydroelectric unit consisting of both water wheel and generator may be on occasions a prolific source of "buck passing," which is heartily indulged in by engineers in the field, but in general has had so little firm ground to stand on that no one has wanted to post it up for studied criticism. As a result, the operators have sometimes been caught between the upper and nether millstones. In the end their difficulties were straightened out, but after months or even years of inconvenience or worse.

So the writer is heartily in favor of anything which tends to call this matter to attention and brings out for the general benefit experience which so far has been locked away in filing cabinets.

An alternating-current generator is a machine which will oscillate. Its period is infinitely long at no load and decreases as the load builds up. Larger machines have a longer period than small machines. The period of even the largest machine at full load is seldom slow enough to synchronize with impulses originating in a water wheel, although inductive load and the reactance of transmission lines may slow down the rate of oscillation of a generator to where it will fall in step with the hydraulic oscillations.

Speaking of the rate of swings, a comparison of calculated and observed rates may be of interest. For instance, take the case of a group of 65,000-hp units, operating at full gate, connected through 28 miles of heavy transmission line to a group of 45,000-hp units, operating at about 0.8 gate. About 100,000 hp is passing through the line. The calculated period of the larger units at full noninductive load by the formula given by the author is 85 cycles per min. The actual observed period of the individual generators varies between 77 and 84 per min. The oscillation period of the 45,000-hp units at full load is calculated to be 100 cycles per min. The observed period of the individual units varies between 92 and 116 per min. The effect of the transmission line is obviously small. At lighter loads, the frequency is observed to drop some 20 per cent.

This example of hydroelectric-generator swings should not be confused with system swings. Take the case of two systems each with some 750,000 hp of generating capacity connected through a weak transmission line 215 miles long. With 30,000 hp passing through the tie, the period of the swing is 24 cycles per sec and the amount of the swing is some 15,000 hp. But while this is going on, the individual generators of the system are swinging at their own higher periods.

Hydraulic-turbine oscillations are always at a comparatively slow period. The writer has never observed recurrent surges in a low- to medium-head turbine at a rate much lower than 30 or greater than 60 per min, and doubts if it is possible for them to exceed the latter rate by much. However, it should not be forgotten that impulses may be transmitted materially to the generator when its period is a multiple of that of the water wheel.

The hydraulic designers are the ones who must deal first with the problem of power swings. They should receive the full collaboration of the operators in so far as their intentions go regarding generator characteristics and system connections. However, requirements of system stability and the geographic locations of power sites often permit very little leeway for helpful changes in generator design, other than the addition of damper windings. But that is a case of attacking the symptom instead of the disease.

J. P. Growdon[4] and D. J. Bleifuss.[5] It has long been known

[3] Construction Engineer, Bureau of Reclamation, United States Department of the Interior, Grand Coulee Dam, Wash.

[4] Chief Hydraulic Engineer, Aluminum Company of America, Pittsburgh, Pa. Mem. A.S.M.E.

[5] Assistant Hydraulic Engineer, Aluminum Company of America, Pittsburgh, Pa.

that occasionally objectionable power swings are observed in hydroelectric units, but to the writers' knowledge, the author is the first to discuss them publicly. Heretofore, such difficulties have been treated as dark secrets between the purchaser and the manufacturer, otherwise the purchaser has suffered in silence.

The author states in conclusion that six facts are definitely established. Proceeding to a discussion of these points in the same order, the writers offer the following:

1 It is probably true that power swings chargeable to a hydraulic turbine are always accompanied by draft-tube surges, but perhaps not necessarily by penstock pressure fluctuations. It is likewise true that draft-tube surges do not always result in power swings. This may be because the surges themselves are irregular, or because the natural period of the generator does not coincide with that of the surges, i.e., there is no resonance. However, the absence of power swings in the presence of draft-tube surges is not evidence that the unit has been correctly designed; on the contrary, the presence of the surges is evidence of incorrect design. It is certain that no design could result in absolutely smooth flow; it is equally certain that bad design will result in very rough flow.

2 The writers agree that swings are caused by variation in torque on the runner, caused by draft-tube disturbances. These disturbances, of course, are due to unstable flow conditions, which in turn are the result of excessive swirl in the water or improper distribution of flow. The ideal condition would be that in which all water flowed vertically as it left the runner, and the draft tube was filled with water flowing at a uniform velocity. For any given runner, at a given speed, this condition is approximated at only one combination of gate opening and head, but divergences from this condition are minimized by correct design.

3 The writers agree that the magnitude of the swings is dependent upon the relation between frequency and magnitude of disturbances on one hand and the natural frequency of the unit on the other, if there are no contributing conditions in the connected system.

4 The writers agree that by avoiding resonance between frequency of surges and vibrations of the generator, serious swings may be avoided. At this point, however, they wish to emphasize that this is not the complete story. Although the swings may be thus avoided, the tendency may be there, and the efficiency of the unit consequently less than should be expected. It would seem that a far better method of prevention would be to design the turbine so that surges do not occur.

5 The writers think that while power surges of 10 per cent of the rated capacity of a unit may be tolerable, they are still most undesirable.

6 The writers agree that power swings can be reduced or eliminated by admitting air to the draft tube. They realize that normal operation of a Francis turbine involves admission of certain amounts of air at certain gate openings. Admission of air in greater amounts than these, and for the purpose of reducing or eliminating swings which have developed, must involve some loss of power. As to draft-tube alterations, the writers have no experience, but wish to indulge in a little speculation. It appears that the difficulties of placing fins in a draft tube already built might be enormous. Consider a unit discharging 4000 cfs, with maximum velocities of 40 ft per sec, and the problem of putting in fins which will stay is a real problem. Further, swirling in a draft tube indicates that the water is leaving the runner with some inclination from the vertical; this inclination varies with the gate opening, and it would appear that when it is a maximum the fins must cause considerable disturbance and consequent loss of power.

The writers wish to point out that either admission of air, or alteration of the draft tube is a palliative or partial remedy, and to remind the profession of the old adage concerning the desirability of "an ounce of prevention."

In explanation of the writers' position, they wish to cite a specific example, where power swings on large units were sometimes of such magnitude as to preclude operation at full load.

Each unit consisted of a Francis-type turbine and an a-c generator. Turbines were rated at 55,500 hp at 135-ft head, the speed was 120 rpm, and the WR^2 about 66,920,000. Using the author's formula for a generator connected to an infinite system, the natural frequency is found to be about 85.5 cycles per min. The draft tube was of the simple elbow type, divided for some distance in from the mouth by a vertical pier.

When the first unit was put on the line, it was allowed to carry 8000 kw for several hours. Then the load was increased to 15,000 kw and it carried this load overnight, although swings of about 2000 kw were noted. The next day load was increased by increments of 5000 kw to the maximum of about 39,000 kw. At a load of 30,000 kw, power swings of an amplitude of 6000 to 10,000 kw were observed, increasing slightly above this load. These swings had a frequency of about 80 cycles per min. They were not consistent. They would at times arise and die without apparent cause, when there was a constant load on the system. The electrical system was investigated for possible resonance or disturbing conditions; nothing was found which could in any way contribute to the swings. Swinging occurred over the entire gate-opening range.

The draft-tube discharge was very turbulent; at the higher loads most of the water appeared to be leaving through the right one half of the right one half of the draft tube. At lower gates, there was actually re-entrant flow in the left half of the tube. Variations of several feet in tail-water elevation demonstrated that it had no effect on the power swings; they were observed at high tail water as well as low.

The portion of the draft tube just below the runner was lined with steel. On the upstream side of this liner there is a mandoor. A pitot tube was inserted horizontally through a stuffing box in this door, and conditions of flow were studied at an elevation 7.5 ft below the center line of the runner or, rather, the center line of the scroll case. The pitot tube was so constructed that it could be rotated, and thus the angle of flow as well as velocity could be determined. A mercury manometer was used in connection with the pitot tube. Observations were taken in as far as 3 ft from the draft-tube liner; since the draft tube has here a diameter of about 14 ft, conditions of flow were determined in the outer 67 per cent of the draft-tube area. Results of a Gibson test on the unit were available, so that the discharge for any given gate opening and head was known. Thus, knowing the vertical component of velocity over 67 per cent of the draft-tube area, it was possible to estimate very closely the vertical component of velocity in the remaining 33 per cent.

For each set of measurements, the turbine gates were blocked at a certain opening, and conditions were such that head and tail water did not vary. A constant discharge was thus assured. Readings were started with the pitot-tube orifice pointing straight up; the tube was then rotated, stopping every 30 deg for an observation. The difference between the legs of the manometer, in inches of mercury, was recorded at each observation. These readings were plotted as follows:

A circle was drawn, the circumference representing a zero reading of the manometer. Pressures were plotted radially outward from this circle, vacua radially inward, at the directions observed. A smooth curve connecting the plotted points resulted in a characteristically pear-shaped figure, the major axis of which represented the direction of flow.

The water whirled with the runner at all gates; the inclination of flow from the vertical varied, for instance, from 51 deg at 0.3 gate to 18 deg at full gate, 15 in. inside the liner. Vertical components of velocity varied as follows:

1 At the liner, 19 ft at 0.3 gate to 9 ft at full gate.
2 Two feet in from the liner, 7 ft at 0.3 gate to 21 ft at full gate.
3 At the center, zero at 0.3 gate to 0.5 gate, a maximum of 45 ft at full gate.

Thus two things were apparent (1) there was excessive swirl, (2) there was a very uneven distribution of velocity. The first indicated that water was leaving the runner at an incorrect angle; the second, that it was leaving the runner in the wrong places. From the figures stated, it will be noted that, at full gate, the vertical component of velocity varied from 9 ft at the liner to 45 ft at the center. Most of the discharge was concentrated at the middle of the tube.

It was speedily found that, by admitting air to the space underneath the runner through the hollow turbine and generator shafts, the power swings could be greatly reduced or entirely eliminated; this fact, with other observations, led to the conclusion that the trouble was caused by disturbances in the draft tube.

Unfortunately, the admission of air resulted in a power loss of from 1500 to 2000 kw as determined by an integrating watt-hour meter, and was accompanied by a distinctly objectionable whistling noise.

The vacuum gage on the draft tube was unsteady, but never indicated a variation regular enough to account for the power swings, and penstock pressure never varied more than 1 lb on the gage.

The turbine manufacturer studied the problem thoroughly, experimenting both on the units in the field and on models, and finally decided on an alteration of the runner. Each runner was cast steel, 155 in. in diam, with 15 buckets. At the lower edge of each bucket a roughly triangular piece was removed, about $24^1/_2$ in. long, and varying in width from $9^1/_2$ in. at the band to 0. This piece was drilled and chipped out at its junction with the band and burned elsewhere. The remodeled runner operates satisfactorily with no air coming through the hollow shaft, and there is a slight increase in power as compared with the original runner operating with no air. An automatic air valve in the cover plate admits air up to about 0.85 gate opening. Maximum amplitude of swing with the remodeled runner is 2000 kw.

The writers wish to state that the turbine manufacturers deserve great credit for their determined attack on what was, at the time, a new problem, and for their arrival at a fundamentally correct solution.

R. G. MacDonald.[6] The writer concurs essentially with the conclusions of the author. The bases of the writer's opinions are specific instances in which approximately the same phenomena and the same effects of corrective measures have been observed.

Unfortunately, at this time, the identity of the plants from which data were collected cannot be revealed, due to its confidential nature. However, without reference to the plants or the identity of the equipment manufacturers involved, some of the conditions which were observed before and after corrective measures were applied will be outlined briefly.

In one instance a unit of moderate rating, when connected to a very complicated system with extremely long interconnected transmission lines, and a very large system WR^2, at a "critical" turbine gate opening, were subjected to power swings of about 25 per cent of the load being carried at the time, and reflected swings of about 10 per cent of the load carried were observed at very large units which were at the time operating in parallel with the smaller unit. Upon separating from the last-mentioned system, swings on both systems almost completely disappeared. Bearing in mind the fact that the gate opening, magnitude, and frequency of the draft-tube swings remained unchanged, it is obvious that alterations of the system characteristics were alone responsible for the power swings.

After the separation there still remained at least 600 miles of transmission systems connected in parallel, but the WR^2 was a small fraction of that existing during the first test when all units and systems were in parallel. This combination resembled a three-tine fork, each tine being a transmission line of 250 miles or over in length, the handle representing the loading of each system. At the time of separation, the central tine was removed leaving a Y-shaped transmission-and-distribution system. No undue power swings were caused by the addition, at the junction of the two transmission lines, of another system approximately 100 miles long. The combined WR^2 in this case remained at a low value.

It was learned that changing the magnitude and/or the frequency of the draft-tube swings also altered the values of the load swings, and in most cases maneuvering completely removed objectionable power swings.

The writer is familiar with one plant where all draft tubes have nearly the same swings, with respect to value and frequency, where different units are operated over isolated transmission systems having dissimilar characteristics. In some instances power swings are in evidence and in others none exists. Therefore, it follows that units operating on a given system may have power swings on another, due to changes in system characteristics.

Considering the most troublesome unit in this plant, at approximately one-half load on the turbine, power swings equal to about $^5/_8$ of the rated capacity were present.

Oscillograms were taken to record the frequencies of the draft tube and power swings and the natural frequency of the system. It was found they had approximately the same period. The natural period of the system was determined by taking an oscillogram of the armature current and a timing wave during a paralleling operation with the incoming machine slightly out of phase with the transmission system. Excellent pictures can be obtained by the proper timing and operation of an oscillograph. Films can be superimposed making frequency relations obvious by inspection.

A companion unit of the same dimensions and capacity which had draft-tube fins did not produce power swings in excess of 10 per cent of the rated capacity. The fins used were similar to those described by the author. During the test, the turbine gates were set at the most critical point. Free air was admitted through the fins. Thus the installation of fins in the draft tube reduced swings to about $^1/_{10}$ of their former value.

It is interesting to note the reduced value of power swings obtained when two similar units, one with draft-tube fins and the other without, were operated in parallel. This appears to prove that reduced power swings result from both a change of system characteristics and the addition of a stabilizing unit, the draft-tube swings of which have been brought under control.

At this point, the writer wishes to supplement the author's sixth conclusion by the following statement: The corrective effect of air in the draft tube is proportional to the ability of the equipment to cause the air to reach the points where it is most needed.

Installation of hydraucones, fins, air, and other devices at least partially correct power-swing troubles arising from draft-tube swings. This indicates that factors in design can be considered

[6] Boulder City, Nev.

rather than changing the speed as would be indicated by Fig. 5 of the paper.

It appears that the only manner in which this problem can be solved, as a matter of prevention rather than correction, wherein much psychology must of necessity be involved, lies in newer and better methods of model testing. It appears to the writer that actual pressures and of course velocities, together with scale models of penstocks and draft tubes, must be employed in testing model runners. This sort of testing would be in addition to the orthodox "flume" test as now practiced. Much about cavitation could be learned at the same time.

L. F. Moody.[7] The author has made a useful contribution in calling attention to a problem which has received little attention in the literature, and in investigating and recording factual data and certain conclusions relating to the influence of some of the chief factors involved. The problem is a complex one, and as the author points out, further analysis is needed to establish a basis of theory. It is hoped that he and others will continue this investigation so that we have a rational framework behind the empirical conclusions.

Some preliminary hypothesis seems necessary if we are to try to account for the phenomena of power swings. It seems to the writer that we cannot explain the action as due primarily to such factors as elastic pressure waves in the water column, which have a constant frequency depending only on the length of the conduit and the wave velocity, both of which are constant, or torsional vibration of the turbine shaft and runner, which also has a constant frequency. Nor can we explain it as a slower surge of the water column as a whole, treated as an inelastic medium. Liquid in a U-tube, having free surfaces, can be made to oscillate harmonically; but the turbine water column terminates in fixed head- and tail-water surfaces. The writer has from curiosity set up the equation for accelerated flow in the system, imagining a momentary disturbance of equilibrium; but the solution is similar to that for a suddenly opened valve at the end of a pipe line. The flow approaches the steady value asymptotically along a smooth curve of logarithmic form, and is nonoscillatory.

These considerations lead the writer to suggest the presence of an elastic medium, such as an air or vapor cavity, somewhere in the system. The point where this may be expected is around the axis of the draft tube just below the runner. Under part gate operation, the reduced discharge through the constant runner areas of course results in reduced relative exit velocity and consequent forward absolute whirl of the outflow. The draft-tube vortex involves flow separation near the axis and invites the formation of a hollow core in which entrained air can accumulate; and probably in many cases where power swings and draft-tube surges are marked, a vapor-filled cavity is formed. After the foregoing suggestion was offered the writer had the opportunity of witnessing a motion picture which it is hoped can be shown again. This was contributed by I. A. Winter of the U. S. Bureau of Reclamation and showed the flow within a transparent turbine model. At part gate operation this illustrated clearly the presence of a vortex core, accompanied by instability of flow.

The surging of the draft-tube water column, resulting from the presence of air or vapor, may be of more consequence in its direct effects than in the power swings it causes in the generator output. If the turbine setting does not provide much margin over the critical cavitation coefficient of the turbine, a unit which would operate perfectly under steady conditions may cavitate when a draft-tube surge sets in, the cavitation then accentuating and maintaining the surge.

[7] Professor of Hydraulic Engineering, Princeton University, Princeton, N. J. Mem. A.S.M.E.

The method of combating surges, vibration, and power swings by air admission has of course been often used. Fortunately gate-controlled air admission is provided in most modern turbines of higher specific speeds, although special means may have to be added to get the air into the vortex core. The writer might mention one case where an air pipe was inserted through the draft-tube wall, extending near enough to the axis to reach the vortex core and effectively keeping the surges within bounds. Guiding fins on the draft-tube wall are an undesirable remedy, from considerations of turbine efficiency.

Since power swings and surges occur in turbines under fixed-gate operation, it is likely that similar phenomena may occasionally occur in pumps, particularly in propeller or mixed-flow pumps and, in general, whenever whirl may be induced in the suction space.

J. F. Roberts.[8] The six conclusions at the end of the paper form a complete summary, but it is believed the fifth is open to discussion. This fifth conclusion reads as follows: "That power swings as much as 10 per cent of the rated output of the generating unit can be tolerated without harm to the operation of the unit or stability of the transmission system." It is possible that the author is endeavoring to educate the users to expect this much power swing. However, while the writer would not state definitely that 10 per cent swing might do serious damage, he feels that it certainly would be objectionable and cause uneasiness to the operator. Considering that, with a 50,000-hp unit, this would mean a power swing in the order of 5000 kw, it would certainly occasion comment. Possibly, with a 3000- or 4000-hp unit, a power swing of 300 or 400 kw might not be considered objectionable; but in general, it is felt that 10 per cent is two or three times what could be passed without serious objection.

Regarding the fourth conclusion, that resonance between the draft-tube surges and the natural vibration of the generator may be avoided during design, this would involve a large amount of money if it were done by increasing the WR^2 of the generator. For instance, doubling the WR^2 of the generator would reduce the ratio between the frequency of the disturbing forces and the natural frequency of the electrical system from 1 to 0.75, or only 25 per cent; but such an increase in the WR^2 of the generator would probably amount to a considerable percentage of the original cost of the generator. If the result can be achieved by the use of fins installed in the draft tube or by the admission of air under the runner, these solutions are far more economical than the increase of WR^2 of the generator.

The author does not state whether or not the addition of the fins affects the performance of the draft tube and the over-all efficiency of the unit. The writer believes such a statement would be enlightening to the members of the Society.

R. E. B. Sharp.[9] The author has called attention to an important factor in the design of hydroelectric units, and has submitted valuable data for the study of the phenomenon of power swings. The writer is as yet able to offer only one instance of a power swing and its relation to draft-tube surges. In this instance: Rpm = 187.5; observed frequency of draft-tube swings at about 0.82 gate = 80 to 86 per min = S, whereas $\frac{\text{rpm}}{3.6} = 52$,

$$F = 46{,}000\sqrt{\frac{f}{c}} = 46{,}000\sqrt{\frac{25}{13{,}700{,}000}} = 62.2;$$ power swing

[8] Principal Mechanical Engineer of Design, Tennessee Valley Authority, Knoxville, Tenn. Mem. A.S.M.E.

[9] Chief Engineer, I. P. Morris Division, Baldwin-Southwark Corporation, Philadelphia, Pa. Mem. A.S.M.E.

5000 kw (full load about 46,000 kw); penstock pressure swings 115 to 125 lb per sq in.

The wide discrepancy between the author's value for S and that actually observed may be due to the large gate opening at which the draft-tube disturbances occurred in this instance. On the other hand, another unit in the same station of different design encountered draft-tube disturbances just as severe but at a much higher frequency, about the same as the normal rpm of the unit, namely 187.5, but with no power swings. The draft-tube design as well as the runners were different for the two units.

For the instance cited, at least, severe power swings resulted where S actually was more than 50 per cent greater than the value indicated by the author's empirical formula $S = \frac{\text{rpm}}{3.6}$. A more accurate method for determining this frequency, therefore, appears desirable. If the undesirable relation between F = natural generator frequency and that of draft-tube swings is to be avoided, where possible, in the design state it is naturally important to predict closely the dangerous zone to be avoided. While air admission valves are today a standard turbine accessory, and they are known to reduce or even eliminate draft-tube surges, it is, of course, wise where practicable to avoid the zone of resonance.

From a broad standpoint, it appears important to the writer that turbine manufacturers exchange complete experience data relative to draft-tube surges, both in cases where power swings have and have not occurred, in order to be in the most favorable position to reduce or eliminate, if possible, the tendency for such surges to occur. Due to the many factors which enter into this problem, this procedure should result in its quickest solution to the benefit of all concerned.

G. R. Strandberg.[10] The data collected to date on the subject of power swings have been rather limited since in most cases the load swing has been so small in comparison to the size of the system to which the units have been connected that system operation was not affected. The writer has observed load swings on units of several plants built from 1912 to recent years and has data showing a maximum load swing of about 20 per cent on units of one plant.

The author states that in cases of power swing there is always a pressure swing in the penstock accompanied by a vacuum swing in the draft tube and that maximum pressure in the first case occurs with maximum vacuum in the latter. If the surges in the draft tube were in phase over the entire draft tube, it would seem to the writer impossible for an increase in vacuum in the draft tube to cause a pressure rise in the penstock. In one installation, gages at quarter points in the draft tube showed that the surge was not in phase at all points. Diametrically opposite points were out of phase 180 deg and points 90 deg from each other were out of phase 90 deg. The phase rotation was clockwise on units rotating clockwise looking down on the unit. It is possible that the pressure swing in the penstock is caused by the rotation of the vacuum surge around the draft tube passing the nose point of the scroll case. It would be interesting to know whether pressure swing in the flume or load swing has occurred in any plant having closed flume setting with no scroll-case nose point connecting the wall to the speed ring.

In one plant, where two units were connected to a single transmission line, the indicated maximum combined load swing was 3 times the indicated maximum load swing of a single unit and the same indication was obtained at both the generating and the receiving ends.

Vertical steel-plate fins installed in the draft tube below the runner in an effort to correct load swings materially reduced them, and the reduction was increased as the width of fin increased. Tests indicated little or no change in reduction whether the fins were located immediately below the runner or several feet lower in the draft tube. With too wide a fin, however, the draft tube became noisier and the indications were that the width of fin would have to be limited for structural reasons. The fact that such fins materially reduce the load swing indicates that the rotating component in the unit discharge has a material relation to the load swings.

I. A. Winter.[11] The writer has had occasion to observe the phenomenon described by the author and is greatly impressed by the apparent agreement with the conclusions expressed and results obtained for installations familiar to the writer. The paper quite properly is limited to a discussion of power swings associated with resonant pressure changes in the draft tube, although the title would indicate a much broader field of application.

Power swings from other sources in an interconnected hydroelectric system are of a nature equally as involved and difficult of solution as the power swings described in the paper. Notable among these objectionable phenomena of regulation and control are those of incipient instability of hydraulic penstock systems with surge tanks, where the length of penstock is greater than 4 to 5 times the head on the unit, and the inherent inability of present-day governors to effect proper distribution of load between hydrounits operating in parallel as required for efficient operation, and to carry correct time throughout a 24-hr period as is now universally expected by electric-clock users.

A series of tests was conducted at the Guernsey power plant of the North Platte Project in Wyoming for the purpose of determining if the so-called incipient instability[12] of relatively long penstocks with surge tanks and under low heads and the draft-tube-surge phenomenon are tangible and inviolate or if other unknown factors could be responsible for the troubles now attributed to these phenomena.

The Guernsey power plant consists of two 3400-hp vertical-shaft, single-runner, Francis-type, spiral-casing turbines operating at 240 rpm under an average effective head of 80 ft. Each turbine is equipped with a conical-plate steel draft tube discharging into an open rectangular flume. Power water is supplied through a 12-ft-diam single penstock 850 ft in length, terminating with bifurcated branches, 8 ft 6 in. in diam and at a distance approximately 70 ft from the point of attachment to the turbine-scroll cases. In the 12-ft-diam penstock immediately above the bifurcated branch, there is located a simple surge tank, 22 ft in diam, and 85 ft in height with a restricted orifice in the bottom 7 ft 6 in. in diam. Units A and B in this plant were installed at different times and are of different manufacture.

Analytical investigation of the hydraulic characteristic of the penstock system made before the tests were started indicated that the period of the incipient surge should be approximately 55 sec. Using the author's Equation [1], it was estimated that the frequency S of the draft-tube surge if present would be approximately 67 cycles per min. Observations made during the tests established the period of the secondary surge in the penstock and surge-tank system as being 54 sec with an amplitude of 0.25 ft

when discharging a total flow of 462 cfs, which is in substantial agreement with the calculated values.

Unit *A*, when operating at 30 per cent gate opening, developed a surge in the draft tube of 54 cycles per min with pressure variations from 5 to 10 ft of water. The draft-tube pressure gage on unit *B* was quite steady. The total load on the distribution system in which the units were generating amounted to only 5000 kw and no evidence of power swings coordinated with the draft-tube surge in unit *A* could be observed. It is, therefore, quite obvious that resonant pressure surges in the draft tube cannot alone be responsible for objectionable power swings in the distribution system. It was also demonstrated that the pressure surges are not a characteristic of the type of draft tube, since both units *A* and *B* have identical draft tubes of the straight conical type. A further conclusion which may be drawn from these tests is that the formation of resonant surges in the draft tube can be prevented by the proper design of turbine runner.

Field investigations of the draft-tube surges made at Guernsey had been preceded by experiments made on a 6-in. model turbine in the laboratory of the Denver office of the Bureau of Reclamation, using scroll cases and draft tubes made of pyralin, which permitted visual observations of the phenomena as developed both in the scroll case and draft tube. Motion-picture records made of these tests show clearly the formation of a void at the runner tip, which gradually tapers in size to a point and disappears as it reaches the horizontal discharge portion of the draft tube. The conical-shaped void has a spiral motion at its boundary identical with that of the ordinary surface vortex with the exception that the spiral has a second motion of rotation which is about the center of the draft tube and has a frequency of rotation at its tail described by the author as being approximately $^1/_3$ of the speed of the turbine. The use of pyralin models of the type described opens the field of investigation of homologous turbines for individual designs which will establish the characteristics of the runners with respect to the formation of the void at the tip of the runner. Should this procedure be followed, it is conceivable that runners could be designed which would be entirely free from the troubles now being experienced.

From the limited amount of data available, a magnification factor of 1.5 or less using curve No. 2 in Fig. 4 of the paper may be tentatively selected as indicating that power swings, resulting from resonant surges in the draft tube, will not cause operating difficulties. A study of the magnification factors for a number of units installed or contracted for is shown in Table 1, using notations identical with those of the author. Significant facts revealed by these figures are as follows:

Unit No. 1 with a magnification factor of 2.1 developed power swings of a magnitude such that the unit could not be operated in parallel with a system carrying a load in excess of 1,000,000 kw. This unit was corrected by the admission of air to the center of the runner, thereby permitting a more uniform volume to be maintained in the void forming immediately below the tip of the runner. This correction demonstrated that the formation of the void alone is not detrimental but it is the making and breaking of the void that creates the objectionable surges.

This solution of the difficulty has been fully described by the author but the writer does not agree that the admission of air breaks up the surge in the manner of the draft-tube fins shown in Fig. 7.

Of second interest in Table 1 is unit No. 2 with a magnification factor of 1.6. This unit developed trouble identical to unit No. 1, but of lesser magnitude, and was placed in successful operation in the same manner as described for unit No. 1.

Unit No. 3 in the table has a magnification factor of 5 and power surges developed so critically that the unit could not be operated throughout approximately 60 per cent of the power range. The use of compressed air forced in at the center of the runner failed to correct the troubles as described for units Nos. 1 and 2. Units Nos. 3 and 4 are units of identical design and capacity. When units Nos. 3 and 4 are operated in parallel, the magnification factor is reduced from 5 to 1.6 and it is possible to operate both units satisfactorily throughout their entire power range with a moderate amount of compressed air (350 cfm) admitted at the center of the runner. Unit No. 3 has fins installed as illustrated in Fig. 7, which are effective in breaking up the swirls and thereby reduce the draft-tube surges which permits operating the unit throughout its entire power range. Comparison of these two units, when operating singly and in parallel, is an outstanding example of the conclusion drawn by the author that the magnitude of the power swings depends upon the relation between the frequency of the draft-tube surge and the natural frequency of the generator.

Further examination of the units listed in Table 1 tends to demonstrate the conclusion that a magnification factor of 1.5 and below represents a reasonably safe installation factor. For example, unit No. 5 is the Guernsey unit previously described with a magnification factor of 1.2. No trouble of any nature could be traced to this unit in the development of unstable power swings in the generating system. Unit No. 6 has been given a preliminary test with the results as indicated in the table and it appears that correction by the admission of air to the center of the runner will be necessary to eliminate power swings effectively due to surges originating in the draft tube.

Units Nos. 7, 8, and 9 are units which have not been installed but are under construction or contract and will be placed in operation in the near future. It appears that units Nos. 7 and 9 may be expected to give no trouble from power swings originating in the draft tube. However, it is proposed to investigate unit No. 8 with models using pyralin draft tubes and scroll cases for the purpose of determining whether the runners as designed are favorable or unfavorable from the standpoint of the development of a spiral void below the runner.

For the convenience of those interested in investigating the effect of the electrical characteristics of a particular generator or transmission line, the following formulas are applicable:

The value of *Pr*, Equation [7] of the paper, for a particular generator may be calculated as follows:

$$Pr = \frac{dP}{d\delta} \text{ times kva rating of machine} \quad [9]$$

where

$$\frac{dP}{d\delta} = \frac{eI}{X_d}\cos\delta + \frac{e^2(X_d - X_q)}{X_d X_q}\cos 2\delta \quad [10]$$

e = per unit terminal voltage
I = per unit field current
δ = torque angle in electrical radians

The value of Pr' for a particular transmission line may be calculated as follows:

$$Pr' = \frac{dP'}{d\delta'} \text{ times kva base used in computing reactance} \quad [12]$$

where

$$\frac{dP'}{d\delta'} = \frac{E_s E_r}{X_{sr}} \cos \delta'$$

E_s = per unit voltage at generator terminals
E_r = per unit voltage at receiving end substation low-voltage bus
δ' = angle between E_s and E_r
X_{sr} = per unit reactance of system between E_s and E_r

and where δ' is determined by

$$P' = \frac{E_s E_r}{X_{sr}} \sin \delta' \quad [13]$$

= per unit power transfer on kva base used in computing reactance

In summary it may be stated that the author offers an empirical method of calculating the natural frequency of draft-tube surges, reviews the method of calculating the natural frequency of the electrical system, and concludes that the factor having the greatest influence on the magnitude of the power swings is the relation between the frequency of the draft-tube surge and the natural frequency of oscillation of the generator and its interconnected power-distribution system. When based on the meager experience with units as outlined in Table 1, the following additional conclusions may be drawn:

(*a*) A magnification factor of 1.5 or less indicates that power swings will not cause any operating difficulty.

(*b*) The effect of the transmission line is to lower the natural frequency of the electrical system.

(*c*) For the case of one generator connected to a long transmission line, the effect of the transmission line must be included.

(*d*) For the case of two or more generators operating in parallel, the maximum frequency approaches the maximum frequency of one generator connected to an infinite bus.

(*e*) A runner designed to avoid excessive whirl at the center of the draft tube throughout the critical range will not produce power swings of the character described in the paper.

Author's Closure

Mr. Darland mentions the venting of the cover plates at the Cushman No. 2 hydroelectric plant. This is one of the few cases where venting reduced the power swings without causing a material reduction in turbine efficiency. The power swings in this case were small, being less than 5 per cent of the rated output and, thus, a large reduction in the swings was obtained with a small amount of air admitted to the draft tube.

The close agreement Mr. DuBose obtained between calculated and observed values of the natural periods of oscillation of various generators is very gratifying and establishes the fact that the natural period of a generator may readily be calculated during the design stage.

Mr. DuBose questions whether it is possible for draft-tube surges to exceed 60 cycles per min. Fig. 3 of the paper mentions draft-tube and penstock pressure surges at the rate of 320 per min in a 1700-kw, 260-ft head, 900-rpm turbine. The frequencies of both the draft-tube and penstock surges were carefully observed at this plant and there is no question regarding their occurrence at this high rate.

Mr. Growdon and Mr. Bleifuss state that the difficulty of placing fins in draft tubes already built might be great. However, experience has shown that properly designed fins are quite easily installed either in low-head plants of large physical dimensions or in high-head plants where high velocities are encountered. Fins thus properly designed and installed will remain in place as long as the draft tube does.

Experience with models and field tests on draft-tube fins has also shown that, when properly designed and located in the draft tube, they will not reduce the maximum output of the turbine and will reduce the maximum efficiency only slightly if at all. This is explained by the fact that, at the best efficiency gate, the flow in the draft tube is very nearly axial, the fins, therefore, presenting but slight obstruction to the flow at this point. However, part-load efficiency may be reduced as much as 1 per cent, depending upon the amount of whirl in the draft tube.

The detailed description of Mr. Growdon and Mr. Bleifuss of their investigations of power swings in a 55,000-hp, 135-ft-head turbine is a valuable contribution and certainly indicates the true source of the draft-tube surges and disturbances.

Mr. MacDonald's description of the variations in load swings with a change in the characteristics and setup of the transmission and distribution system opens up a field for further and more thorough investigation.

Mr. Roberts is correct in stating that a 10 per cent power swing might be objectionable and might cause uneasiness to the operator. However, this is not true in all plants. There is a case on record where a number of duplicate units developed power swings of 10 per cent of the rated output of the turbine. It was demonstrated on one of the units that the power swings could be eliminated by the installation of fins in the draft tube with only a slight loss in efficiency. However, the owners of the plant preferred to operate the remaining units with the power swings present rather than to install the fins. These units have been in operation for nearly 10 years. There are numerous other cases where units have been in operation for 10 years or more with power swings of 10 per cent or greater.

The author agrees with Mr. Roberts that changing the WR^2 of the generator would be an expensive method of avoiding resonance conditions. A change in speed of the unit might be less costly and might be likely to give more definite results.

Mr. Sharp's apparently limited experience with power swings seems to indicate that, where the draft-tube surges occur at the larger gate openings, the frequency is somewhat greater than given in the author's empirical formula. One of the theories for the origin of draft-tube surges, which the author is investigating at the present time, seems to indicate that the frequency will increase with an increase in gate opening.

Mr. Winter's description of the draft-tube surges at the Guernsey power plant, which did not produce any power swings, and his table showing the magnification factors and field results of various installations, are an excellent illustration of the theory advanced by the author that resonance conditions must be present before the draft-tube surges can produce serious power swings. We should, therefore, not lose sight of the fact that the electrical system is a contributing factor in the production of power swings and that part of the responsibility should be so delegated, especially when exact resonance conditions are encountered.

It seems fairly well established at the present time that draft-tube surges are caused by the whirl of the water in the draft

tube, which whirl is produced by the angular flow of the water leaving the runner vanes. The consensus of opinion of those discussing this paper seems to be that draft-tube surges can and should be eliminated by proper runner design. However, a hydraulic-turbine runner can be designed to give axial discharge for only one gate opening and for only one speed. For any other gate or for any other speed there will be a whirling discharge. Since turbines usually have to operate at various gate openings and sometimes have to operate under a wide range of head at fixed speed (which corresponds to a varying unit speed), draft-tube whirl will be present under some of the conditions of operation. Also, in some plants the tailrace elevations may vary considerably with a consequent variation in draft-tube conditions.

Therefore, it may become exceedingly difficult to design a runner which will operate satisfactorily under a wide range of conditions with the high efficiency and high specific speeds demanded at the present time. It may then be necessary to make use of such devices as fins in the draft tube to assure smooth operation under the various conditions.

At the present time, dividing walls and splitters are used near the exit of the draft tubes. Fins and baffles are used in the suction pipes of pumps to straighten out the flow and increase the efficiency of the pump. Baffles are used to guide the flow of air and water around elbows with a minimum of loss and disturbance. Fins are used in impulse-wheel nozzle pipes to prevent whirling water from distorting or breaking up the jet. Similarly, fins in hydraulic-turbine draft tubes, properly designed and installed to counteract the bad effects of whirling water, may become a standard part of turbine installations as a definite insurance against rough operation and excessive power swings, regardless of improvements in runner design.

Generator Characteristics as Affecting System Operation

By SHERWIN H. WRIGHT,[1] EAST PITTSBURGH, PA.

In an interconnected power system the frequency regulation and tie-line power swings are influenced by the electrical characteristics of all electric equipment connected to the system, including generators, lines, and miscellaneous motors, as well as by the mechanical characteristics of all rotating apparatus. In this paper the interrelated action of these factors is visualized by means of the mechanical analogy developed in connection with power-system stability, and this is augmented by a discussion of angular displacement with load and kinetic-energy values for typical machines, generator reactance, and short-circuit ratio.

Introduction

THE OBJECT of this paper is to discuss some of the more important characteristics of synchronous generators which affect frequency regulation and tie-line power swings.

In observing the system operation of interconnected electric-power systems, with speed regulation and tie-line loading particularly in mind, one is struck by the great number of variables, interrelated in a complex manner, the composite action of which determines the actual frequency regulation and tie-line loading characteristics observed. For example, if at a given instant a frequency corrective action is initiated, the results obtained depend not only upon the electrical characteristics of generators, transformers, lines, and load, but also upon the mechanical characteristics of all rotating equipment connected to the generators and motors throughout the system. Likewise, the power swings on interconnecting transmission lines are in fact electromechanical oscillations which involve the same factors mentioned.

In visualizing and analyzing these matters, the electrical engineer is prone to, and justified in, reverting to concepts and methods developed in connection with power-system stability. As used here, "power-system stability" is concerned with the successful parallel operation of a-c machines as affected by the electric power transmitted; considerable attention was focused on it, and a practical analysis made, when long-distance power transmission came to be explored.

Mechanical Analogy

Since system stability has many elements in common with the problems of frequency regulation and tie-line power swings, it will be useful to refer to the mechanical analogy of power-system stability, developed by S. B. Griscom (1).[2] Fig. 1 shows a model of this mechanical analogy, and lists the electrical quantities involved in power transmission and their mechanical analogies. Some of these models are in use by utilities and universities.

This mechanical model is not limited to illustrating electric-power transmission in high-voltage transmission lines. It simulates electric-power transmission between any two points of known voltage connected by an impedance which can be taken as pure reactance (represented by the spring). In Fig. 1 there are two arms fixed to separate hubs which are mounted concentrically but free to turn independently. The cord passing through the pulley has one end fixed to each hub so that a weight on the pulley tends to separate the two arms, being opposed by the coil spring connected near the arm ends. The orthodox description of this analogy is in terms of voltage and current vectors, as suggested by the analogies listed in Fig. 1. However, it may be more convenient to look upon the two arms not as vector voltages but instead as radial chalk marks on the shaft ends of two synchronous machines, these chalk marks being viewed in the light of a stroboscopic lamp.

Suppose for example, we are considering the action of a single generator with respect to a large system of capacity relatively so great it may be considered as an "infinite system." Imagine the system simulated by a single huge equivalent synchronous machine which when running maintains exactly 60-cycle speed and constant terminal voltage. Imagine this machine to be beside the single generator. Suppose that, with both the generator and system machine at a standstill, we find they are 2-pole machines, and so place a radial chalk mark on the shaft end of each in line with the center of the North field pole. When running, the system chalk mark is represented by the arm in Fig. 1 labeled motor voltage, its terminal voltage by the radial distance to the point of spring attachment and, for an infinite system, this arm would be anchored. The generator chalk mark is represented by the arm labeled generator voltage; the inertia of this arm and hub simulate that of the actual generator. With the generator "floating" at no load, the chalk marks viewed in stroboscopic

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Hydraulic and Power Divisions and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

light would be in line, no angle between them and, in Fig. 1, the two arms would be coradial, the spring being absent. As the generator prime-mover gate is opened, the generator mark will shift ahead in the direction of rotation as seen in the light of the stroboscopic lamp. In the model, Fig. 1, this loading is simulated by placing a weight on the pulley, stretching the spring. If in the model the weight is added suddenly, there will be overswing, the spring stretching on its first swing beyond its final equilibrium position.

Should this generator, while floating at no load, be retarded as by the brakes on a hydroelectric unit, its mark would shift behind the system mark and the generator would draw power from the system, and this action is again simulated by the model.

The model in Fig. 1 is so constructed that the loading of the generator and the motor is simulated by means of a single weight connected by a pulley and cord in such a way as to produce rotational forces on generator and motor arms. The model might as well have been made with two separate but equal weights (each weighing one half that used in Fig. 1), one for generator load and one for motor load. However, unless the two weights are exactly equal a net torque would exist and a net rotation of the two arms would take place. This net rotation would simulate what actually takes place in a system when load is increased or decreased and system frequency changes slightly before the governors operate.

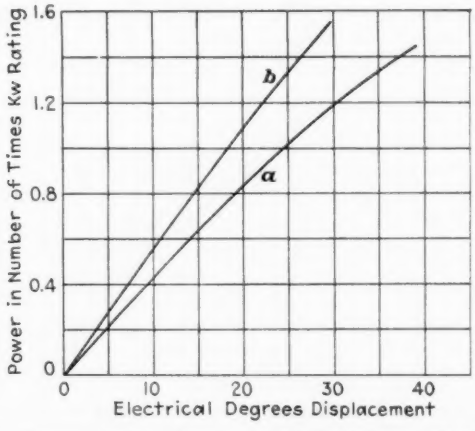

FIG. 2 POWER-ANGLE CURVE OF WATER-WHEEL GENERATOR; STEADY STATE, RATED VOLTAGE

(*a* Field-current constant at no-load value. *b* Field-current constant at value required for rated load at 0.9 power factor; this is 1.8 times value in *a*.)

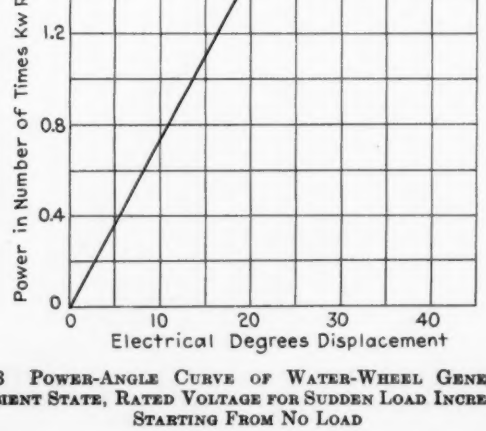

FIG. 3 POWER-ANGLE CURVE OF WATER-WHEEL GENERATOR; TRANSIENT STATE, RATED VOLTAGE FOR SUDDEN LOAD INCREMENTS, STARTING FROM NO LOAD

Here again the mechanical analogy allows visualization of both the electrical and mechanical factors, for both steady-state and oscillatory conditions.

ANGULAR DISPLACEMENT VERSUS LOAD IN TYPICAL GENERATING UNITS

The angular displacement in actual hydroelectric and turbogenerator units is illustrated in Figs. 2, 3, 4, and 5. A generator is electrically "stiffer" under suddenly changing load conditions than it is under gradually or slowly changing load conditions. This is due to the tendency of the field winding to maintain its flux linkages and therefore internal-voltage constant at the value existing before the sudden load change occurs. This is exemplified in Figs. 3 and 5 which show that to develop any given value of electric-power output, the angular displacement need not be as large for transient as for steady-state conditions. By sudden change is meant one, for example, involving an oscillation having a period of less than 1 sec or, to be more precise, less than the transient time constant of the machine.

The curves for transient conditions merely show the angular displacement that must exist in order for the generator to develop corresponding values of electrical kw output. They do not show the maximum angle through which a machine will swing under conditions of sudden load changes because, in this case, the mechanical inertia causes overswing.

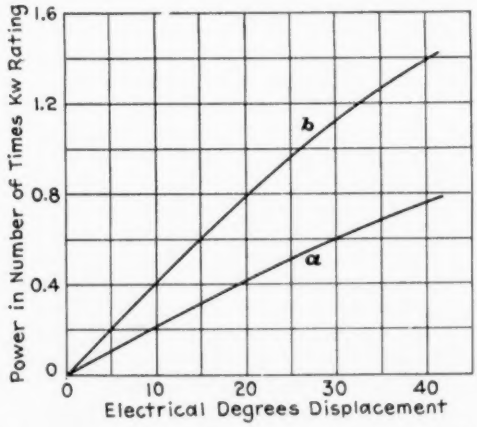

FIG. 4 POWER-ANGLE CURVE OF TURBOGENERATOR; STEADY STATE, RATED VOLTAGE

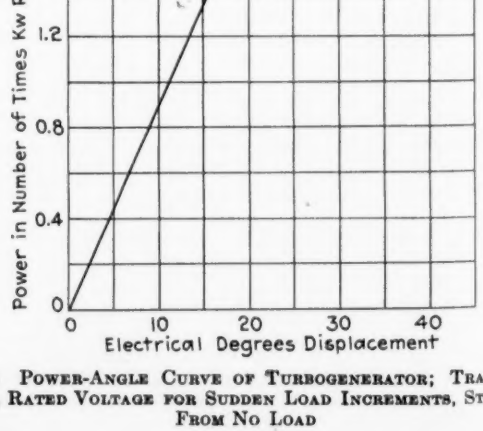

FIG. 5 POWER-ANGLE CURVE OF TURBOGENERATOR; TRANSIENT STATE, RATED VOLTAGE FOR SUDDEN LOAD INCREMENTS, STARTING FROM NO LOAD

Quantitative Analysis

In addition to visualizing these phenomena, it is pertinent to review some of the mathematical relations. As given in Fig. 1, the power P transmitted between two points having voltages E_s and E_r with the reactance X and phase angle ϕ between them, is $P = \frac{E_s E_r}{X} \sin \phi$. (For a 3-phase system, using line-to-line voltages in kilovolts and reactance per phase in ohms gives total power in megawatts (thousands of kilowatts).) This, of course, neglects damping torque which is generally small, being proportional to the slip frequency.

This equation then defines conditions completely, providing they are steady-state conditions so that inertial effects are absent. Under oscillating or transient conditions, however, an attempt at a formal mathematical solution leads to an elliptic integral. In multimachine transient-stability studies, this is circumvented by employing a step-by-step solution, usually with the aid of the a-c-network calculator where the power system is set up in miniature. It is interesting, however, to investigate an approximate solution for the two-machine case when oscillations are small enough in amplitude so that the cosine of the angular change may be taken as unity and the sine as equal to the angular change itself. In this case, the period of the natural-frequency oscillation is

$$T = \sqrt{\frac{4\pi W}{f_0} \times \frac{X}{E_s E_r} \times \frac{1}{\cos \phi_0}} \text{ sec}$$

where

W = stored energy at normal speed, in kwsec divided by 1000
f_0 = normal system frequency in cycles per sec
E_s and E_r = fixed voltages of the two synchronous machines or systems in kv, line to line
ϕ_0 = initial phase angle between them
X = reactance between them in ohms per phase

When one machine or station is swinging with respect to a large or relatively "infinite" system, W is the stored energy of that one machine. When the two machines or systems involved have comparable values W_1 and W_2 of stored energy, W in the formula is replaced by $W_1W_2/(W_1 + W_2)$. A single unit or station swinging with respect to a large system may have a period of less than 1 sec, while two large systems may swing with a period of several seconds.

For this two-machine case, the amplitude of the oscillation is independent of the system inertia, if variations in prime-mover input and shaft loads are neglected. The period however depends upon the stored energy. The period may be increased by increasing reactance but, as seen from the previous power equation, this would handicap the tie by reducing the maximum power which could be transmitted. In the two-machine case the overswing can be determined readily, as in stability studies, by the "equal-area method" (3). Analysis of amplitude and period for any particular system becomes quite complicated when governor operation is involved. A practical solution probably necessitates carrying out a step-by-step process, with the aid of an a-c-network calculator.

Machine Reactance

The machine reactance involved in these system oscillations or changes depends upon the period and duration of the oscillation. A quantity used commonly in synchronous-machine short-circuit and stability calculations is "transient reactance." Its name suggests use under any transient condition. However, transient reactance accurately characterizes a machine only at the instant when a sudden change in armature current takes place. In practice it is usually applied only where the time interval being investigated is roughly less than the machine transient time constant. When generator loading is being changed at a slow rate such as 20 per cent load in 5 sec, transient reactance is not applicable. The machine reactance under such conditions changes with load because of saturation. If a voltage regulator changes field current, thus affecting internal voltage, this must also be taken into account. Furthermore, when load is changing slowly on a salient-pole machine (such as a water-wheel generator, in contrast to a cylindrical-rotor turbine generator) the two-reaction theory involving a direct axis reactance and a quadrature axis reactance is applicable.

Stored Kinetic Energy

The stored energy in a system may be estimated from a knowledge of the rating and type of all connected machines, including load as well as generating equipment. In the case of the generating equipment, this is a straightforward calculation when the stored-energy value for each individual unit is available. When the WR^2 in lb-ft^2 is known, the stored kinetic energy is given by

$$W = 2.31(10^{-7})(\text{rpm})^2(\text{lb-ft}^2) = \text{kwsec}$$

When individual values are not available, estimates may be made from the data given in the following section. The energy stored in motor loads may form a large percentage of the total system stored energy and, in such cases, should be included. In estimating these the connected-motor capacity should be used rather than the net power supplied. The section following gives representative values of stored energy for the three types of rotating-machine load, i.e., synchronous motors, induction motors and rotary converters.

Having determined the total stored energy in a system, its change for a given frequency change can of course readily be computed since it varies as the square of the frequency. When frequency changes, another factor to be considered is the variation of shaft torque exerted by the motor-driven loads themselves Few data are available on this point, partly because any system power measurements will be greatly affected by voltage variations, lighting load, for example, varying as the 1.5 to 2 power of the voltage. Some measurements indicated the total system load varying approximately as the square of the frequency. The rate at which frequency changes from one value to another determines the relative importance of this load characteristic with respect to the total system stored energy, the latter being the dominating factor when the frequency changes at a rapid rate. When attempting to evaluate this particular characteristic from system measurements at different frequencies, it is essential that any change in voltage be taken into account lest it give false conclusions.

Stored-energy values of generators are conveniently expressed in kwsec per kva of rating so that, knowing this value for any class of machine, the stored kinetic energy at rated speed of a particular unit is readily evaluated as the product of its kva rating and the kwsec per kva, the result being energy expressed in kwsec. Conversion to other units such as hp-hr or ft-lb can readily be made. For example, multiply kwsec by 737.6 to obtain ft-lb, or multiply kwsec by 0.369 to obtain ft-tons. Comprehensive stored-energy data are given in (2) and repeated here.

Fig. 7 gives the stored energy of hydroelectric units, total of the generator and the water-wheel runner, the water wheel being about 15 per cent of the total. Fig. 6 gives stored energy for large turbogenerator units, condensing as well as noncondensing. It is to be noted that while the 3600-rpm noncondensing turbogenerator units have values which are of the same order as for water-wheel units, the 1800-rpm and 3600-rpm condensing

units have kinetic-energy values much greater, twice as much or more. Thus while a 10,000-kva slow-speed water-wheel unit possesses about 1.75 kwsec per kva, a 10,000-kva 1800-rpm condensing turbogenerator unit has about 9.4 kwsec per kva. The energy in these 10,000-kva units at rated speed would be 17,500 kwsec (or 6450 ft-tons) for the water-wheel unit, and 94,000 kwsec (or 34,700 ft-tons) for the turbogenerator unit.

The effect of increasing water-wheel-generator inertia upon

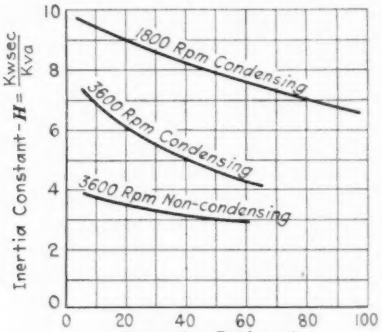

FIG. 6 INERTIA CONSTANTS OF LARGE TURBOGENERATORS; TURBINE INCLUDED

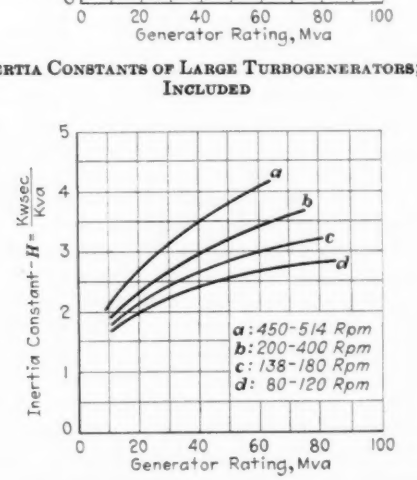

FIG. 7 INERTIA CONSTANTS OF LARGE VERTICAL-TYPE WATER-WHEEL GENERATORS
(Curves include allowance of 15 per cent for water wheels.)

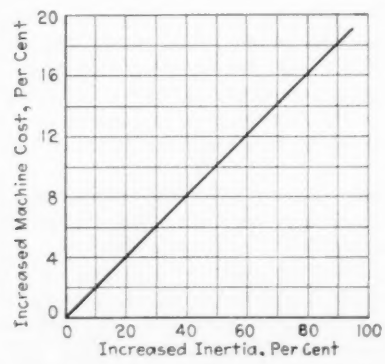

FIG. 8 APPROXIMATE COST OF INCREASING INERTIA OF LARGE VERTICAL-TYPE WATER-WHEEL GENERATORS

the cost is illustrated approximately in Fig. 8. Such increases in inertia are desired not only for hydraulic reasons but also occasionally for stability reasons.

For rotating machines other than hydroelectric and turbogenerator units, the following table affords average values from which stored energy may be estimated.

	Kwsec per kva
Condensers	
Large	1.25
Small	1.00
Synchronous motors	2.00
Induction motors	0.50
Rotary converters	2.00

SHORT-CIRCUIT RATIO

Mechanical energy is put into the shaft of an a-c generator and electric energy taken from the stator terminals. Between the rotor and stator is an air gap and, because of this, it is often said that all energy input to the shaft must "cross" the air gap. What allows this energy to cross the air gap is a magnetic field or flux which exists in it, called the air-gap flux. Anything that affects this air-gap flux also affects the power- or energy-trans-

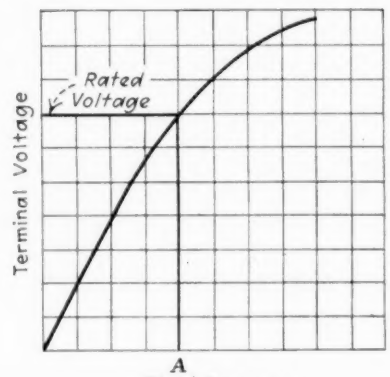

FIG. 9 NO-LOAD SATURATION CURVE

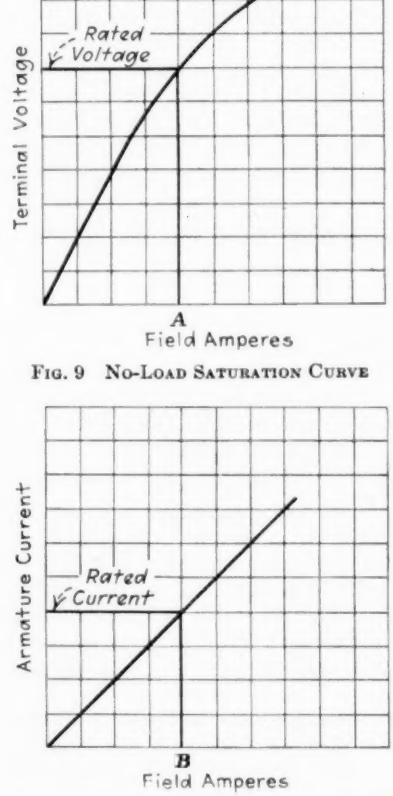

FIG. 10 SHORT-CIRCUIT SATURATION CURVE

mitting ability of the air gap and, therefore, the ability of the machine to put out electric energy.

Air-gap flux is usually thought of as being determined primarily by current in the field winding and this is illustrated by any no-load saturation curve, Fig. 9, which shows how, at no load (armature winding open), the armature voltage varies with field current. However, current flowing in the armature winding has a decided effect on the air-gap flux and a particular "type" of armature current has a strong demagnetizing or weakening effect on the air-gap flux. This "type" of armature current is commonly known as zero-power-factor lagging current or as demagnetizing current and is the kind that flows when the armature is shorted at its terminals or when it is connected to an inductive load. Under actual operating conditions in a system, a generator usually supplies current which has a demagnetizing component. Thus it requires more field current to produce any specified amount of

air-gap flux when armature demagnetizing current is flowing than when there is no armature demagnetizing current. Under actual operating conditions, the air-gap flux is the resultant of that which the rotor-field current tries to produce, minus the bucking effect of any armature demagnetizing current that is present.

In order to gain an idea of how much weakening effect a given amount of armature demagnetizing current has on a given machine the following test may be made:

Short-circuit the three armature terminals and then apply sufficient field current to cause rated armature current to flow. It requires a certain amount of air-gap flux to cause this armature current to circulate, even though the terminal voltage is zero. This test thus measures the amount of field current required to produce a certain amount of air-gap flux when being "bucked" by a specific amount of armature demagnetizing current. The greater this required field current, the weaker is the field in relation to the armature. A "strong" machine is thus one in which this required field current is low, since that indicates air-gap flux is determined principally by the field current. Suppose this required field current is 500 amperes. Since this is an abstract quantity with little meaning in itself, in order to compare machines, it must be possible to express this in per cent or per unit with respect to some reference level. The field current required for rated voltage at no load is a handy and definite reference; suppose it is 550 amperes. Just how can the no-load field current be made useful as a reference? The natural thing to do is to take a ratio and, if it is to be indicative of the relative strength of field with respect to armature, this ratio must be the no-load value of 550 amperes divided by the short-circuit value of 500 amperes field current, giving 1.10.

This ratio of (no-load-rated-voltage field current) to (field current required to circulate rated armature current on 3-phase sustained short circuit) is called the short-circuit ratio and the American Institute of Electrical Engineers definition is in these terms. Thus, from Figs. 9 and 10, short-circuit ratio $= \frac{A}{B}$. Because of the fact that, when the machine is short-circuited, the armature current is almost exactly proportional to field current Fig. 10, it turns out that short-circuit ratio is equal to the number of times rated armature current which flows on sustained 3-phase short circuit, when the field current is set at the value required for rated voltage at no load.

For a generator which is operated with field current manually controlled, short-circuit ratio is an indication of the steady-state stability characteristic of the machine, provided that the field current is normally set and left at a definite field value such as the no-load-rated-voltage value. However, if this same machine has its field current automatically controlled, as by a generator voltage regulator (as is almost always the case with water-wheel generators), then short-circuit ratio is not a direct indication of the steady-state stability characteristic because, as armature demagnetizing current increases and thus tends to reduce the air-gap flux, the voltage regulator will boost the field current. The automatic control of kw output and speed by a governor has its counterpart in the generator voltage regulator which automatically controls field current, using terminal voltage as an index.

Conclusions

The analysis of frequency regulation and tie-line loading in extensive power systems is a complicated matter which can be visualized to a fairly complete degree by means of the mechanical analogy developed in connection with power-system stability.

In studying frequency regulation in a system, the conditions are such that synchronous machines ordinarily cannot adequately be characterized by transient reactance as they are in transient stability studies. The action of voltage regulators and the effect of saturation on the synchronous reactance must be considered.

The a-c-network calculator which allows quantitative analysis of a power system in miniature, and which is used in steady-state as well as transient stability studies, affords a means of analyzing frequency regulation in an interconnected system.

Steam-Turbine Governors

By REED J. CAUGHEY,[1] SCHENECTADY, N. Y.

This paper has been prepared as a contribution to a symposium on the subject of steam-turbine governors. The importance of the subject at present arises more from the increasing complexity of interconnection requirements than from any definite deficiency in existing apparatus. Attempts have recently been made to draft specifications for governing equipment that might be applicable both to steam and hydraulic prime movers. The purpose of this paper is to state briefly the essential characteristics, functions, and behavior of governing apparatus both for condensing and superposed turbines. Definitions are suggested for terms and phrases frequently used without definite significance. In conclusion the essential points of a brief specification are outlined for the purpose of discussion.

THE governing requirements for steam-turbine generators, in regard to stability and safety of operation, can generally be determined by the manufacturer and each turbine is supplied with a governing mechanism by means of which the manufacturer endeavors to meet these requirements. These requirements vary considerably with the type and size of turbines as will be explained later.

On the other hand, the characteristics of turbine-governing mechanisms to suit them best to the particular requirements of a purchaser's system and load usually cannot be so readily determined by a manufacturer. In addition the effect of turbine-governing characteristics on power-system stability is a controversial matter and warrants more investigation. This discussion has been planned with the idea of aiding the purchaser in determining and stating the governing characteristics desired for a particular turbine generator to suit it in the best way to his system, and to permit the manufacturer to interpret these requirements and make his design such as will meet them.

The satisfactory operation of the governing mechanism of a steam turbine depends upon the sensitivity and response of this mechanism.

The relation of these two characteristics of a governing mechanism to the regulation, rapidity of load change, and protection against overspeeding is useful in determining the design limits of a governing mechanism.

To develop the effect of these relations, this paper will discuss: (1) General principles of governing; (2) governors and their limitations as speed indicators; (3) governing mechanisms and their limitations due to regulation and rapidity of load changes; (4) protection of the steam turbine against overspeeding. In addition (5) a short description of the governing problems encountered in the design of superposed steam turbines is included with (6) a tentative specification for steam-turbine-governing mechanisms.

General Principles of Governing

The governor of a steam turbine is shown diagrammatically in Fig. 1. It may be a simple governor controlling the steam valves as shown in *A*, or it may operate the steam valves through the controlling mechanism as shown in *B*. It may also operate the steam valves through a primary relay and control mechanism as shown in *C*. In all of these arrangements, the governor of a steam turbine is designed to control the power output with a nominal variation in turbine speed and to prevent dangerous overspeeding of the turbine. The method of controlling the output will be discussed first.

As the load upon the turbine changes, there will be a change in turbine speed, providing the steam input, and hence the power output, of the turbine buckets remains constant. It is the function of the governor to measure this speed change and to change the steam input to suit the new load. To change the steam input, the governor is designed so that a change in its speed of rotation is converted into a corresponding displacement of the governor weights or equivalent. By means of any of the arrangements shown in Fig. 1, this displacement in turn actuates the steam valves controlling the steam input to the turbine. The amount of this displacement required to move the steam valves from wide-open to shut (total valve stroke) or vice versa is called the "effective stroke" of the governor. The regulation of the governor is the speed change required to cause the governor to move through its effective stroke.

Under steady-state conditions, Fig. 2 shows a definite relationship between governor speed and effective governor stroke. Fig. 3 shows a similar definite relationship between total valve stroke and the effective stroke of the governor. In Fig. 4 these same data are replotted showing the relationship between governor speed and total valve stroke. This last figure also shows that, for each speed of the turbine, there is a fixed valve position and, therefore, a fixed steam input.

Governors and Their Limitations as Speed Indicators

In Fig. 5 governor speed is plotted against the effective stroke of the governor. Line *AB* is the same as line *AB* in Fig. 2. A governor which has no internal friction and does no external work will have the characteristics shown by this line. In this paper this form of governor will be called a perfect governor. With a perfect governor, speed change and response are simultaneous.

An actual governor has internal friction so that a speed change is necessary to build up a force to overcome this friction. This change in speed without governor response is shown by the lines drawn through *C*,*C* on each side of the line *AB*. Lines are drawn on both sides of line *AB*, since the internal friction of the governor is resisting the governor response as its speed either increases or decreases. This change in speed *C* without governor response is a measure of the sensitivity of the governor.

Besides overcoming internal friction, any actual governor as shown in Fig. 1 has to perform external work in order to move the steam valves. This external work has the same effect as the internal friction and further reduces the sensitivity of the governor. This effect is shown by the lines drawn through *D*,*D* on either side of the line *AB*.

In order to reduce the external work done to a minimum, a power amplifier is required whose power is controlled by a valve moved by the governor. This valve is called the primary pilot valve and the complete power-amplifying device is called a relay mechanism. The combination of this relay mechanism and the

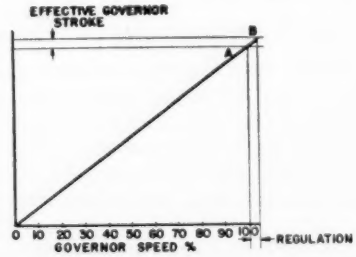

FIG. 2 RELATION BETWEEN GOVERNOR SPEED AND EFFECTIVE STROKE

(This diagram shows how a speed indicator functions as a governor. In this and succeeding diagrams straight-line relationships have been used for simplicity. In actual governors and governing mechanisms these relationships deviate more or less from the straight line. However, such deviations are not important to a correct understanding of governor behavior.)

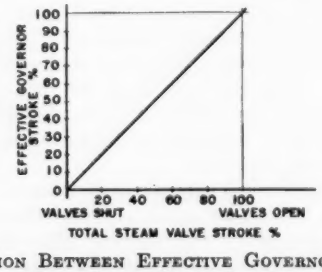

FIG. 3 RELATION BETWEEN EFFECTIVE GOVERNOR STROKE AND TOTAL STEAM-VALVE STROKE

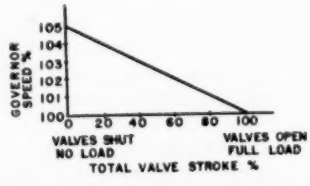

FIG. 4 RELATION BETWEEN GOVERNOR SPEED AND TOTAL VALVE STROKE

(The diagram is derived from the relations in Figs. 2 and 3, and shows that for each speed there is a definite valve position and steam input.)

governor is called a relay governor, and it is shown in Fig. 1(*C*). The effect of using the relay mechanism is to reduce the amount of external work that the governor has to do. In Fig. 5 the effect is to move the lines passing through *D*,*D* closer to the lines passing through *C*,*C*. This effect is true when the rate of change in speed of rotation of the governor is small. As the rate of change in speed of rotation of the governor increases, there will be a further delay in governor response as compared to the response of a perfect governor. This delay is called lag and is shown by the lines drawn through *E*,*E* at either side of the line *AB*. The greater the rate of change in speed of rotation of the governor, the greater the lag.

GOVERNING MECHANISMS AND THEIR LIMITATIONS DUE TO REGULATION AND RAPIDITY OF LOAD CHANGES

In the preceding section, the action of the governor is analyzed

The action of the governor when operating the steam valves will be discussed next. In order to show the effect of a change in steam input upon a turbine, the relationships between turbine speed and effective governor stroke, valve stroke, and time are shown in Fig. 6. If the turbine loses full load, the steam valves must move through their total valve stroke. In order to move the steam valves through their complete stroke, the governor must make its complete stroke as shown at *A*. The speed change required for this movement is the regulation as shown by the vertical ordinate for charts *A*, *B*, and *C*. In these charts the regulation is shown as 5 per cent. As the governor makes its effective stroke, the steam valves make their total valve stroke. The speed change for this total valve stroke is shown at *B*.

If the steam input to the turbine remains constant, the time required for the 5 per cent speed change will be as shown in *C* and will be fixed by the rate of acceleration of the turbine rotor.

In order to obtain a total valve stroke, corresponding to effective governor stroke, it is necessary to have the time required for the valve to make its total stroke no greater than the time required for the speed to reach the value represented by the regulation. This is shown at *D*.

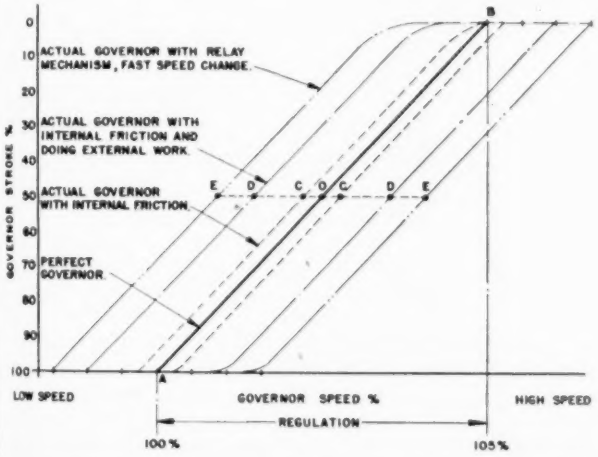

FIG. 5 COMPARISON OF ACTUAL GOVERNOR PERFORMANCE WITH PERFECT GOVERNOR BEHAVIOR AS REPRESENTED BY STROKE-SPEED LINE *AB*; ALSO SHOWN IN FIG. 2

(The "lag" is $= EO$ or less. The lines through *C,C* and *D,D* show elements contributing to lag. The distance $= CO$ is a measure of the sensitivity, being smaller the greater the sensitivity.)

In the ideal case, the time available for total movement of the steam valve under a full-load change will be the time required for the speed to change an amount equal to the regulation for which the governor has been set.

There are numerous practical considerations which make it difficult to approach this ideal case. In the case where a controlling mechanism is used Fig. 1(*B*), there will be a time delay, as time is required to initiate any motion which uses a fluid as the power medium. The magnitude of the time delay of a controlling mechanism is a function of the quickness and amount of movement of the main pilot valve. The power required to move this main pilot valve is supplied by the governor and, as shown in Fig. 5, this is obtained at the expense of sensitivity of the governor.

It will be seen, therefore, that if the load changes are slow with correspondingly slow speed changes, an extremely accurate governing mechanism may be designed. This is due to the fact that these slow speed changes require slow motion of the steam valves which may in turn be obtained by a small main pilot valve with a small stroke and with a correspondingly small amount of external work done by the governor. When, however, the load changes are fast, with correspondingly fast speed changes, then the design of an extremely accurate governing mechanism becomes difficult. To obtain a fast movement of the steam valve, a large main pilot valve with a large stroke is necessary, and this in turn requires a large amount of external work by the governor and a loss in its accuracy.

For this reason, relay governors have been developed which impose a relay mechanism between the governor and the controlling mechanism as shown in Fig. 1(*C*). This relay has an additional time delay which must be taken into account when determining the response of the governing mechanism.

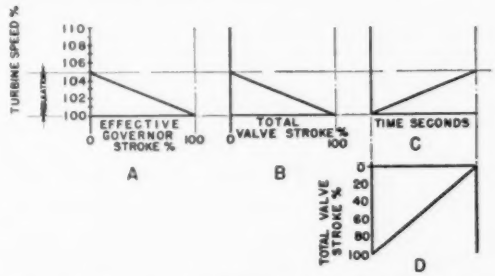

FIG. 6 IDEAL RELATIONS BETWEEN TURBINE SPEED, EFFECTIVE GOVERNOR STROKE, VALVE STROKE, AND TIME TO ACCELERATE THROUGH FULL REGULATION

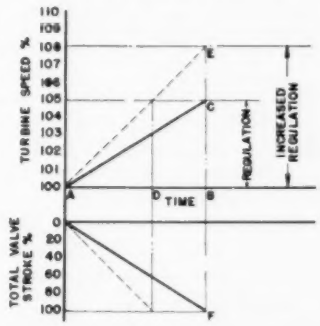

FIG. 7 RELATION BETWEEN VALVE-OPERATING TIME, REGULATION, AND ACCELERATION WITH AN IDEAL GOVERNING MECHANISM

(This diagram shows that the slower the valves or the greater the acceleration, the greater must be the regulation in order to have perfect governing.)

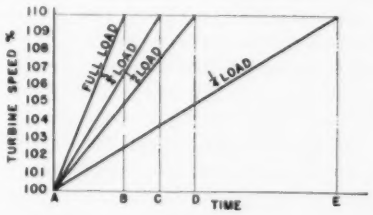

FIG. 8 RELATION BETWEEN AMOUNT OF INSTANTANEOUS LOAD CHANGE AND TIME REQUIRED TO ACCELERATE TURBINE ROTOR TO 110 PER CENT

(The smaller the instantaneous load change, the slower may the valves operate in order to follow the speed.)

It has already been noted that the steam valves must make a complete stroke from wide-open to shut in the time required for the steam turbine to change its speed an amount equal to the regulation. This is shown in Fig. 7, where the turbine speed *BC* has changed 5 per cent in the time *AB*. Since with a perfect governing mechanism the steam valves will be shut when the governor has made its effective stroke, the time for 100 per cent valve stroke will also be represented by time *AB*. If, however,

the speed increases 5 per cent in the time AD, then either the valve must be able to make its complete stroke in this same time, or the regulation must be increased as shown by the line BE so that the speed rise, represented by the regulation, will require as much time as the valve closing time AB.

A perfect governing mechanism locates the steam valve at the new load point at the same time that the steam-turbine speed reaches the speed corresponding to this new load.

As is shown in Fig. 8, a given turbine rotor will accelerate to a given speed in the time AB for a full load change. It will accelerate to the same speed in the time AC for a $^3/_4$ load change and in the time AD and AE for $^1/_2$ and $^1/_4$ load changes. This indicates that, for a given turbine rotor, the less the instantaneous load change, the slower the valves need to move in order to follow the speed.

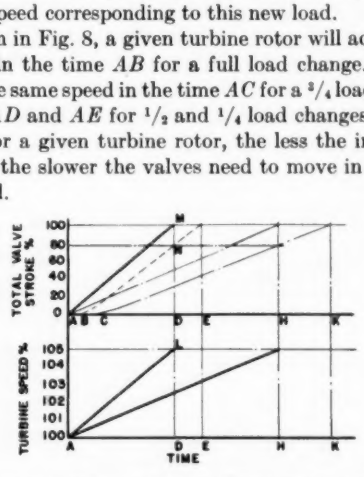

FIG. 9 RELATION BETWEEN VALVE-OPERATING TIME, ROTOR-ACCELERATION TIME, AND LAG OF GOVERNING MECHANISM
(This shows that the slower the valves move, the slower must be the turbine acceleration in order to obtain the same lag.)

In general, steam turbines fall into two classes as far as governing is concerned. These classes are, first, a single turbine in an isolated factory or power plant operating on a variable load and, second, a number of turbines in large central stations connected together on a common distribution system.

Steam turbines in actual service are not called upon to make full load changes continuously, except under abnormal power-system conditions. In view of the foregoing limitations, it is necessary for the designer to know the magnitude and rate of all load changes. This will depend upon the character of the load and the number and size of the turbines connected together. Knowing the magnitude and rate of all load changes, it is possible to design a governing mechanism which has any specified lag. This lag will not be exceeded as long as the magnitude and rate of the load changes are not more than has been specified. Besides the magnitude and rate of load change, the entrained steam between the steam valves and the turbine exhaust is another determining factor not only of the type of governing mechanism but also of the possible lag which can be obtained.

If the time required for 100 per cent total valve stroke is AD in Fig. 9 and the turbine rotor changes speed 5 per cent in this time, then there will be perfect following of the turbine speed by the valve, providing the regulation is 5 per cent. If, however, the valves have a time delay of AB and a speed of movement represented by the time BE, then there will be a lag of the valves of 20 per cent of the stroke as shown by the line MN. When the valves have a time delay represented by AC and a time for 100 per cent stroke of CK, then to obtain the same lag the time required for the rotor to accelerate must be AH which necessitates a smaller or slower load change.

The ability of the governing mechanism of a steam turbine to position the steam valves for a given load change without sustained movement of the steam valves is called stability. The stability of a governing mechanism depends upon the magnitude of the lag shown at MN, Fig. 9.

As this lag of a governing mechanism is a function of the speed of response of this mechanism, it follows that the regulation of the governor, as defined previously, materially affects the characteristics of the governor.

Stability of the governing mechanism, therefore, should be defined in terms of regulation and speed of response of the governing mechanism. Stability, of course, cannot be obtained without a certain sensitivity. In general, the slower the response of the governing mechanism, the greater must be the regulation of the governor if the sensitivity remains constant, in order that the governing mechanism may have a minimum lag.

In Fig. 10, if the steam valves can make their complete stroke in the time AB, then if the rotor acceleration is fixed by the line AC, a 3 per cent regulation will permit the steam valves to reach the position corresponding to the speed.

If the steam valves require the time AD to make their complete stroke then, when the speed reaches 103 per cent, the valves will have completed only 60 per cent of their stroke (or a lag of 40 per cent) and it will be necessary to increase the regulation to 5 per cent in order to permit the valves to be in the proper position corresponding to the speed.

As speed of response over a certain value is difficult to obtain, governing mechanisms must be designed with adequate regulation.

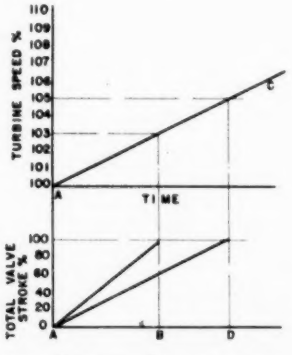

FIG. 10 RELATION BETWEEN VALVE-OPERATING TIME AND REGULATION
(This shows that with a fixed rate of acceleration the slower the valve-operating time the greater must be the regulation in order to have perfect governing.)

This means that, from the definition of regulation, a considerable speed change of the turbine is necessary to change the load from full load to no load, or from no load to full load. This characteristic of governing mechanisms has necessitated speed-correcting devices in governing mechanisms which permit correcting the speed of the steam turbine after a speed change which has automatically followed the load change. This speed-correcting device on steam turbines has taken various forms, either hand-operated or automatic. The latter fall into two general classes, i.e., speed-resetting devices or automatic frequency control, and self-restoring devices or droop correction.

The variation from normal speed which the steam turbine maintains, after the speed change due to regulation has been restored, is termed droop of the governing mechansim and is given as the per cent speed variation from normal speed.

PROTECTION AGAINST OVERSPEEDING

As has been stated previously, the governor of a steam turbine has another function besides the accurate proportioning of the steam input to power output. This function is to prevent a rise in speed sufficient to trip the emergency governor on loss of full load. If the loss of load is instantaneous, the rate of speed change will depend on the WR^2 of the steam-turbine and generator rotors. In this case, lag of the governor may be compensated for

by an increase in the speed of the controlling mechanism. With an accurate governor, the speed of the controlling mechanism may be slower as in either case the steam valves must be at no-load position when the speed has increased the specified amount.

If it is desired to have the valves closed when the speed reaches 110 per cent, as shown in Fig. 11 and, if the time required for this speed change is represented by AB, it will be possible to accomplish this by moving the valve through 100 per cent stroke in the time AB or delaying the starting of valve movement by the time AC and then moving the valve through 100 per cent stroke in the faster time CB.

The ability of the governing mechanism to prevent excessive speed rise on loss of full load depends upon the magnitude of the instantaneous load changes for which the governing mechanism was originally designed. In general, it may be said that unless the governing mechanism is designed to follow accurately

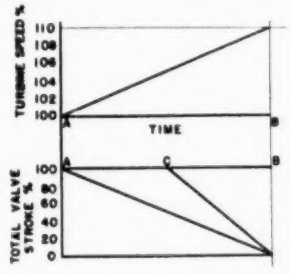

FIG. 11 RELATION BETWEEN TURBINE ROTOR ACCELERATION AND VALVE-CLOSING TIME

(This shows that the more lag there is, the faster must the valve move in order to prevent the turbine speed exceeding a set limit.)

an instantaneous full-load change, the amount of overspeed on loss of full load will be the limit in design of the governing mechanism.

With the governing mechanisms designed to prevent excessive overspeed, it will be found that automatically a smaller WR^2 high-speed steam turbine will be obliged to have a more responsive governing mechanism than a low-speed steam turbine having larger WR^2.

SUPERPOSED- AND EXTRACTION-TURBINE GOVERNING

Superposed and extraction steam turbines require governors and governing mechanisms, the functions and characteristics of which are similar to those used with condensing turbines. For controlling the steam input a pressure governor is used. This pressure governor responds to changes in pressure. For superposed turbines, it is not generally necessary to use the speed governor for controlling the steam input and, in this case, the speed governor is used as a pre-emergency governor only. The rapidity of the load change and the WR^2 of the turbine rotors are not used in the control-mechanism calculations for this class of turbine. In place of these effects, the rapidity of the change of steam flow and the volume of the back-pressure steam-distributing system are used. For superposed turbines, the governing mechanism is designed to prevent excessive overspeeds of the turbine. The back-pressure governor and the controlling mechanism are designed with the necessary sensitivity and response to produce stable operation.

Stability of operation on this type of turbine is more difficult to obtain than stability of a condensing turbine controlled by a governing mechanism. This is due to the fact that in general the volume of the exhaust piping between the superposed turbine and its associated low-pressure turbines is relatively small. The result of this small volume is the same as having a steam turbine with a very small WR^2 per kilowatt and means that the rate of change of pressure is much faster than the rate of change of speed on this same type of turbine.

The design of the pressure-governing mechanisms, therefore, following the same specifications as outlined for governing mechanisms, must be sensitive and responsive enough to provide stable governing. For the same reasons, when the speed of response has been made as fast as is practical, then the regulation of the pressure governor must be increased to a value which will produce stable operation. This increase in regulation, as in governing mechanisms, has made necessary pressure-resetting devices on pressure governors. These devices may be either hand-operated or automatic. The latter may be either pressure-resetting or pressure-restoring.

The design and operation of large superposed turbines have presented some problems which have not been encountered so far on either the smaller turbines of this type or on condensing turbines. These problems have been to determine the constants to be used in designing in order to fulfill the requirements previously outlined. These large superposed turbines have smaller rotors than condensing turbines having the same kilowatt rating. This means that the WR^2 per kilowatt is less and that the acceleration of the steam-turbine rotor and generator is much faster than has been encountered on other turbines. The size of these turbines requires, of course, large steam valves so that the steam-pressure drop may be held to a minimum and the efficiency improved. These large steam valves require large forces to operate them. They must also open and shut quickly so that the governing mechanism will function as outlined previously. The speed of operation of the steam valves on this type of turbine must be exceedingly fast in order to be able to follow the very fast speed change of these steam turbines.

It is not uncommon to use 100 hp to 200 hp for the movement of these valves. This power must be controlled by both the governor and the back-pressure governor with the proper sensitivity and response. This requires powerful and sensitive governors, which have a minimum of time lag and which can control this power accurately.

Extraction turbines differ from the superposed turbines since, in general, both governing and pressure governing are necessary in order to obtain the satisfactory control of power output and extracted steam.

All of the problems outlined previously, covering both governing mechanisms and pressure-governing mechanisms, apply to this type of turbine. It should also be noted that this type of turbine comes under the class of a turbine generally connected alone to a system, which condition may produce larger load changes on the steam turbine. The governing mechanisms for this type of turbine, therefore, must be more sensitive and more responsive.

This type of turbine, for this reason, is generally equipped with relay governors in order to secure the degree of sensitivity required. The relay governor produces more external work with less speed change, thus increasing the sensitivity and response and permitting very close speed control.

This type of governor is designed with a large regulation and is generally equipped with automatic speed control so that the speed is held within close limits.

GOVERNING-MECHANISM SPECIFICATIONS

At present no definite specifications covering requisites for governing mechanisms have been laid down by various steam-turbine users. It has, therefore, been necessary to design the governing mechanisms so that they will function in the most efficient manner, based upon the manufacturers' best information as to operating requirements.

We, as manufacturers, have in the past asked groups of steam-

turbine users to discuss with us their requirements for governing mechanisms. However, until recently for the most part we have had to form our own ideas as to these requirements.

Within the last few months, however, a group of utility operators under the leadership of the Hydraulic Power Committee of the Edison Electric Institute has submitted a tentative governing specification for prime movers. Using this specification as a basis of approach, we have attempted to formulate a governing-mechanism specification for steam turbines used in central stations. The minor changes made are the result of considering the transient requirements and the complete governing mechanism rather than the governor alone.

To the standard governing mechanism used by central stations at present, there has been added in the proposed specification regulation and droop control. A discussion of the value of these features in central-station operation might be in order following this paper.

These specifications have been written to cover all of the points brought out in this paper. The several headings apply to the various requirements for governing mechanisms as outlined. Each heading has first a definition and then a specification.

Sensitivity. The ability of the steam valves to respond to a certain sustained speed change. The sensitivity of a governing mechanism should be such that response of the steam valves will occur with not more than 0.04 per cent speed change of the turbine. The sensitivity of the governor should be such that response of the governor will occur with not more than 0.02 per cent in speed change.

Droop. The steady-state change in speed for a full-load change. Droop shall be adjustable from zero to the regulation of the governor and this adjustment will be indicated.

Regulation. The speed change necessary to move the steam valves from zero load to full load with no droop correction. The regulation shall be adjustable from 2 per cent to 6 per cent and will be indicated.

Stability. The ability of the governing mechanism of a steam turbine to position the steam valves for a given load change without sustained oscillation of the steam valves.

Overspeeding. The turbine speed shall not exceed 110 per cent speed on the loss of full rated load.

Response. Perfect governing-mechanism performance is the exact following of the speed-load position by the steam valves. In practice the steam valves always lag behind the speed-load position. For a 6 per cent governor regulation, this lag should be not more than 20 per cent of the total steam-valve stroke when the instantaneous load change is not more than 50 per cent of full rated load.

Speed Adjustment. Possible from 98 per cent at no load to 102 per cent speed at full load.

Load Limit. Adjustable and its position shall be indicated.

It is hoped that this paper, together with the foregoing tentative specifications of a governing mechanism will enable steam-turbine operators and designers to formulate more definite specifications for governing mechanisms which will permit the better functioning of steam turbines in all central-station service.

Discussion

J. C. Hobbs.[2] Governor engineers are to be commended for their intricate analytical work in devising a mechanism which functions in a manner responsive to some motivating force. When every part functions perfectly according to the fundamental theory without lost motion, without wear, without dirt, without falling apart, without breaking, and without lubrication or without any one of hundreds of other troubles, reliable satisfactory operation is secured; but, unfortunately, nothing is perfect. Beginning even with the governor-engineers' design and following with the manufacturers' workmanship and material, the erectors' technique, and the operators' treatment, there always seems to be some minor cause for what sometimes becomes a major accident. Today, manufacturers' organizations appear to be striving more for the complex and, as a result, illustrations could be cited in great number where complexity has caused complications while the manufacturer remains complacent.

No criticism should ever be made without at least voicing a constructive thought or, better yet, a solution. Therefore, without attempting to provide a detailed design for any of the myriad governor problems, it is suggested that the first and fundamental requirement of any governor, where safety and reliability are paramount, is that the governor design and construction shall be as simple as it is possible to construct and still obtain a practical performance of the desired functioning. Each and every governor design should be critically analyzed with a view to determining whether this group or that group of parts might not be replaced with a single part and so on until the minimum combination of moving elements remains. This suggestion is made in the interests of both the operators and the manufacturers, since whatever results in good operation also results in lowered costs for manufacturers, due to reduction in service expense and, in addition, life and property are safeguarded.

R. W. McLaughlin.[3] This paper presents a well illustrated résumé of the problems connected with the design of turbine-governor mechanisms. The brief statement of the case surrounding extraction-type turbines and of the fact that they require the most sensitive governing mechanisms available is well founded. However, due to the high sensitivity and responsiveness of these governors, it is not always necessary to have the governors set for broad regulation, which requires an automatic frequency control to prevent excessive speed variations.

It has been found in numerous instances, where good frequency control was desirable but not of sufficient value to warrant purchase of automatic frequency-controlling equipment, that the extreme sensitivity and rapid response of the governors made it entirely satisfactory to set them for 2 to 3 per cent regulation. That is, with no manual correction of speed whatever, should the electrical load and extracted steam flow either or both together, gradually vary from zero to the maximum for which the machine was designed, their resultant variation in speed would be less than 1 cycle above or below normal. Thus, with the normal variations of load and extracted steam flow which, though often sudden, are only a fraction of the maximum capacity, manual correction of frequency is required only at protracted intervals. Perhaps one of the most difficult applications of this type which has been worked out successfully is the case of an extraction turbine which operates alone in an industrial plant. The governing mechanism on this machine is taxed quite severely, since it serves an electrical load, the bulk of which consists of spot-welding equipment and plant-lighting equipment, neither of which provides the system with any rotating inertia. The surge in power which results from several spot welders striking simultaneously necessitates continual rapid movement of the governor, since the system inertia is so small that the turbine speed is affected by these power surges, even though they are of short duration.

Probably these results could not have been accomplished without the use of a fully compensated valve gear, by means of which either the governor or extraction pressure regulator can

[2] Vice-President in Charge of Manufacturing, Diamond Alkali Company, Painesville, Ohio. Mem. A.S.M.E.

[3] Turbine Engineering Department, Elliott Company, Jeannette, Pa.

correct variations in the medium it controls without disturbing the other. A further requirement is the use of a double oil relay governor somewhat different in arrangement but similar in principle to that illustrated in Fig. 1 (*C*) of the paper. Furthermore, the accomplishment of such results can scarcely be expected without the designing engineer being fully equipped with advance information furnished by the purchaser with respect to the anticipated details of operating requirements before the design is started, which, as the author suggests, is all too often not the case, as future operating requirements are often unpredictable.

R. B. Smith.[4] This paper presents a summary of the salient features of the governor problem from the static viewpoint. Undoubtedly, the author would be one of the first to agree that a satisfactory solution to the problem necessitates a study dynamically in which the time lags as a result of inertia are included. In many respects there is a similarity between the governor and the vibration problem. Since the question is essentially dynamic, it seems rather unfortunate that more analytical and experimental analyses are not common in our technical literature. A start was made some years ago by Tolle (1)[5] and Stodola (2). This was extended in both a practical and analytical way by Freudenreich (3), and more recently by the efforts of Stein (4) and Luoma (5). In this country, the attention of the Process Industries Division of the A.S.M.E. in its subcommittee on Industrial Instruments and Regulators has been devoted to fundamental study of this problem along analytical lines, and with promising results.

While it has been pointed out in this symposium that a satisfactory governor is in the end one which meets the requirements of the customer is it not also true that a satisfactory governor can be more properly described as one which is dynamically and transiently stable? Dynamic instability, usually termed hunting, meets the author's definition of stability. Its determination necessitates a consideration of the time lags outlined in the author's Fig. 5 and a consideration of these lags in respect to the prime-mover system as a whole. Transient instability arises when, under sudden changes, the governor does not function properly or fails to keep the machine from overspeeding or tripping.

Either of these two types of instability may arise from two sources—a forced instability or an inherent instability. Forced instability can be thought of as arising from external causes such as excessive backlash or from friction; it is indicated in part by the lag *OC* in Fig. 5. An inherent instability arises when the various time lags which exist within the system, and which are attributable largely to inertia, bear an improper relation to the dynamics of the rest of the prime-mover system. It is particularly in the investigation of these dynamic lags that analytical in combination with experimental analysis has proved helpful. As a general statement, it can probably be said that a few years ago instability of a forced nature was the most common governing difficulty. With the advent of the high-back-pressure machine, having a high rate of maximum initial acceleration, and particularly when it operates in conjunction with lower-pressure turbines, the difficulties arising from an inherent instability of the system have assumed a much more important aspect.

W. Trinks.[6] The illustrations of Fig. 1 (*A*, *B*, and *C*) are apparently quite diagrammatic, because the springs between the centrifugal weights would have to be so wound that they have less than no length when free from tension; or else they must be so wound that they exert considerable tension when coiled tightly. Both feats are difficult.

The reason for this may be readily seen: In an isochronous governor, centrifugal force is proportional to distance of center of weights from the axis. The spring must be free from tension when the centers of gravity of the weights are in the axis. Since the spring is shown shorter than the distance between the weight centers, it must have a negative length, when free.

It may be possible to coil the spring so as to exert tension when coiled tightly. If so, the writer would appreciate directions on how to do it.

With regard to nomenclature, the following may be mentioned: Although the Power Test Code Committee has settled on certain names, attention should be given to the fact that within the Society there is another committee which deals with regulation and control and which is busily engaged in standardizing names for instruments such as are used to control pressure, temperature, rate of flow, and the like. It would be unfortunate if two committees within the same society selected different names for the same quantities. They should cooperate.

S. H. Hemenway.[7] The opinion has been expressed that all governors on a system should respond to a speed change of 0.01 per cent to avoid tie-line load swings; also, that the purchaser should specify governing characteristics to take care of the magnitude and rate of load changes on the system. This will stand further study, of which the following are indications:

Many types of governors have obtained stability by having a temporary speed droop *OC*, Fig. 12 of this discussion, greater than the settled speed droop *OA*. This was accomplished on the flyball governor, Fig. 13, by a dashpot on the operating lever. The effect of having the governor respond to smaller speed changes can be seen by disconnecting the dashpot, or by allowing the dashpot some lost motion *Y*. This dashpot arrangement for securing stability has been used on pressure regulators as well as speed governors. In a few cases where it was permissible to try this lost motion, a rapid hunting resulted. Variable droop can be obtained by adjustable automatic speed-resetting means.

A governor in which the speed-sensitive element is of the no-travel type is shown in Fig. 14. In this case, with movement of the governor, the compensating piston *E* increases or decreases the pressure over the dashpot piston *G*. Properly proportioned, this arrangement is nearly equivalent to the dashpot of Fig. 13. It is as stable and reliable as the governor having appreciable travel of the speed-sensitive element, and there would appear to be no reason for prejudice against it on this score. A similar dashpot *H*, Fig. 15, is shown for a no-travel pressure transformer-type of governor.

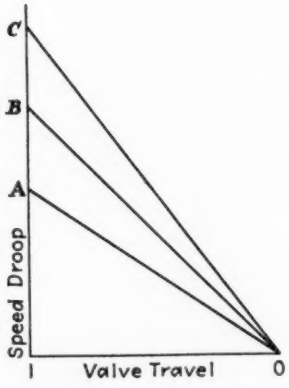

FIG. 12 SPEED-DROOP CURVES OF FLYBALL GOVERNOR

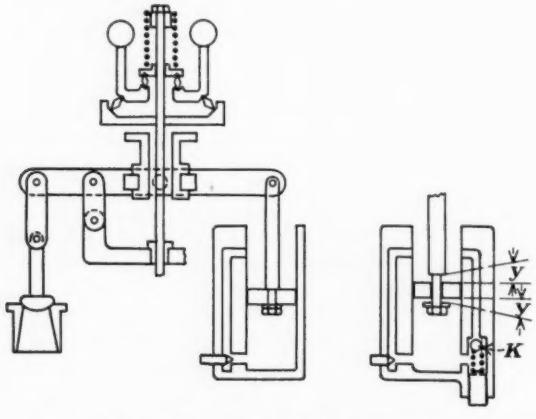

FIG. 13 TYPE OF FLYBALL GOVERNOR

With any of these governors, the temporary speed droop in the closing direction can be reduced from *OC* to *OB*, Fig. 12, by a spring-loaded relief valve *K*, Figs. 13, 14, and 15, to limit the dashpot action in the closing direction, thus limiting the speed jump with loss of full load.

The governors described in the papers[8] show the trend to more intricate and involved mechanisms to satisfy the increasing requirements. If purchasers specify in detail the governor characteristics, there will be a tendency to "play safe" and result in governors of greater intricacy and difficulty of maintenance. Before proceeding in this direction, it would be well to get together those experienced in these problems to outline the sensitivity and speed of response that is desirable considering the following:

1 Tie-line load change
2 Load changes due to "faults"
3 Resulting change in boiler output

4 Maintenance of voltage and electrical stability.

Theoretical studies of these factors can also be made with profit, before radical changes are made in governing apparatus. The writer believes there will be agreement that there are many conditions under which slow response has a stabilizing effect.

There has always been a question of the accuracy of measurement of speed, load change, pressure changes, and governor movements. If specifications can be drawn up to provide the sensitivity at different frequencies of equipment for measuring these values, and such equipment can be produced to these specifications by instrument makers and used for all such testing, it will clear up many discrepancies.

[Mr. Hemenway submitted with his discussion suggested terms for governor and control apparatus which have been turned over to the A.S.M.E. Power Test Code committee on Speed, Pressure, and Temperature Responsive Governors. This Committee is shortly to revise and enlarge the present Code.—EDITOR.]

Constant System Speed and the Steam-Turbine Governor

By A. F. SCHWENDNER,[1] SOUTH PHILADELPHIA, PA.

The demand for constant system speed is a current problem of power-generating systems. Electrical stability, governor, governing-valve characteristics, and other factors play their part in the problem. In this paper only the effect the governors and governing valves have in maintaining or disturbing the system speed is discussed. New governing systems are described to show the extent to which the turbine manufacturers go in trying to meet the demand for better system speed. The author points out that, when the governor characteristics of all units in a power-generating system are known, the combination of units used for certain load blocks can be determined not only for the best generating economy but also for better system speed. This information can be used to specify required governor characteristics for new units to further improve the system speed. Attention is called to the need for uniform governor performance and testing specifications.

THE last twenty years have brought many changes in the power-generating field. From small isolated power plants, large interconnected power-generating systems have developed. System frequency has improved from $^1/_2$ to 1 cycle total change, decreasing to 0.2 cycle maximum allowable change, and time errors have decreased to within 1 sec. Most of these improvements have been obtained without material changes to the then existing governors. The control-room operators have more work to do. Automatic frequency-control equipment has been installed, actuating one or several of the synchronizing motors of the governors. The increased use of hydraulic power has brought new problems, but the large systems have taken care of these without changing the governor (specifications); in most cases by increasing the turbine-governor speed variation, that is, the change in speed between no load and full load on a unit.

With the increased use of faster and more sensitive frequency recorders, short period frequency swings are shown which did not appear on the less sensitive instruments previously used. Load changes are observed between units in a power plant which do not correspond with system load changes or total plant output. There are several reasons for this performance. Neglecting the effect which electrical stability, low short-circuit ratio of generators, and harmonic pulsations of load may have in the frequency and load swings, only the part the governors and governing valves have in the problem will be considered.

Governor performance in the past was judged by its synchronizing ability and the amount of frequency change when carrying reasonably steady load with the unit on the line by itself. On larger systems where more than one unit was required to carry minimum system load, a governor was judged good if it synchronized well and showed very little change on the steam-flow chart. From the manufacturer's point of view, a governor is good if it satisfies the customer's requirements. Specifications very seldom called for more than a governor with 4 per cent speed regulation (a change in speed of 4 per cent from no load to rated load). If a governor could synchronize reasonably well with 4 per cent speed regulation and was sluggish enough not to show too much steam-flow fluctuation on the chart, it was considered satisfactory. The frequency recorders did not show momentary frequency swings, and slower changes of 0.2 cycle plus or minus were then accepted as satisfactory.

Sensitive Governors Required

The introduction of the superposed turbines and the larger-capacity 3600-rpm units brought a new type of steam-turbine generating unit into the power systems. The small rotor inertia and consequent high rate of acceleration inherent in this type of unit require fast and sensitive governors so that the units may be synchronized well. A sensitive governor which follows the smallest changes in frequency does not have a smooth steam-flow chart. If a unit with a sensitive governor is put on the line with a unit which has a sluggish governor, the steam-flow changes shown on a recording meter will increase, and will increase further with the additions of other units with sluggish governors.

A sluggish governor or governing system requires a certain amount of speed change before the governing valves begin to move. The centrifugal force of the governor weights and the governor spring force balance at any speed point. If there is a larger amount of friction between the governor parts, the speed will have to change until the difference between the centrifugal and spring force is sufficient to overcome the friction. The same is true with an oil governor. The oil pressure produced by the governor impeller acting on a relay or bellows is balanced by a spring force in the same manner as in a flyball governor. Between the governor and the governing valves there may be one or several servomotors and their linkage. Lack of response in relays and backlash in the linkage alone, or coupled with a governor having friction, may require considerable speed change before the governing valves begin to move. The speed change required to move the governor is not necessarily constant through its total stroke. The change in sluggishness and the difference in load change for the same frequency change, but at another governor or load point, require a thorough study of the governing characteristics of each unit, before a study of system control characteristic is attempted.

A 50,000-kw unit with a governor adjusted for 4 per cent speed regulation will usually show approximately 2000-kw load change with 0.1 cycle change in frequency, assuming straight-line load and governor travel characteristics. This is not always the case, however. Some 50,000-kw units will show 4000-kw load changes with 0.1 cycle change in frequency at some load points while, at other load points, the load change may be less than 1000 kw. Very few governing valves have straight-line flow and lift characteristics. Fig. 1 shows a governing-valve characteristic curve with four governing valves. The governor-servomotor travel, or governor-sleeve travel with flyball governors, governor-impeller oil pressure with oil governors, or rotor speed are shown on the vertical axis, while the steam flow or, with some correction, kilowatt load is plotted on the horizontal axis.

[1] Westinghouse Electric & Manufacturing Company.

Contributed by the Power Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Line *A* is the theoretical speed variation of the governor while the valve curves 1, 2, 3, and 4 show the amount of deviation per valve. A change of 0.1 cycle in frequency shows a 2000-kw change on the *A* line, while the same frequency change shows 3000-kw load change on the No. 1 valve line between 0.3 and 0.4 and 750 kw between 0.6 and 0.7 cycle. This load change in terms of speed variation would mean that when the unit load changes 3000 kw with 0.1 cycle speed change it has less than 3 per cent speed regulation, and with 750-kw load change 11 per cent.

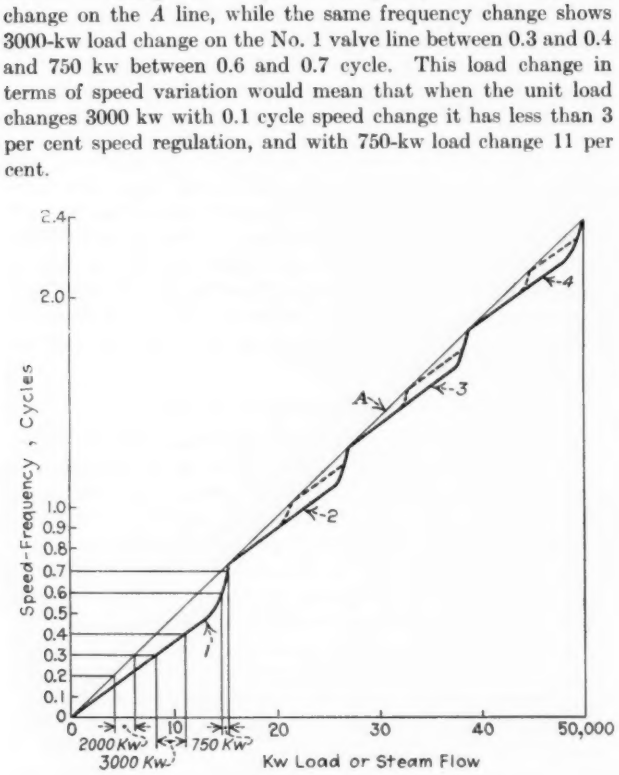

FIG. 1 GOVERNING-VALVE CHARACTERISTIC CURVE

The tail end of the governing-valve curve is determined by the minimum pressure drop allowed across the valve to obtain maximum full valve efficiency. The effect of this curve on the governing of the unit can be reduced by increasing the number of governing valves as shown by the dash lines, by the use of cams or by setting each governing-valve opening closer to the preceding valve. There is very little difference in the rate of load change on the newer units, but some of the older units may show considerable load change between different points of the governor travel.

EFFECT OF SLUGGISH AND SENSITIVE GOVERNORS

Fig. 2 shows the difference in load change between units with 4 per cent and 6 per cent speed-regulation governors, also the effect of a sluggish and a sensitive governor on a system which has only two units on the line with 50,000-kw capacity each. To be able to show the effect of a sluggish governor better, it is assumed that the unit having a 4 per cent speed variation has a sluggish governor which will not respond to a frequency change of less than 0.3 cycle, and that the unit having 6 per cent speed variation has a very sensitive governor. Following the line showing 0.2 cycle change on the 4 per cent governor, it is seen that the turbine load should increase 4000 kw while the unit with the 6 per cent governor should pick up 2800 kw. With only the two units on the line, each carrying a certain load with 60-cycle frequency, a system load increase of 6800 kw is assumed which normally will drop the system frequency 0.2 cycle. With the 4 per cent governor not responding to a change less than 0.3 cycle, the system frequency must drop 0.3 because the 6 per cent governor picks up only 4000 kw out of the total of 6800 kw with that frequency change. However, as soon as the 4 per cent governor moves at that frequency change, it picks up 6000 kw or assumes a valve position equal to it. The system load increases only 6800 kw while the combined increase in valve openings can carry 10,000 kw. The excess steam flow will increase the system speed and so reduce the load on the 6 per cent governor to 800 kw with a system frequency drop of 0.057 cycle from its original value.

The steam-flow chart on the unit with 4 per cent speed variation will show only one change in flow equal to a load increase of 6000 kw. The flow chart on the unit with 6 per cent speed variation will show a flow increase equal to 4000 kw, then a decrease of 3200 kw. The frequency recorder will indicate a decrease in frequency of 0.3 cycle, then an increase of 0.243 cycle. When the frequency and steam-flow changes on each unit are compared with the system load change, the first impression may be that the unit with the 4 per cent governor is the better of the two as it picked up more of the load change with only one change on the flow chart, and very little final change in frequency. However, as pointed out previously, without the 6 per cent governor the frequency changes would have been considerably larger.

The condition just described is multiplied many times on a large interconnected system. The units on the line will have some sensitive and some sluggish governors. There will be units carrying load at full-open-valve points while others run at intermediate points. A small frequency change may move a few

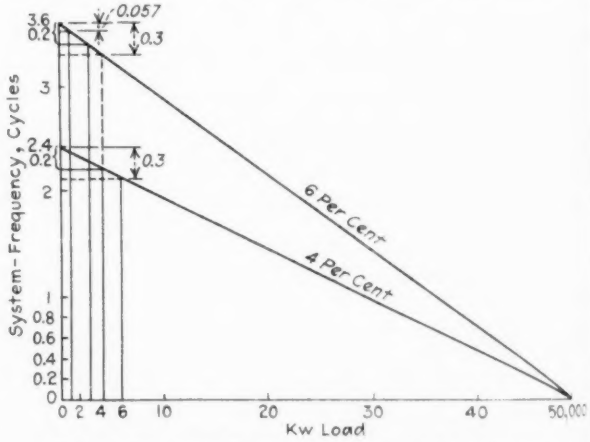

FIG. 2 GOVERNOR SPEED VARIATION AND LOAD CURVE

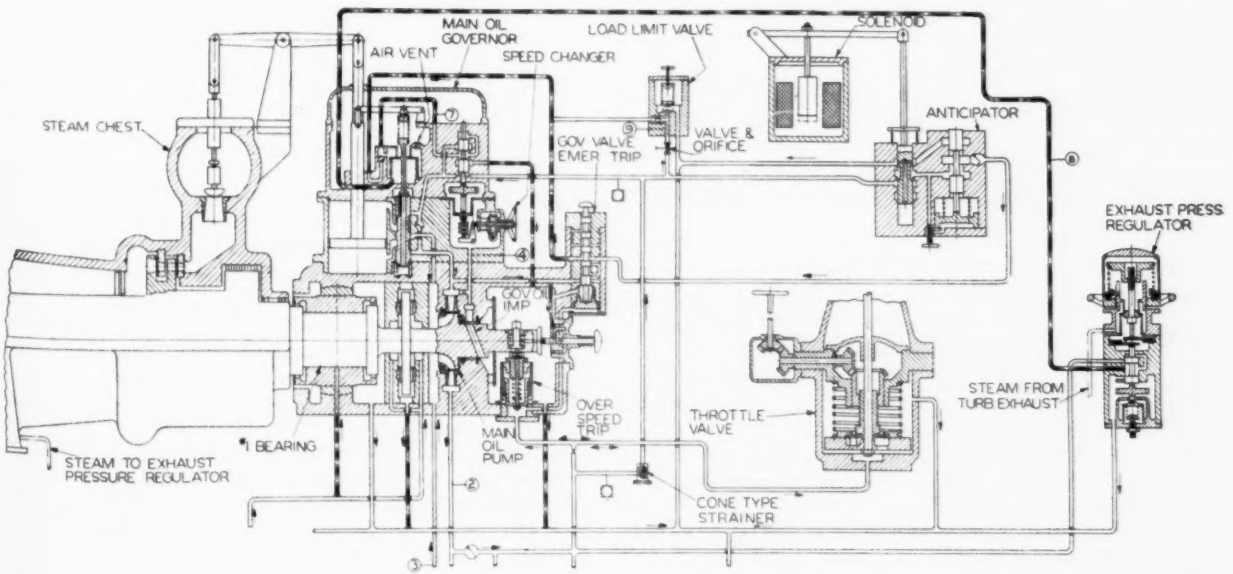
sluggish governors while others will start as soon as the frequency changes a trifle more. The sensitive governors in the meantime will try to correct for the movements of the other governors.

EXHAUST PRESSURE REGULATORS

The superposed turbines operating with exhaust pressure regulators will add to the present disturbances. Suppose the high-pressure unit has 50,000-kw capacity and exhausts into a header feeding the two 50,000-kw units described. Assume that the contract calls for a 4 per cent governor in the high-pressure unit. It will be sensitive in order to be able to synchronize properly. Repeating the previous performance, the system load is increased by 10,800 kw or the total change of load with 0.2 cycle frequency drop. Dropping the frequency 0.3 just before the sluggish 4 per cent low-pressure-unit governor begins to move, there will be 6000 kw on the high-pressure and 4000 kw on the 6 per cent low-pressure units. A 6000-kw increase on the high-pressure unit will increase the low-pressure header pressure because only one unit is increasing its steam demand and only the amount required for the 4000-kw increase in load. The exhaust

pressure regulator will start to decrease load on the high-pressure unit. The time lag depends upon the low-pressure header volume. Just then the low-pressure 4 per cent governor will begin to move and will pick up 6000 kw, which in turn drops the low-pressure header pressure and so starts to increase load on the high-pressure unit. The governing valves on all three units will now be open to carry an increase in load equal to about 16,000 kw and the frequency will rise, unloading the high-pressure and 6 per cent low-pressure units. Due to the time lag in the low-pressure header, the frequency may change three to five times before equilibrium is established against the two changes described.



The high-pressure unit, when exhausting into a low-pressure system with sensitive governors and having sufficient capacity to take all the steam from the high-pressure unit, can be balanced so that with load changes the exhaust steam equals the steam demand of the low-pressure units with very little correction by the exhaust pressure regulator. But at times the high-pressure unit may have only one or two low-pressure units taking exhaust steam. The high-pressure unit following the frequency changes will change the exhaust-steam flow beyond the requirement of the low-pressure units. Hence, the exhaust pressure regulator must correct the steam flow after each frequency change and, because of the header lag, will cause additional frequency changes.

There are other factors which can disturb the system speed, but their effect is relatively small and the cycle long. The practice of using the newer turbines as base-load units does not help the system speed. To be able to obtain the best efficiency of a base-load unit, the load set on the governor should not change with small frequency changes of the system. The governor speed variation is normally increased above the other units in the system. That by itself does not help if the base-load unit has a sensitive governor while the majority of the other units in the system have sluggish governors. The new units have very little rotor inertia and so the governors cannot be made very sluggish before they become unstable.

Eliminating Effect of Sluggish Governors

Most power-generating systems have a high percentage of old units in the power plants. At the time of installation their performance was satisfactory. Some of the governors on the old units are sufficiently sensitive not to cause frequency disturbances. A good many of the others can be made reasonably sensitive. There may be a few that will require new control equipment. The capacity of the sluggish units in relation to the system capacity and the number of sensitive governors on the system will determine largely the need for new control equipment. To eliminate the effect of the sluggish governors on the system speed, the simplest method is to take the units off the governors by a load-limiting device in such a manner that the governor will cut in, in case of a rise in system speed above the speed set by the limiting valve, but will not increase load when the system speed drops. In itself this would decrease the available generating capacity in case of system disturbances. To overcome this objection the load-limit device can be made to release its limiting effect if the system speed drops below a set speed. With this equipment, the load on the unit will not be affected by the normal speed change of the system, but will still be available for emergency operation.

Control equipment has been developed for the growing demand for better system speed variation. To reduce the effective changes in speed variation due to governing-valve characteristics, the multivalve steam chest with diffuser-type valve seats was developed. The flow-lift curve of a diffuser-type valve seat is a straight line up to 85 per cent of its full steam flow. The length of the curved section is determined by the allowable pressure drop through the valve. The curved section is relatively small even

with very low steam-pressure drops with this type of valve and seat. A cam in the servomotor follow-up linkage can correct the slight deviation from the straight line, but the error is so small that the use of a cam has not been found necessary.

The speed-responsive element in the governor is designed to give a maximum sensitivity and fast response. Fig. 3 shows an oil-governor control system. The rotation of the turbine shaft establishes a pressure in a chamber surrounding the shaft. This pressure is maintained by the centrifugal force of the oil in the inclined hole drilled in the shaft connecting the pressure chamber to drain. Oil is supplied through an orifice into the pressure chamber from the main oil pump, also located on the turbine shaft.

The small amount of oil flowing through the orifice into the pressure chamber maintains a pressure which varies as the square of the turbine speed. To increase the sensitivity and response of the servomotor to respond to very small speed changes, the relatively small pressure changes produced by the centrifugal force of the oil in the inclined hole, otherwise called the governor impeller, are magnified in the governor transformer. By the use of a rotating relay or valve and the use of bellows, the small governor-impeller pressure changes are increased in the ratio of 5 to 1 without friction or measurable time lag. The transformed or secondary pressure controls the servomotor-operating-piston position through a pressure-responsive device in the follow-up linkage. An increase in the control pressure applied in the pressure-responsive device will move the operating piston in the closing direction. Through a system of check valves, other pressure impulses controlled by regulators, responding to functions other than speed, may be applied in the pressure-responsive device of the servomotor. In Fig. 3 the load-limit valve, load-dump anticipator, and governing-valve emergency trip all act on the top chamber of the pressure-responsive device. The exhaust pressure regulator, as shown, is connected to the lower chamber of the pressure-responsive device.

The pressure-responsive device responds to the highest of all pressures applied or connected to the top chamber. The higher pressure will close the check valve in the other regulators maintaining a lower pressure. Any of the regulators can decrease the load regulated by another regulator by increasing the regulating pressure above the pressure of the controlling regulator. The regulator with the highest pressure will control the load and no regulator connected in the same regulating pressure system can increase the load.

Load-Limit or Steam-Flow-Limit Valve

The load-limit or steam-flow-limit valve shown in Fig. 3 is a spring-loaded cup-shaped valve which maintains an oil pressure corresponding to the setting of the compression spring.

By setting it to a valve opening equal to a single boiler capacity, the load on the unit cannot be raised above that with the speed changer or the exhaust pressure regulator. When the unit is required as base-load generating equipment, the load limit can be set to any desired load demand while the secondary pressure, regulated by the speed changer, can be set just below the pressure of the load limit so that normal frequency changes will not affect the load on the unit. When a superposed unit is controlled by the exhaust pressure regulator and it is desired to cut out the response of the governor to frequency changes, the load limit may be set in the same manner as above. In many installations the operation of the superposed unit, when controlled by the exhaust pressure regulator, is more satisfactory with the governor not responding to speed changes. To eliminate the need of the load limit for this condition, the exhaust-pressure-regulator control pressure can be applied on the top chamber of the pressure-responsive device in some cases. In this manner, while the exhaust pressure regulator controls the steam flow, all the other control features are cut out automatically.

The speed regulation of the governor may be changed by changing the fulcrum point of the servomotor follow-up link. This arrangement is used if the speed regulation is set to a permanent figure. In the future the need may arise to have governors which can change the speed regulation while the unit is carrying load, to satisfy the constant system-speed demand of the system with different combinations of units on the line. The governor can be furnished with a different transformer housing which allows the transformed or secondary pressure to enter the chamber located below the transformer relay or valve through an orifice and air bell. The regulating or admission valve is so constructed that the secondary pressure may be partly or fully applied below the transformer relay obtaining partial or full-speed compensation. The change is gradual and can be adjusted while the unit is in operation.

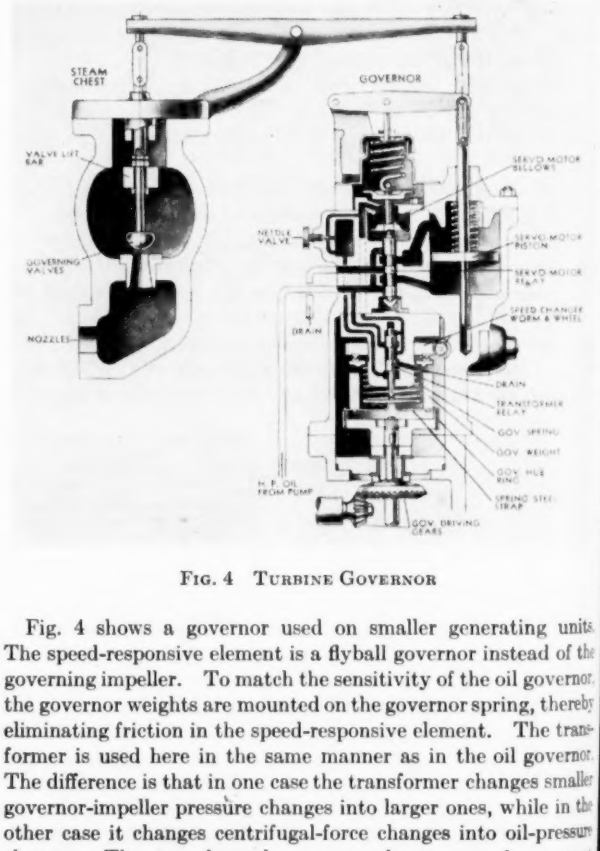

Fig. 4 Turbine Governor

Fig. 4 shows a governor used on smaller generating units. The speed-responsive element is a flyball governor instead of the governing impeller. To match the sensitivity of the oil governor, the governor weights are mounted on the governor spring, thereby eliminating friction in the speed-responsive element. The transformer is used here in the same manner as in the oil governor. The difference is that in one case the transformer changes smaller governor-impeller pressure changes into larger ones, while in the other case it changes centrifugal-force changes into oil-pressure changes. The transformed pressure change per 1 per cent speed change is the same in both governors and all the governor characteristics described apply also to the smaller governor.

Industrial power plants tied in with power-generating systems should be considered as part of the system. There are many industrial power plants with up-to-date generating equipment maintained in excellent operating condition. There are others, however, and some with quite large generating capacity where the equipment, particularly the governors, are not kept in as good operating condition. The reaction on the system speed caused by the faulty operation of these governors is determined by their capacity against that of the system. The governor performance characteristics of industrial plants, particularly the ones with large generating capacity, should be checked along with the generating units of the power system.

Systematic Study of Governor Performance Needed

It does not help the power systems when the manufacturers supply generating units with governors capable of the widest changes in control characteristics and no attempt is made to take advantage of it. A systematic study should be made of the existing governor performances in each power plant of an interconnected power system and existing governor performance corrected to suit system needs as much as possible with the existing equipment. When ordering new units, analyze the required governor performance with all practical combinations of units, power plants, and loads just as carefully as the best combination of steam conditions is determined. The required governor performance should then be specified, including possible changes in characteristics while the unit is in operation or shut down.

A committee should define standards in governor performance and set up methods of checking and testing governor performance.

The range of the variable characteristics should be determined, also which one should be susceptible of change with the unit in operation.

A definite governor-performance specification will help the turbine builders and a knowledge of the limitations of each governor will help the system operators.

Discussion

I. C. Martin.[2] The author states that governing characteristics of all units on the system should be carefully studied and load conditions considered before specifying required governor characteristics for a new unit. It is agreed that this study should be made for the purpose of determining most desirable operating methods. However, it seems that the governor for any new unit should be built with maximum sensitivity, controllable speed of operation, speed-droop adjustability between zero and at least the greatest value for any of the existing units, and provision for any auxiliary controls such as the author mentions. Governors for existing units should be brought up to new unit performance rather than providing for poorer governor performance in new units. Only in this way can maximum system flexibility be obtained. Although unit characteristics and load conditions determine optimum operating methods, full advantage cannot be obtained unless governors on the various units can be adjusted as desired. Governors with the same range of adjustment, whether the units are steam, hydro, or Diesel, present the only means of obtaining maximum system flexibility for both current operating methods and possibility of future changes. Therefore, it would seem to be that the point of wide range of governor adjustment is most important whether selecting governors for old or new units.

E. E. Parker.[3] The author's explanation of the action of turbine generators with sensitive governors, when paralleled with units having less sensitive governors, should assist in eliminating misunderstandings on this matter. Because of the slower response of the hydraulic-turbine governing mechanisms, such operation has often been encountered in power systems where steam and hydroelectric generating equipment must work together. Failure on the part of a few turbine users to appreciate this has given rise to complaints of governing-mechanism instability where, as the author points out, the governing mechanism is actually doing a better job than are the mechanisms which they consider satisfactory.

Field experience over a number of years with turbine governing mechanisms has established that the slope of the kilowatt-load (or steam-flow) versus governor stroke curve is an important factor in determining whether or not the governing of a turbine will be stable. A number of analytical studies of turbine governing, including governors of both the flyball and oil-pressure type, have shown that the slope of this curve is very nearly inversely proportional to the minimum regulation at which a turbine may be operated with stability. For example, in Fig. 1 of the paper, if the actual governing curve has a slope (speed change per kw input) at any point equal to one half the average, then the minimum regulation for stability must be twice what would be required with the same turbine and governing mechanism if the slope were average at all points.

Thus, it can be seen that, for a given turbine governing mechanism and regulation, the stability of operation can be improved by reducing the variation of the slope of this curve from the average; or for a given degree of stability the regulation can be decreased as the slope of this curve at any point approaches the average. In addition to stability considerations, governing curves with minimum variations of slope are very desirable for good control (either automatic or manual) of the output of a turbine.

Fig. 5 of this discussion shows the governing curve for a tur-

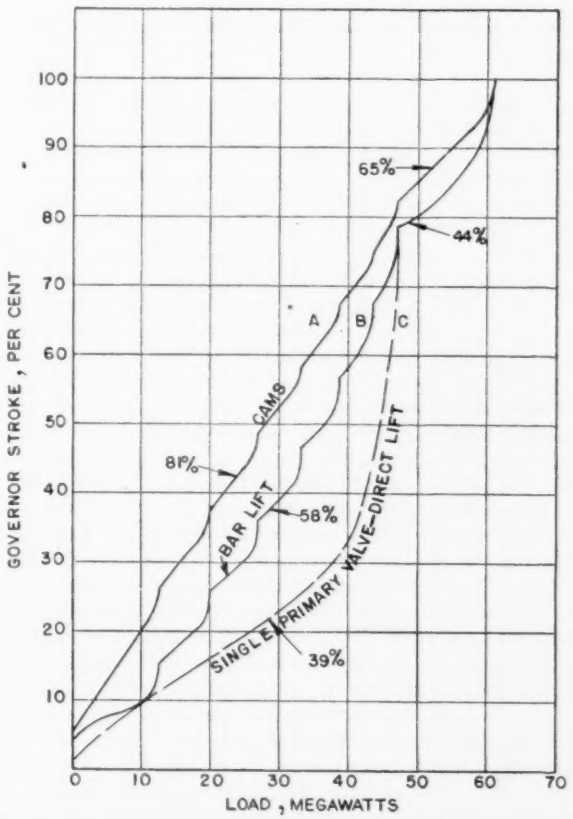

Fig. 5 Comparison of Governing Curves Obtained With Cam- and Direct-Lift Mechanisms

bine of recent manufacture. Curve *A* shows the governing curve when each control valve is operated by an individual cam. Curve *B* shows this same curve for the unit if the same valves are lifted directly by the hydraulic piston or servomotor. For equal stability, the turbine may be operated with 30 per cent narrower regulation if cam operation of the valves is employed, because of the more uniform governing curve.

This particular turbine has eight primary valves and one overload valve under control of the governor. Each primary valve supplies an individual section of the first-stage nozzle. The valves have the so-called "diffuser-type" valve seats. This type of turbine valve seat was first developed to pass a given steam flow through a given valve-seating area with a minimum pressure drop.

The difference in governing curves obtained from cam- and direct-lift mechanisms becomes greater as the number of valves is decreased. For example, if the eight primary control valves used on the turbine considered in Fig. 5 are replaced by one valve, a governing curve as shown by curve *C* results for a direct-lift mechanism. On the other hand, if the single valve were operated by a cam, the minimum slope of the governing curve would be no worse than with multivalve cam operation.

By the use of pilot poppet-type valves, turbines with direct-lift (often called "bar-lift") valve mechanisms are built with governing curves equally as uniform as those obtained with cam-lift mechanism. Equally good governing curves can also be obtained with direct-lift mechanisms by overlapping the governing valves more. However, since increasing the overlap has a detrimental effect on the efficiency of a turbine it is desired to keep the overlap to a minimum.

The use of cam-operated governing valves also permits more latitude in the location and operation of the steam admission valves.

R. B. Smith.[4] The author has developed in some detail the case against the "sluggish" governor. It would seem, however, that the author's criticism is leveled more against the governor with a forced instability, that is, one having external friction and backlash in its mechanism which makes it unresponsive to a primary change until such a change is sufficient to overcome these external influences, rather than one that is sluggish. Actually, it is possible that a governor may be sluggish in the sense that the dynamic time lags inherent in the various parts of the mechanism are so great that it does not respond rapidly and, yet, at the same time, it possesses sensitivity to even small changes in the primary variable. If such were the case, it would undoubtedly be true that, in the author's Fig. 2, both turbines would show a change in the flow chart reading and in exactly the proportion they theoretically should.

The author's cure for difficulty of the nature he describes is a more refined hydraulic system with every effort expended toward the elimination of external effects. While this change is undoubtedly beneficial, it is not necessarily true that the design will result in a stable governor. Undoubtedly as the author is very much aware, the question of stability is a dynamic one, involving a consideration of the inertia effects in the whole turbine-generator system. In the end, it usually resolves itself into a determination of the various time lags in the mechanism, the prime mover, and other parts and a proper interpretation of these lags for the specific design under consideration.

The single-seated venturi-type valve, the characteristics of which are described in Fig. 1, has certain desirable features. It is an adaptation from the original proposal of Ferranti made some 30 years ago. While its use results in a straight-line travel characteristic up to a point higher than for an ordinary plug-type valve, it is difficult to understand how it can influence markedly the hump characteristic which occurs when a valve starts to open. Valve humps can be influenced by the valve lap but, in the main, they are a function of the pressure ratio at which the turbine operates. On condensing turbines, the humps are small but, on noncondensing machines, they are frequently of such an extent that they deserve special consideration in performance guarantees. Somewhat the same situation exists in regard to throttle-valve and governing-valve drops. From the efficiency standpoint, it is much more important to keep them small on noncondensing than on condensing turbines.

When governor difficulties arise, it would appear to be the author's belief that he attributes the source of these generally to the governor operating mechanism. Is this practically always the case or does the author know of difficulties which have their source in the primary element? In other words, are the characteristics of the impeller always as excellent for governing as they theoretically appear to be, particularly when a rapid response is called for?

H. Steen-Johnsen.[5] The author has called attention to the scramble which takes place between sensitive and sluggish governors when the load changes.

The effects of two distinct characteristics are considered, namely:

1 Rate of response or sensitivity (smallest speed change that will cause the governor and valve gear to move).

2 The speed regulation—change in speed from no load to full load.

The governor is an instrument which responds to changes in speed, that is, changes in frequency. From the analysis presented, it appears that for close frequency control the governors used must be sensitive, and have a low speed regulation.

This conclusion appears quite satisfactory when we think of frequency changes as caused by load changes. But we have seen from other papers presented on the subject of frequency control that there are several possible causes of disturbance.

In one of these it was shown how, in a large system with several generating stations interconnected and supplying a diversified load, oscillations will take place between the various points of supply and consumption points of supply and consumption of power, assuming steady load. These oscillations in speed will cause the governors to move the same as a change in load and, if the time lag in the governor action is suitable, it might amplify the swing, rather than reduce it. In other words, while a governor may operate perfectly under one set of interconnections, it may be very bad under another. It might prove interesting to hear the author's comment on possible corrections of this type of difficulty. If the amplitude of the swing is small, a sluggish governor might be advantageous or a heavily damped governor.

Another interesting feature of several power sources tied together is that they often tend to break up a system oscillation by acting as an anchor at a point of maximum swing. Such a condition was observed recently in an industrial plant tied in at the end of a long transmission line. The governor was 7 per cent and not particularly fast, but yet, the chief engineer said that, when the turbine was not on the line, the system was swinging so badly that he could not use his electric razor. Looking at the governor it did not appear to do any particular job. The load did not swing more than 200 kw.

[4] Development Engineer, Elliott Company, Jeannette, Pa. Mem. A.S.M.E.

[5] Turbine Division, Westinghouse Electric & Manufacturing Company, Philadelphia, Pa. Mem. A.S.M.E.

In the old types of flyball governor, the position of the flyballs varies with the governor opening. In the no-load position, the weights are out and, as the load is added, the unit slows down, the weights moving in, opening the governing valve and admitting more steam at a lower speed and lower centrifugal force. The rate of centrifugal-force change varies with the radius, and as a result it requires more speed change to move from no load to $^1/_4$ load than it takes from $^3/_4$ to full load.

This variation is eliminated in the constant-position flyball governor. In this type of governor, the flyballs move only a few thousandths to change the relay position and, therefore, the radius remains the same.

[Mr. Steen-Johnsen submitted with his discussion a nomenclature for steam-turbine-governor performance and characteristics. This has been turned over to the A.S.M.E. Power Test Code Committee on Speed Pressure and Temperature Responsive Governors. This Committee is shortly to revise and enlarge the present Code.—EDITOR.]

G. B. WARREN.[6] It seems to the writer that the author has given the most important criterion as to a governor's excellence, namely, it is a good governor when it satisfies the requirements of the user. In the writer's company, we have taken pains at various times to make sure that the governors as they were built would meet the requirements of the users. Recently, however, newer conditions, largely in connection with system interconnections, have apparently come into existence which are beginning to require governors of greater refinement. There is satisfaction in knowing that these requirements are being scrutinized carefully by a committee of turbine users under the auspices of the Edison Electric Institute, and that a tentative specification will probably result.

In this connection, the writer would suggest to those concerned in formulating this specification that most careful consideration be given to the extent of the refinements which are so stipulated, such as extreme sensitivity, flexibility, etc., in order to be certain that all of the qualities indicated as necessary are really needed or indeed desirable.

It is easy enough for a member of such a committee to say that the sensitivity requirements, or other requirements, should be of a certain character, and yet it may be difficult or disadvantageous from other standpoints for the manufacturers to meet the requirements so specified. The industry might thus be burdened with an unnecessary cost level for regulating equipment.

FRANCIS HODGKINSON.[7] It seems that these two papers[8] and the present interest in the subject have been brought about by the modern practice of superposing high-pressure-turbine elements over existing prime movers. These types of turbines, because of their range of steam expansion have small physical dimensions relative to their capacity or steam flow. Their WR^2 is relatively low; the writer is informed that, in several cases, the rate of acceleration of the rotor system with full steam flow and without load approximates 700 rps.

The author of this paper has pointed out that satisfactory governing devices, which are capable of conforming to any reasonable specification, except perhaps that of rapidity of valve motion, have been available for years. It is true that at least some manufacturers have applied governors to steam turbines which were without sensible friction, of extreme sensitivity, and which had close regulating characteristics with stability, commencing with the Parsons steam relay governing system of almost 50 years ago.

It has been pointed out that, in the case of multivalve turbines, a more nearly straight-line characteristic (speed versus output or steam flow) may be obtained if each valve is operated by an individual cam. In contrast to this, a case has been cited of a turbine, controlled by a single throttling valve, which gave anything but a straight-line characteristic and which could not be stable at all points of load except with extreme speed variation between zero and full load. Years ago, valves were arranged with ports in such manner that equal increments of flow were obtained with equal increments of valve travel and straight-line regulating characteristics obtained with single-valve turbines.

The authors of these papers and some discussers have emphasized the need of a standardized basis for a specification for governors, which would also set up appropriate nomenclature. This is desirable, since considerable confusion seems to exist on both matters.

The writer wishes to point out that among the A.S.M.E. Power Test Codes is one on "Speed-Responsive Governors." This is a test code with rules for tests and, as such, necessarily sets up nomenclature and bases for specification, the latter without numerical values. It would seem, therefore, that the Power Test Codes would be an appropriate channel for carrying out the suggestions which have been made.

As chairman of the main committee of the Power Test Codes, the writer has no hesitation in stating that the various committees will always seek the collaboration of other sections of the Society.

This particular code was issued 12 years ago and is now obsolete. It was written at a time when we did not have much conception of the purposes of codes. It requires revision, and a complete reorganization and enlargement of the individual committee to deal with the matter would seem to be advisable. Its scope should be increased to include pressure- and temperature-responsive devices limited, however, to performance and exclusive of details of construction of mechanisms.

NOTE: A joint discussion by S. H. Hemenway of this paper and the paper, "Steam-Turbine Governors," by Reed J. Caughey, appears on page 191 of this issue of the Transactions.

AUTHOR'S CLOSURE

The author is grateful to Mr. Martin for putting the important factors in system and governor-characteristic study in a short condensed form. We all agree that maximum sensitivity, straight-line load and speed characteristics, and all the other controllable features are required to obtain maximum system flexibility. The question arises what is the numerical value of maximum sensitivity and how straight the load and speed line should be for satisfactory operation. Mr. Warren and Mr. Hemenway stress the fact that to obtain the foregoing maximum performance characteristics, considerable and probable unjustified increase in the cost level may be necessary. It would help everyone concerned if the various committees of turbine users and turbine builders would jointly determine and define the required maximum sensitivity; and also the maximum allowable deviation from the straight load and speed line, with a method for testing, which would still be satisfactory to the turbine users and not put unnecessary burdens on the manufacturers.

Mr. Parker shows a considerable difference between the bar-lift and cam-operated valves. The author has had no difficulty in obtaining initial valve-lift load angles between 75 to 80 per

[8] This discussion applies jointly to the present paper and the paper, "Steam-Turbine Governors," by Reed J. Caughey, which appears on page 191 of this issue of the Transactions.

cent without the use of the pilot poppet-type valves. Flexibility in the location and operation of steam admission valves can be obtained without cumbersome governor or power linkage by using individual valve servomotors. The servomotors are operating the valves directly and are connected to each other and the governor through the control pressure oil line. On one unit seven governing valves which were located at different points on or around the turbine cylinder were operated in this manner successfully.

Mr. Smith's discussion clearly shows the need for nomenclature defining forced instability, sluggishness, external friction, and so on. The author wants to point out that a sluggish governor as described in his paper is not necessarily an unstable one. He purposely exaggerated the sluggishness of the sluggish governor so that the effect could be shown better on the curve. In actual operation there are few governors which do not respond to a frequency change of 0.1 cycle. A governor with a so-called dynamic time lag will respond in the same manner as the sluggish governor described in the paper if the load changes are sudden. Only with slow load changes or after conditions are settled will the flow chart readings be proportional with the theoretical flows. The question of governor stability concerns the design of the control equipment only. The paper described the performance of governors in actual operation, and the turbine users will not accept an unstable governor. The author is thankful to Mr. Smith for bringing into the discussion the hump characteristic of the valves at opening points. It should be considered when maximum allowable deviations are considered from the straight load speed line. There were difficulties with the governor impeller in the beginning as with any other type of new control equipment. It has been corrected, but there was no trouble following rapid speed changes.

Mr. Steen-Johnsen discusses a few interesting system disturbances and their relation to governor performance. Nothing short of a complete check of governor performance on all the units in the system with tie-line load changes and the resultant frequency changes will give sufficient information to be able to correct the disturbance.

Mr. Hodgkinson is correct in stating that governors and governing systems have been built in the past which are able to satisfy up-to-date demands on sensitivity and regulation. Straight-line regulating characteristics can be obtained with ported single valves if high pressure drops are permissible. With low pressure drops a cam is required to bring the single ported valve up to straight-line performance.

The A.S.M.E. Power Test Codes on Speed-Responsive Governors seem to be the proper channel to set up nomenclature, method of tests, and performance specifications. It will have to work in conjunction with other committees so that its specifications are in line with the performance requirements.

Mr. Hemenway calls attention to a governor characteristic which is seldom considered. There is a considerable difference between the instantaneous or temporary speed regulation and the settled speed regulation on some governors. Mr. Allen of the Pennsylvania Water and Power Co. has some quite interesting tests on governor characteristics taken with his recording instrument.

The manner whereby a high temporary speed regulation can be added on existing governors which otherwise would be unstable with low speed regulation is quite clever. The desirability of having such characteristics on some units which may be tied to others without the same characteristic will have to be investigated. Mr. Hemenway and Mr. Warren stress the need of further investigation to establish minimum values which will be satisfactory from the system's point of view. Instruments for testing governor performance have been available and new ones are being developed so that testing governor performance will not be an impossible undertaking.

The Field of System Governing

By ALBION DAVIS,[1] SAINT LOUIS, MO.

The field of system governing lies between the problems of pulsating loads and electrical stability on the one hand and frequency or time control on the other. It is concerned with the short period swings or hunting action for which poor governors are usually responsible. With proper instruments, poor governor units may be detected readily and corrections made. Sensitive governors may be substituted for them. The paper discusses some of the elements of governing from the standpoint of the system operator and suggests certain essential requirements which new governors should meet.

A YEAR ago, the author appeared before the Prime Movers Committee of the Edison Electric Institute with a paper covering some of the system aspects of governing. A portion of the material presented at that time will be used again in this paper. The shortcomings of some governors will be contrasted against the good points of others in an effort to throw more light upon what governors really do on our systems and how much benefit may be derived from investigations and improvements in the field of system governing.

This paper is not concerned directly with the problems of electrical stability, the problems of relaying, or those dealing with harmonic pulsations of power output, resulting from hydraulic conditions in penstocks or draft tubes, or from the amount of "rubber" in the ties between the different rotating masses of the system. These transient effects usually occur within periods of less than 1 sec. They come within the field of system relaying—a field already comprehensively explored by electrical men. Nor is this paper concerned directly with the operating problems of maintaining accurate time and keeping average frequency within reasonable bounds for commercial purposes. This "frequency control" or "time control" is obtained by means of automatic or manual adjustment of the settings of the governor. Such adjustments are concerned with changes of speed which take place generally over periods of more than $^1/_2$ min.

The field of system governing lies in between the problems of transient pulsations on the one hand and frequency or time control on the other. Governors are primarily concerned with adjustments within periods from $^1/_2$ sec up to 1 or 2 min. They are concerned with, and in most cases responsible for, the short period swings of speed on isolated systems and swings of tie-line loadings on interconnected systems, both of which affect system economy and the quality of service to customers.

Over short periods, the system-load curve is what the governors and regulation by the operators make it. Inadequate governors produce swings which amount to a continuous but somewhat irregular hunting action. These swings, superimposed on the real changes of average speed due to load changes, make it impossible for either the manual or the automatic operator to detect the small changes of load trend quickly and to provide for them with correspondingly small changes of prime-mover output.

The wider the fluctuations caused by the governors, the more difficult it becomes for the operator to minimize the number of load adjustments made on the different units of the system. More frequent and heavier hit-and-miss prime-mover adjustments will result and plant outputs will fluctuate over a wider range; all of which spells reduced economy of generation.

Over and above the matter of rendering good service, steady and close regulation of frequency will pay actual dividends. In the case of steam units, load swings of any appreciable magnitude will be accompanied by adjustments of boiler controls to meet the new condition and, in the passage of the boilers from one stable condition to another, a loss of economy results. Suppose each such boiler adjustment costs $1 and suppose, because of a ragged speed curve, two or three extra adjustments are required each hour, then in a year the ragged speed curve has cost the system some $20,000. Losses may be of equal magnitude in a hydroplant due to excessive regulation.

On an interconnected system, where governing irregularities show up as load swings on the tie lines, the capacity value of these tie lines may be greatly reduced because of the load fluctuations. With a smoothing out of these load swings by improved governor action, the average tie-line loadings may approach closer to the stability limit of the line, thereby increasing its capacity value.

By eliminating the more violent swings of system speed or of tie-line loadings, the electrical stability of the system will be improved. Ties between generating units and the load will be strained less and may safely carry higher loads than is the case where governors on one section of a system are bucking those of another section over short intervals of time.

The capacity of governors is measured by their "sensitivity," the term being used in the sense of ability to move the control mechanism of the prime mover promptly the correct amount in the proper direction. It does not mean "flighty" or merely rapid, but action of the sort which results in small adjustments made without delay and without overtravel.

The nature of the short 10- to 20-sec swings of system speed, from which so many problems of regulation stem, is often not realized until system speed is recorded by a sensitive high-speed frequency recorder. The ordinary station frequency chart does not record instantaneous values of system speed. The chart may show the high and low points which have occurred and indicate the band within which frequency fluctuates, but the operator is provided with only a vague indication of the rapidity of the fluctuation. The operator may think of the short period swings as "inherent pulsations of load" but they are really fluctuations caused by the hunting action of the governors.

System Tests

Fig. 1 shows frequency charts taken on the Union Electric system. The system supplies a load which ranges from 200,000 kw to well over 400,000 kw. Regulation is divided among units of three plants, the main 300,000-kw steam plant in St. Louis and two 125,000-kw hydroplants connected with St. Louis by transmission lines about 150 miles long. At the left of Fig. 1 are two sections of chart taken from the Leeds and Northrup station recorder upon which the operator must depend in controlling speed. The interval between the vertical time-scale lines is 30 min.

Over the 10-min periods represented by the blocks shown on the charts at the left, there is but little to differentiate the fluctuations of one period from those of the other. However, when

Contributed by the Hydraulic Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

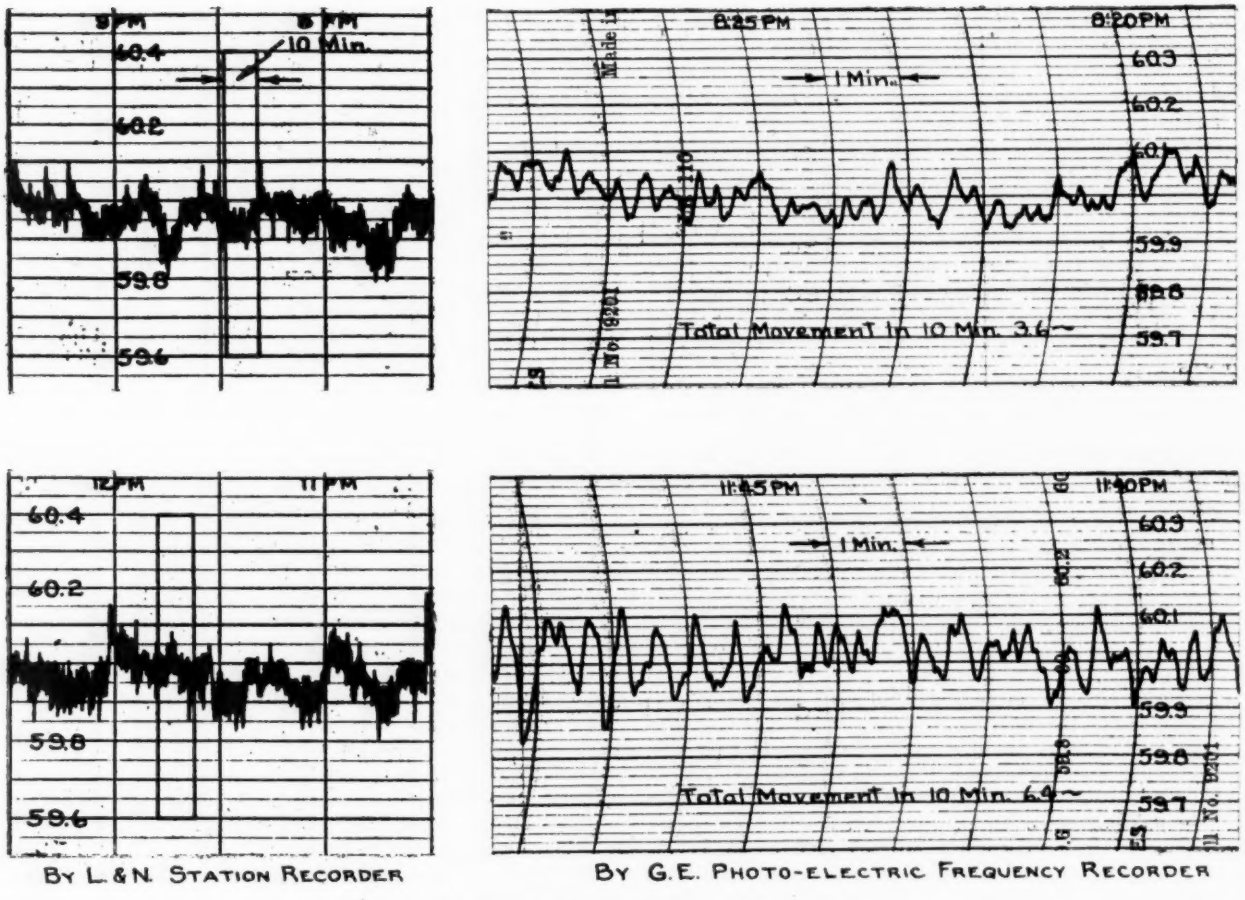

Fig. 1 Governing of Union Electric System Frequency

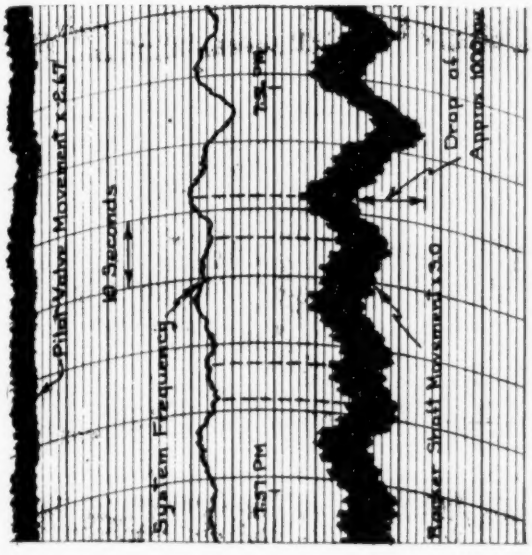
the high-speed charts at the right for the same 10-min periods are studied, a marked difference in the character of the regulation is noticeable. These charts were taken with a high-speed G.E. photoelectric recorder operating at a chart speed of $^1/_2$ in. per min. The total movement of system speed for the upper chart was only 3.6 cycles in 10 min, whereas that of the lower chart was 6.4 cycles in the same time, or nearly twice as great. Whereas the upper chart might be considered fairly good regulation for the system, the lower chart shows poor regulation. In the latter case, the speed is recorded as swinging up and down over a range of about 0.15 to 0.20 cycle.



The difficulty of avoiding bad hit-and-miss adjustments on generating units with the system swinging as shown on the lower chart of Fig. 1 can be appreciated better when it is realized that an adjustment of only 0.02 cycle in speed is required to correct a 1-sec time error in 1 hr. On these swings of speed, the governors of the system pick up and drop from 6000 to 8000 kw of load; although, to correct a drift of average speed of 0.10 cycle in 10 sec requires only 1000 kw.

Total movement of speed, or the summation of all its fluctuations in a given period of time, has been used as a measure of good or bad speed regulation. All system governors, which are regulating, follow these swings. Total movement of system speed is not only a measure of the average rate of change of speed, but a factor which measures relative wear of the moving parts of all the control mechanisms on the system and, to a certain extent, the cost of their maintenance.

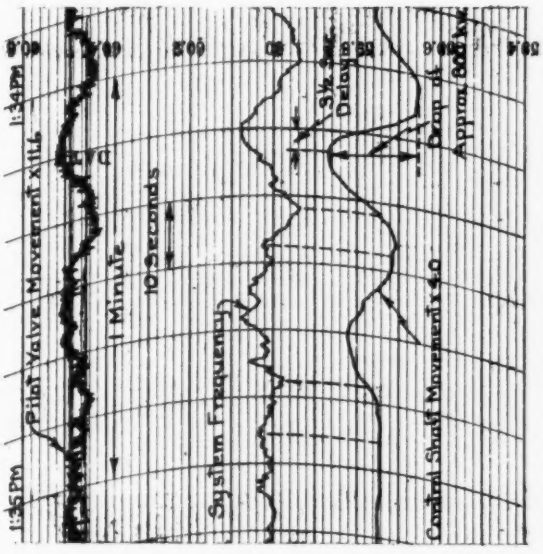


Fig. 2 shows the effect of individual steam governors on system frequency. The charts at the left were taken with the photo-electric meter running at a speed of $^1/_2$ in. per min. Conditions as to the number of units regulating, etc., were the same for both the upper and the lower charts, except for the interchange of steam units Nos. 1 and 2. The upper chart, showing regulation with steam units Nos. 2 and 6, shows roughly half the fluctuation of the lower curve, taken with steam units Nos. 1 and 6 regulating. The total movement of system speed with No. 2 on was 4.8 cycles in 10 min, whereas, with No. 1 on and No. 2 off the total movement of the system speed was 7 cycles in 10 min.

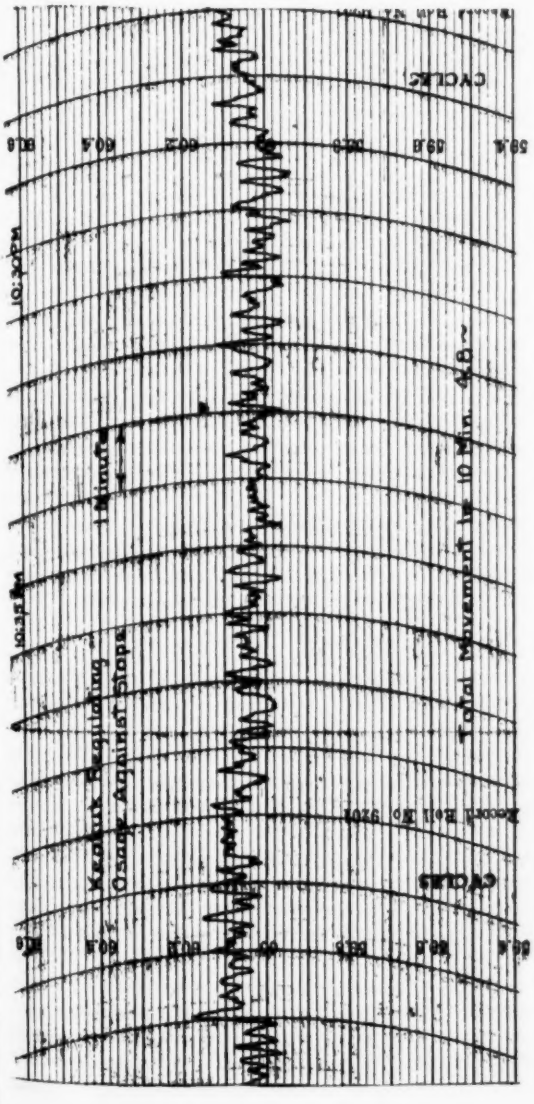
At the right of Fig. 2 are shown short sections of charts run at a speed of 3 in. per min to analyze the performance of the governors on steam units Nos. 1 and 2. These show plainly the reasons for the wide difference in system regulation. For this analysis two mechanical-motion pens were added to record the accuracy of governor response to speed changes. System frequency is recorded in the center of the chart, pilot-valve movement at the top of the chart, and movement of the valve-control mechanism at the bottom of the chart. All three pens travel on the same arcs. For correct governing, each of the mechanical motions should move in the same direction as the change of speed. It is difficult to detect any appreciable inaccuracy in the operation of the No. 2 governor.



The lower chart records poor performance on the part of the No. 1 governor. It is to be noted that on the larger speed change at the right there was a lag of $3^1/_2$ sec between the peak of the frequency curve and the peak of the resultant gate movement. Two cases are shown where there was an increase of speed of more than 0.05 cycle in 6 to 8 sec and yet the governor, during that period, was opening the gates and picking up load; just the

FIG. 2 EFFECT OF INDIVIDUAL STEAM GOVERNORS ON SYSTEM FREQUENCY; HYDROGOVERNORS UNCHANGED

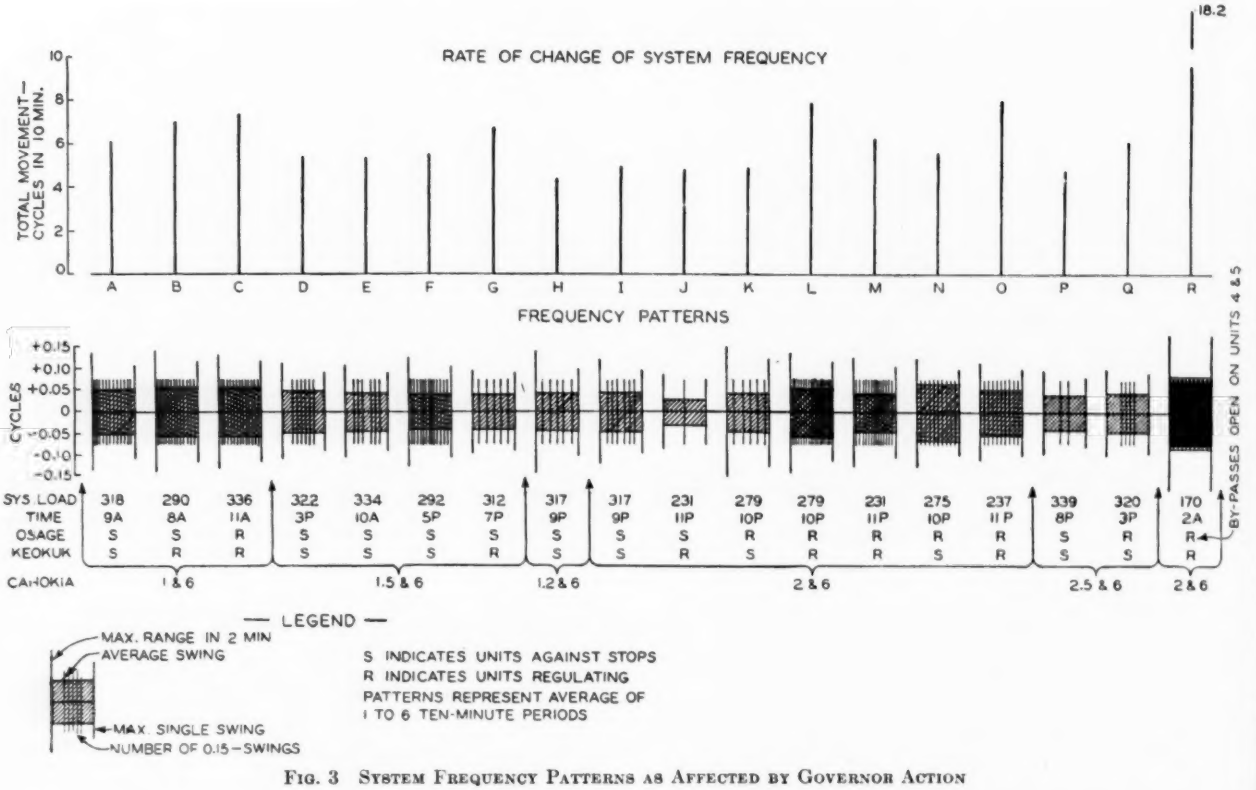

FIG. 3 SYSTEM FREQUENCY PATTERNS AS AFFECTED BY GOVERNOR ACTION

reverse of what it should have been doing. The difficulty with this governor at the time the chart was taken was apparently caused by excessive lap on the pilot valve.

The conclusion that most of the 10- to 20-sec swings of system speed are produced by governor action rather than by changes of load is based on a series of tests which are summarized graphically in Fig. 3. The typical frequency patterns resulting from some 18 different governing combinations are shown in condensed form. For each pattern, the maximum range of speed in any 2 min is shown at the left; the maximum single swing at the right; and in between, the average swing and the average number of 0.15-cycle swings in 2 min. Each pattern represents an average of from one to six 10-min periods. Above each frequency pattern the total movement of system speed in 10 min is shown.

Condensing the charts into these patterns makes it possible visually to differentiate the results of the different governing combinations. Direct comparison indicates that pattern *J* with steam units Nos. 2 and 6, operating with one hydroplant regulating and the other against the stops, is one of the best governing combinations. It is also significant that all of the patterns showing the lowest total movement of system speed occurred when the good steam unit No. 2 was regulating. In the case of pattern *R* at the right of Fig. 3, two hydrounits were operating with their dashpot by-passes open, resulting in a serious hunting of system speed.

Some of the hydrogovernors improved system regulation when working with good steam governors but, when working with poor steam governors or with other poor hydrogovernors, they exaggerated the fluctuations. Close analysis of these tests suggested that, if all governors of the system could be blocked during a period of fairly constant load, practically all of the short period fluctuations of speed would disappear.

To test this idea, advantage was taken of a period when a small section of the load was isolated from the system. The hydrounit, carrying the isolated load, was put on hand control for a short period in order to observe, on the high-speed frequency chart, the changes of speed which occur solely because of the load changes. The results of this test are shown in Fig. 4. At the left is a 10-min stretch of chart, during which the hydrounit was on hand control and there was no change of turbine-gate opening.

Ungoverned, the speed swung over a range of $\frac{1}{2}$ cycle, yet the total movement of speed in 10 min was only 6 cycles. The chart at the right of Fig. 4 shows the same load with the governor in operation, holding constant average speed but swinging the speed up and down over a range of 0.10 to 0.15 cycle, 6 to 8 times per min. Disregarding the section of the chart where the dashpot by-pass was opened, the total movement of the governed system speed in 10 min was 14.5 cycles, more than twice the rate of change which occurred when the load was ungoverned.

TESTS OF INDIVIDUAL GOVERNORS

Fig. 5 has been included to show the range of performance which may be observed on a system when tests of individual governors are first made. It is likely that some good governors and some poor governors will be found. The chart at the left of Fig. 5 is a record of performance of a fairly good hydrogovernor controlling a 25,000-kw vertical unit at a 95-ft head. System frequency is recorded in the center of the chart, gate movement at the left, and pilot-valve movement at the right of the chart. This governor, which is operating on a speed-droop setting of 3 per cent, registers fairly good performance. Gate movements are following speed changes with time delays on the reversals of only about 2 sec.

The chart in the center of Fig. 5 shows poor performance of a governor on a small low-head hydrounit. Gate positions wander badly because the governor is not sensitive to speed changes of less than 0.08 cycle. Time delays on the reversals range from 5 to 8 sec. This poor performance contrasts sharply with that

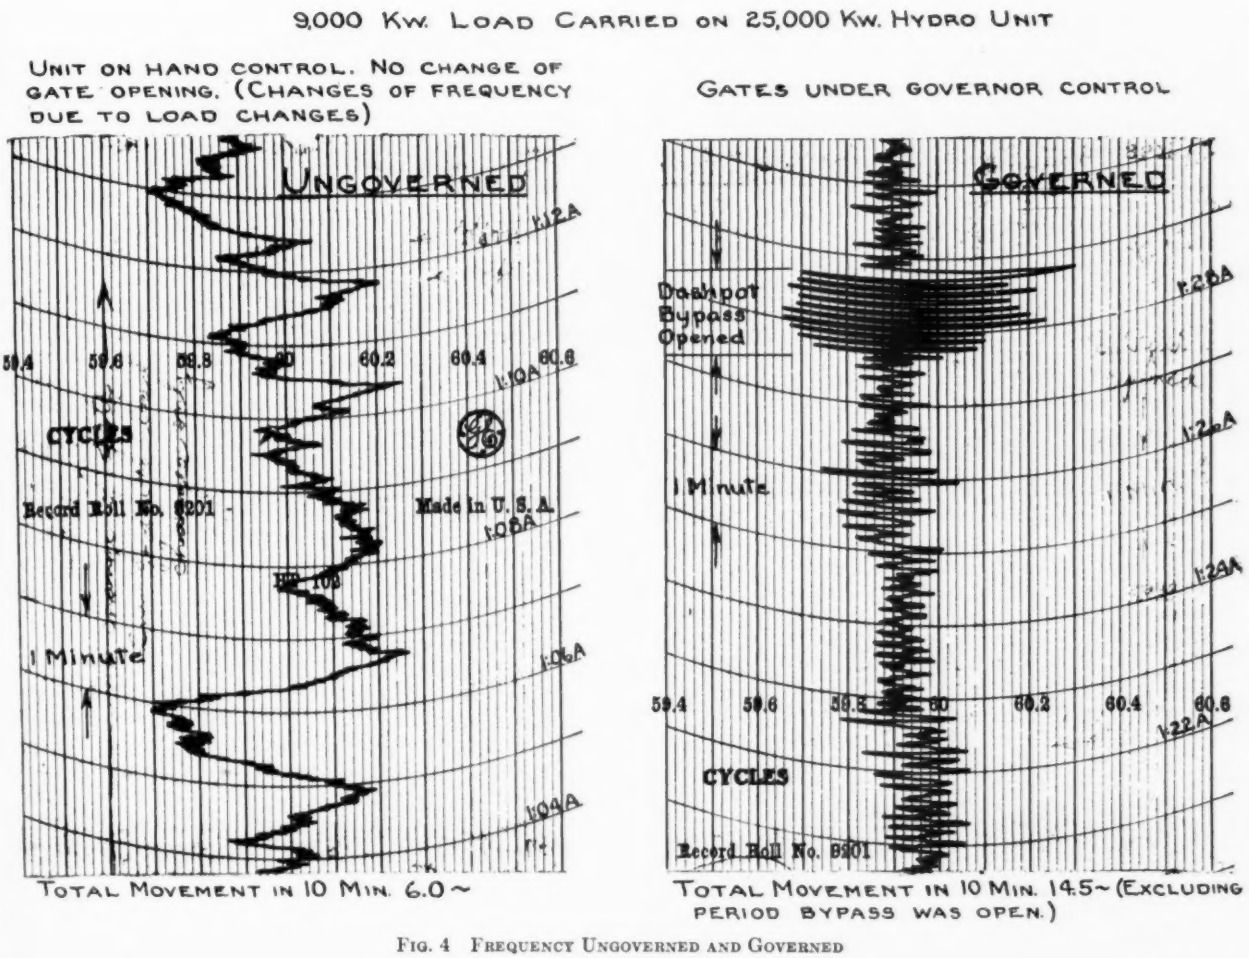

FIG. 4 FREQUENCY UNGOVERNED AND GOVERNED

for the Diesel governor shown at the right of Fig. 5. Movement of the fuel-control mechanism matches system speed with time delays of only about 1 sec.

The contrast of perfection and inadequacy in steam-turbine governors has already been mentioned in connection with Fig. 2. One steam governor was sensitive to less than 0.01 cycle speed change and the greatest time lag between speed changes and valve movement was about $^1/_2$ sec. The other governor was sensitive to only 0.05 cycle and time delays ran up to 3 sec or more. The point to be emphasized here is that there are good, bad, and indifferent steam governors. Likewise there are good, bad, and indifferent hydrogovernors and Diesel governors. The poor governors need to be weeded out and the good ones cultivated.

SOME OF THE REQUIREMENTS OF SYSTEM GOVERNING

At this point the field of governing should again be clearly differentiated from the field of the frequency controller and from the field of stability problems. Automatic frequency controllers are merely automatic operators. Their field is in keeping average frequency at the proper level. Inherently, they are not designed to do the job assigned to governors. Governors have the primary job of making load adjustments quickly and with stability, i.e., with a minimum of hunting. Their field is in making adjustments within periods from perhaps $^1/_2$ sec up to 30 sec. Generally speaking, speed swings having a period of 1 sec or less should not be touched by the governors. They come within the field of electrical stability problems and pulsating loads. Just as the governor should not lap more than a short distance into the stability field, so should the controllers not lap more than a short distance into the governor field. Frequency controllers should not attempt to correct the hunting cycle of governor action nor should governors attempt to correct the hunting cycle of load pulsations.

In controlling the flow of power from their prime movers into any system, governors may be called upon to perform five more or less separate functions as follows:

1 On loss of loads up to the capacity of the unit, the governor must close the throttle promptly enough to prevent any dangerous overspeed. This requirement determines the size, capacity, and timing of the governor.

2 The governor must be able to hold the idling speed of the unit steady enough for synchronizing. This determines the amount of damping action introduced to prevent hunting.

3 The unit must work satisfactorily in parallel with other units regulating normal speed. For this condition a high degree of sensitivity is required with very prompt, though limited, response on the smallest speed changes.

4 On the wider and slower changes of speed that are due to changes of load, the governor should bring on its full quota of load. For such speed changes the governor should bring on more load, proportionately, than it does on the short period governing swings.

5 The governor may be required to bring its unit on as reserve from the no-load idling position, up to partial or full load in a few seconds on speed changes as small as 1 cycle or less.

To attain all these objectives, many compromises in the ad-

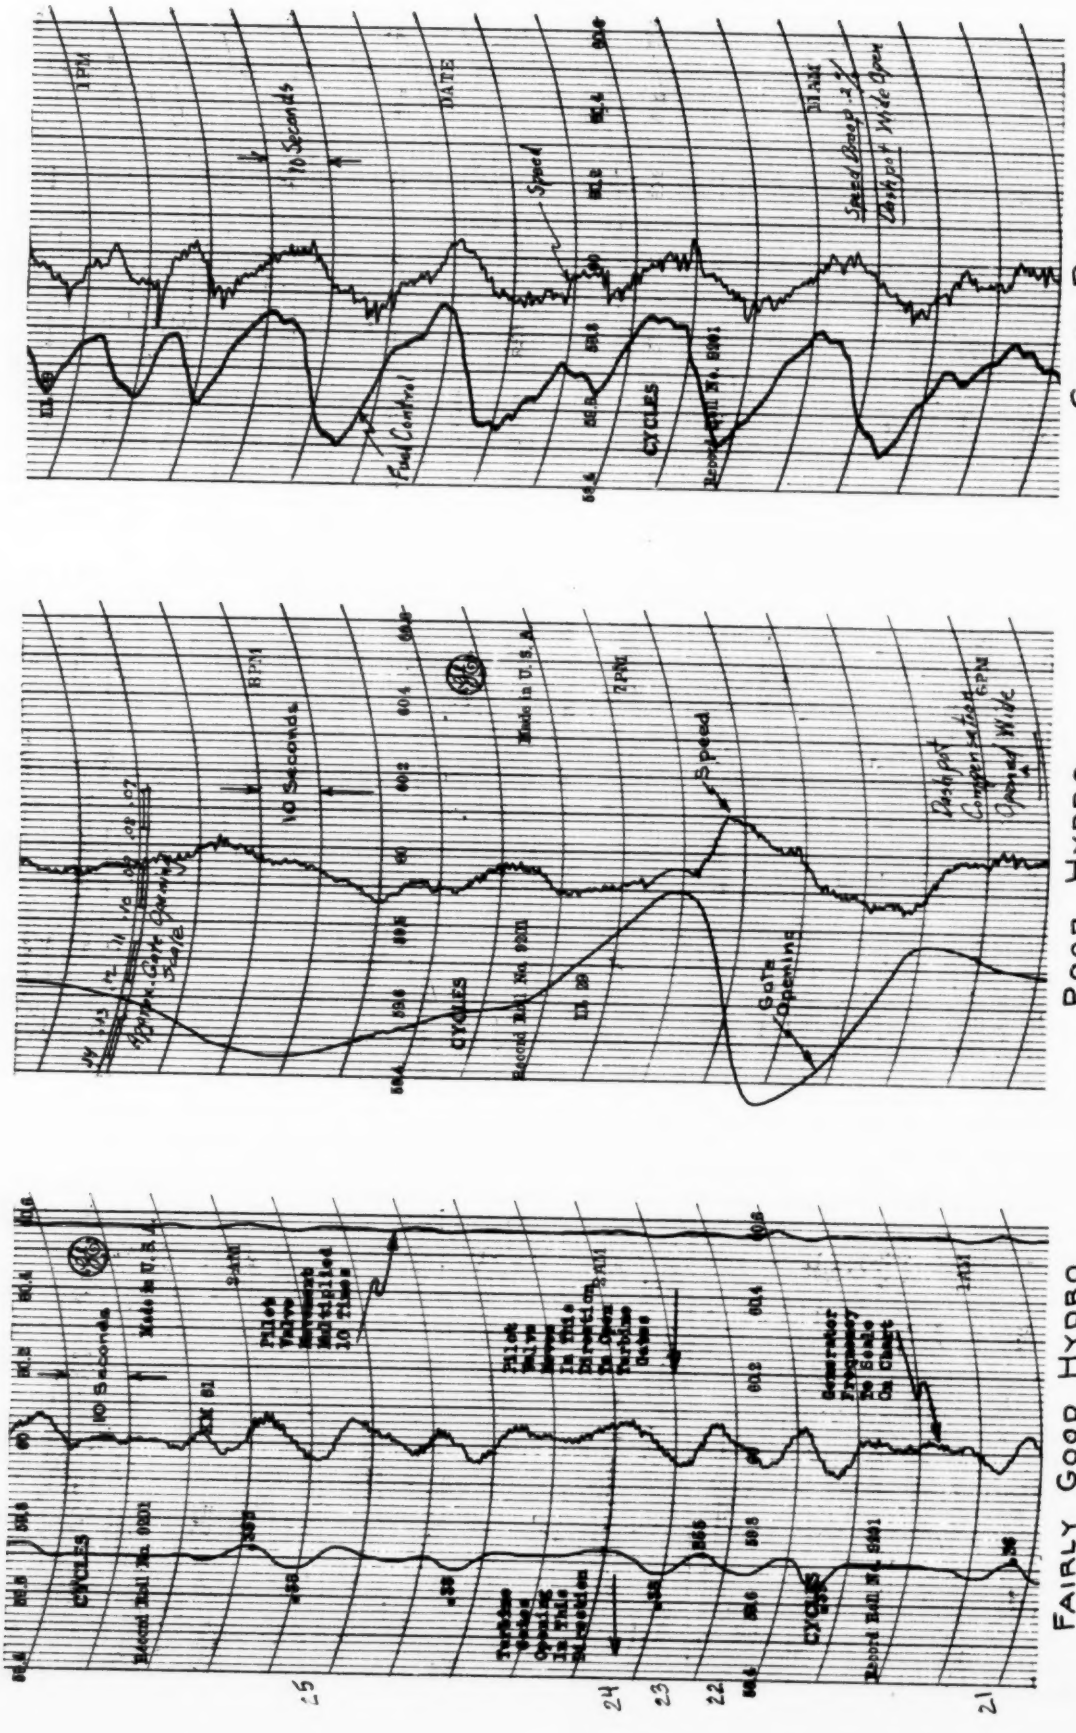

FIG. 5 HIGH-SPEED CHART RECORDS OF INDIVIDUAL GOVERNOR PERFORMANCE

justment and settings of the governors must be made. Often the attainment of one objective precludes the attainment of another. But fundamental to the attainment of all these objectives is built-in sensitivity of the governor—its intelligence, so to speak. Yet the responses resulting from this sensitivity must be properly controlled and adapted to the responses which other governors on the system are making.

Most prime movers utilize oil under pressure for the power to move the control gates or valves. Power is applied through a "regulating valve" controlling the flow of oil into an "operating cylinder" or servomotor. The governing element is actually applied to the regulating valve. This seems to be true of all governors regardless of the type of speed-responsive element used and regardless of the mechanism employed beyond the speed-responsive element.

The governing mechanism consists of three parts, the governor head or speed-responsive element, the regulating valve, and the operating cylinder. As used in this paper, the term "governor performance" applies to the response of the operating-cylinder piston, not to the load response. Although affecting system regulation to a limited extent, the relation between piston movement and power output is here considered a matter of turbine design and, as such, beyond the scope of this paper.

In order to present in more tangible form some of the requirements which might lead to better governing on our systems, the author proposes the following six items as some of the essentials to include in the specifications for performance of new governors on important system prime movers. These items refer to the performance of the governor, not to the design of the governor. Their purpose is to secure a governor sufficiently sensitive that it can perform with stability the five functions which have been listed, as well as to secure a governor which the operating department may readily adjust to the day-by-day requirements of the load.

1 A sensitivity of 0.01 per cent. On a speed change as small as 0.006 cycle (on a 60-cycle system), the governor will pass oil into the operating cylinder in the direction to produce a corrective movement of the control valves or gates.

This is a measure of the precision of the governor head up to the ports of the valve controlling oil flow to the operating cylinder. It is a measure of its ability to detect small changes of speed and translate them into positive movements of the relay valve.

2 Assuming that over the normal operating range the kilowatt output of the unit varies approximately in direct proportion to the movement of the operating-cylinder piston, then the travel of the piston per unit of speed change should be made the same over the full range from zero to full opening, regardless of the initial load setting of the turbine.

This is to obtain a reasonably simple, direct relation between speed change and average load change for the system operator's convenience in assigning normal speed regulation and reserves for maintaining speed in emergencies. On many of the present steam-turbine governors, piston movement per unit of speed change varies over a considerable range. At low loads the movement may be 4 or 5 times what it is at high loads.

3 Travel of the operating-cylinder piston per unit of instantaneous speed change or the "speed droop" of the governor should be made accurately adjustable by hand without the aid of tools while the unit is running. There should be an accurate dial indication of this adjustment. This speed droop of the governor should be made adjustable from zero to 10 per cent of the full travel of the operating-cylinder piston, "speed droop" being defined as the change in speed in per cent of normal required for the governor to move the operating-cylinder piston from the closed to the full-open position.

This is to provide the means of setting the governor at any time for the performance best suited to the system load conditions at the time, and permit convenient testing of the governor for system performance.

4 The governor should be capable of stable operation, either alone or in parallel with other units, when set on a speed droop of 0.5 per cent.

The amount of speed droop required for stable operation is a rough measure of the composite over-all effect of lost motion, friction, valve lap, any inadequacies of port design, slow operating-cylinder response, inertia, and time lag. These factors must be small to meet a specification of stable operation on low speed droop.

5 The governor should be provided with a load-limiting device which is adjustable by hand, without the aid of tools while the unit is running. There should be a dial indication of load and load limit on one scale calibrated in tenths and hundredths of the full travel of the operating-cylinder piston.

This is to permit testing system effects with the governor on or off regulation, yet with the governor left free to drop load on an overspeed. It is also an aid to economic system operation. Many conditions arise when it is decidedly advantageous to operate units on block load.

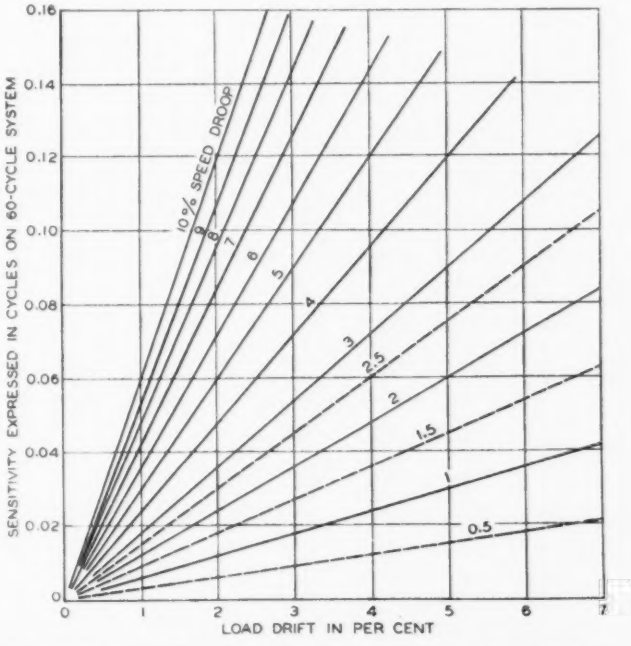

FIG. 6 RELATION BETWEEN GOVERNOR SENSITIVITY, SPEED DROOP, AND LOAD DRIFT

6 The governor should be equipped so that the unit may be synchronized from the switchboard room at any system speed from 5 per cent above to 20 per cent below normal speed, or from 63 to 48 cycles in the case of a 60-cycle system.

This is to make it possible for the switchboard operator to get available generating capacity on the line quickly when he needs it the most. Without this provision, in the event of an unforeseen system split and frequency below the range of the governor, he must either wait until the unit can be synchronized by hand from the governor floor or he must drop customers' load to bring the speed back to the point where he has control of the unit from the switchboard.

With a few governors meeting the above specifications distributed over the system, the load dispatcher has the means at

hand for smoothing out plant load swings as well as tie-line load swings. A few good governors combined with the intelligent scheduling of speed-droop settings by the system load dispatcher would iron out a lot of wrinkles in the load curve and would eliminate much of the seesawing which now goes on between the prime movers on the one end and the load on the other.

Fig. 6 is of interest in connection with the problem of limiting the wanderings of poor governors. It shows the relationship between load drift, sensitivity, and speed droop. For a governor of a given sensitivity, the amount of load drift may be reduced by increasing the speed-droop setting of the governor. The amount of load drift will decrease directly with increase of speed droop. Generally speaking, governors of high sensitivity will be given a greater burden of regulation by lower speed-droop settings, and governors of low sensitivity will be curtailed by higher speed-droop settings.

Work of the Operating Cylinder

The work which the operating cylinders have to do has an important bearing on the speed and accuracy with which the various

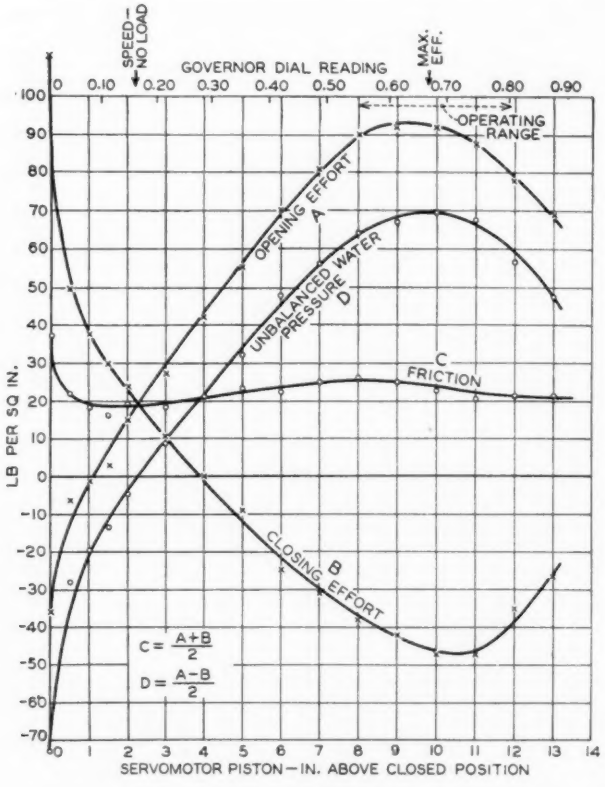

Fig. 7 Unit No. 4 Governing Effort
(25,000-kw hydrounit at 95-ft head; net piston area, 848 sq in.)

settings called for by the governor head are accomplished. The positioning of the regulating valve may be very accurate, and yet, if the porting of the regulating valve, the proportioning of the operating cylinder, and oil pressures are not suited to the effort required to move the gates, large factors of time delay may occur and considerable hunting result.

Fig. 7 gives the result of governor-effort tests made recently on a 25,000-kw, 95-ft-head hydrounit. Tests on this unit may serve to demonstrate elements of governing which are present in any type of system governor. Tests were made in the manner demonstrated by E. D. Searing in an article published in 1908.

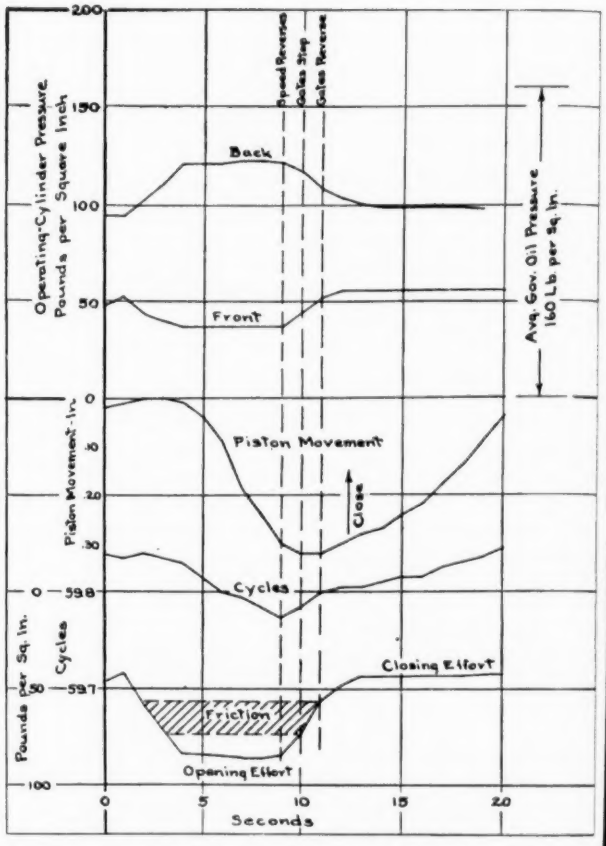

Fig. 8 Operating-Cylinder Pressures and Piston Movement During Normal Governing Cycle, Unit No. 4 Governor

Pressure indicator cards were taken on both ends of the operating cylinders throughout the full range from closed to full-open gate. Unbalanced water pressure and friction were figured from the differences between opening and closing effort. While the effort to overcome friction is practically a constant quantity, the unbalanced water pressure on the gates varies over a wide range. Variations of cylinder pressures, of course, modify the pressure drops available through the ports of the regulating valve and in turn affect the velocity of flow of oil to the operating cylinder.

Fig. 8 shows the variation of operating-cylinder pressures and of piston movements when the governor is responding to a normal system-speed swing. The sequence of events at the time of a speed reversal is of interest. One second after the speed reversed, the differential pressure on the operating-cylinder piston dropped from 85 to 73 lb and the piston movement stopped. In the next second, the differential pressure had fallen to 56 lb and the piston movement started in the reverse, or closing direction. In another 2 sec or less the differential pressure had fallen to 44 lb as the gates continued to close. While the sequence of events in this particular governor is somewhat slow, Fig. 8 demonstrates rather well the changes which occur, and the appreciable time required for oil to pass the ports of the regulating valve and move the gates, in a case where the change of speed is slight.

Fig. 9 shows what happens in the operating cylinder of the same 25,000-kw hydrounit when wide and rapid movements of the gates are called for. For this particular test, the gate opening was swung quickly by hand control from 0.72 gate up to 0.73 gate, then down to 0.55, back to 0.73, and down again to 0.72 gate, all within a period of 6 sec. The maximum rate of gate movement on this test corresponds to a full gate movement in 8 sec. For

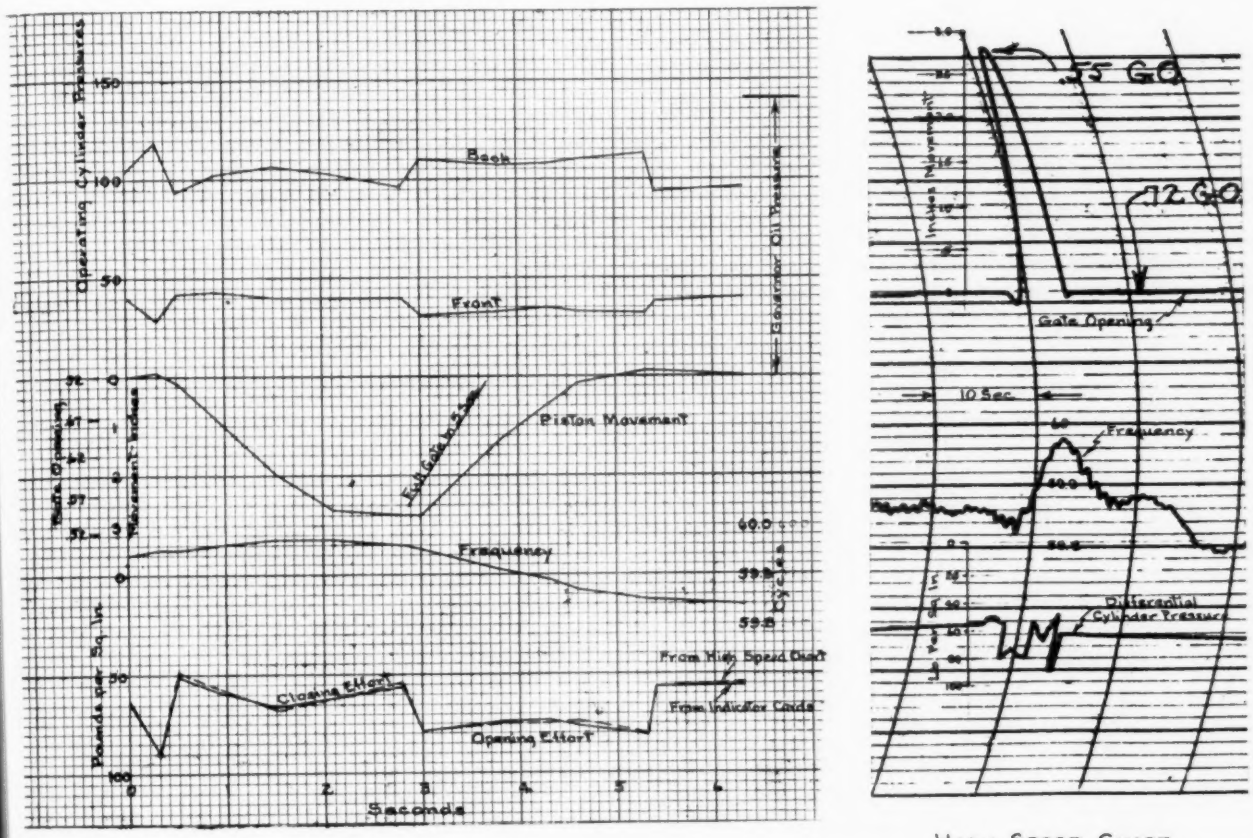

FIG. 9 OPERATING-CYLINDER PRESSURES AND PISTON MOVEMENT DURING RAPID GATE MOVEMENT, UNIT NO. 4 GOVERNOR

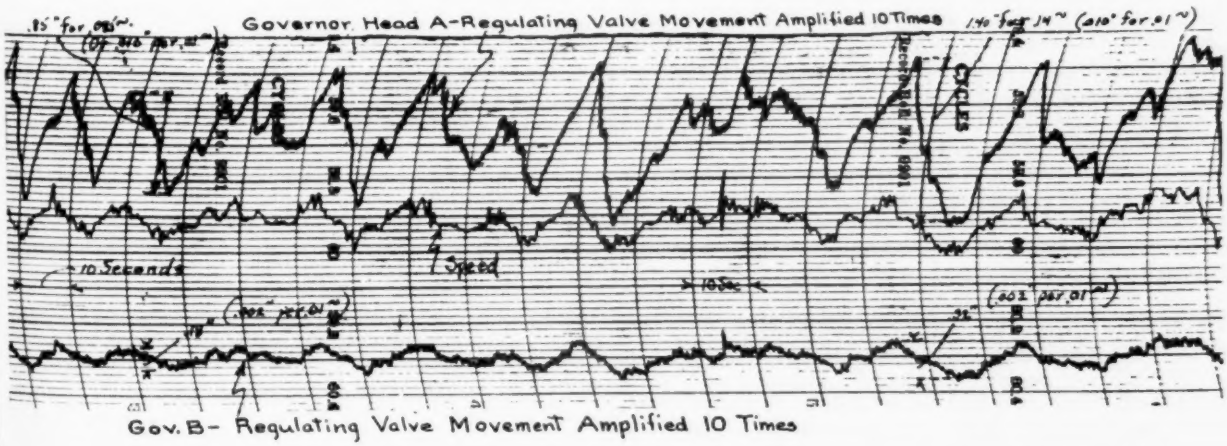

FIG. 10 COMPARISON OF MOVEMENT OF REGULATING VALVES, SHOWING PRECISION POSSIBLE IN SENSITIVE GOVERNOR HEAD

this test, steam-engine indicators were connected to the front and back of one of the operating cylinders, and indicator cards taken for the complete test cycle. The indicators were arranged so that the difference in pressure between the front and back of the cylinder could be recorded on the high-speed frequency chart, simultaneously with system speed and a record of gate movement. Differential pressures are recorded on the frequency chart at the right of Fig. 9.

For rapid movements such as this, there is a momentary inertia effect. On a quick opening the differential pressure swings up for an instant above that required for a normal slow opening movement. After this momentary increase, there is a marked decrease of pressure as the rate of gate movement increases, due to the decrease of penstock pressure and draft-tube vacuum. The opposite effect occurs when the gates start closing. Except for momentary gate inertia effects at the instant of starting a gate movement, there is a marked decrease in the differential pressure required to move the gates at the rapid rates.

These tests are cited to show that the work to be done by the operating cylinder varies over quite a range, which means that pressures across the ports of the regulating valve vary for different gate positions, thereby changing the rate of flow of oil into

the operating cylinder, and its rate of response. The rate of movement of the cylinder piston will vary not only with the port opening but also with the effort required to move the gates.

Control of Regulating Valve by the Governor Head

To make a large regulating valve move in exact synchronism with changes of speed calls not only for mechanical ingenuity but a high degree of manufacturing precision. The amount of movement which can be produced in the regulating valve without measurable error and without time delay measures the skill of the governor manufacturer and grades his product. It is, in effect, another measure of the sensitivity of the governor head.

To give some idea of the precision possible in the movement of the regulating valve, the high-speed chart in Fig. 10 is included. The center graph is speed and the graphs at the top and bottom are regulating-valve movements of two governors amplified 10 times. The governor at the top is producing accurate movements of the regulating valve of as much as 0.01 in. for each 0.01-cycle speed change. The regulating valve is reflecting speed changes accurately and without measurable time delay. In fact, there might be a question as to which was measuring the system speed more accurately, the sensitive frequency meter or the regulating valve. It should be noted that, in this particular instance, the movements were produced mechanically in a 6-in. relay valve. To the author, this is a truly remarkable accomplishment for any governor head. But what is done with these accurate movements of the relay valve in converting them into motion of the operating cylinder is a third phase of the governor story.

Factors Affecting Design of the Ports of the Regulating Valve

Suiting the design of the ports of the regulating valve to system requirements involves so many interrelated factors that it is difficult to say just what features are best. Yet improper features of design can spoil many good features. There are square ports, round ports, thin rectangular ports, vertical ports. Some regulating valves are of large diameter with small axial movement, some of small diameter with large axial movement. There is always the question of how much lap to allow. Should the valve admit oil to the operating cylinder on the very small speed changes and, if so, how much? All of these factors influence the responses of the operating cylinder. But to what extent?

To arrive at some sort of an answer to a few of these questions, a study was made of a governor for the 25,000-kw unit on which the tests were made. The study, which was carried on entirely by computation, was confined to operation of the governor from the regulating valve to gate movements, on the assumption that the regulating valve could be made to follow system speed exactly and with negligible time lag. Various ratios of movement of the regulating valve, ranging from 0.002 in. up to 0.016 in. per 0.01-cycle speed change were used. By first analyzing one factor at a time, methods were finally devised by means of which almost any governor action could be computed and analyzed.

Fig. 11 shows the results of some of these computations for a governor on the 25,000-kw hydrounit. The effect of speed droop was first studied with the governor following the normal system-frequency cycle shown at the top of Fig. 11. This frequency cycle has an amplitude of 0.14 cycle and a period of 20 sec. Using square ports and no compensation, governor action was found to lag a little less than 1 sec behind the speed when on 5 per cent speed droop and 2 sec behind the speed when on 2 per cent speed droop.

Response of the servomotor piston on 2 per cent speed droop is shown in the center group of curves in Fig. 11. Comparison with the curve marked "ideal governor response" will show the time lag. Note that the governor-response curve crests at the point where it crosses the ideal curve. Inherently, the lag of gate movement decreases as speed droop is increased. Doubling the speed droop results in half the time lag. Time lag governs overtravel and the amount of hunting.

Next, the effect of various port arrangements was studied. As shown by the curves marked "square," "round," and "A" ports, it is possible to change the amount of load pickup by changing the port design. It is also possible, by varying the size and

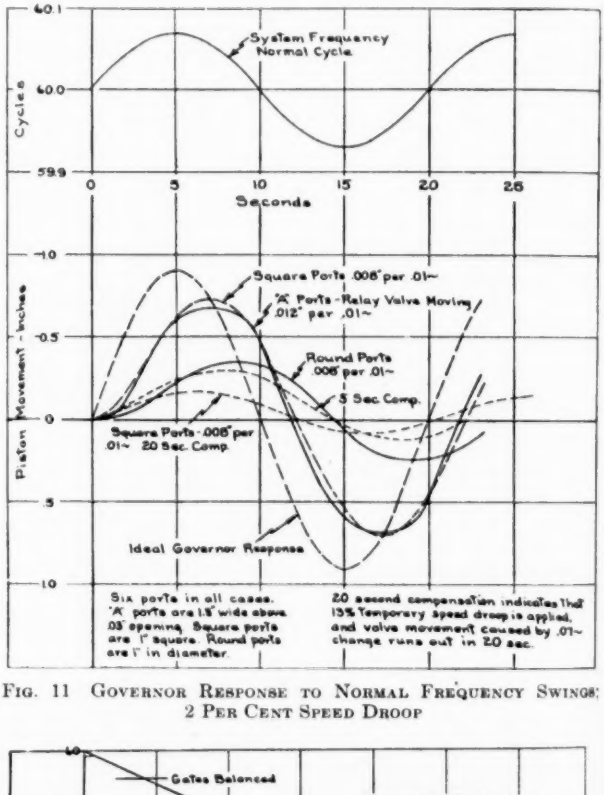

Fig. 11 Governor Response to Normal Frequency Swings; 2 Per Cent Speed Droop

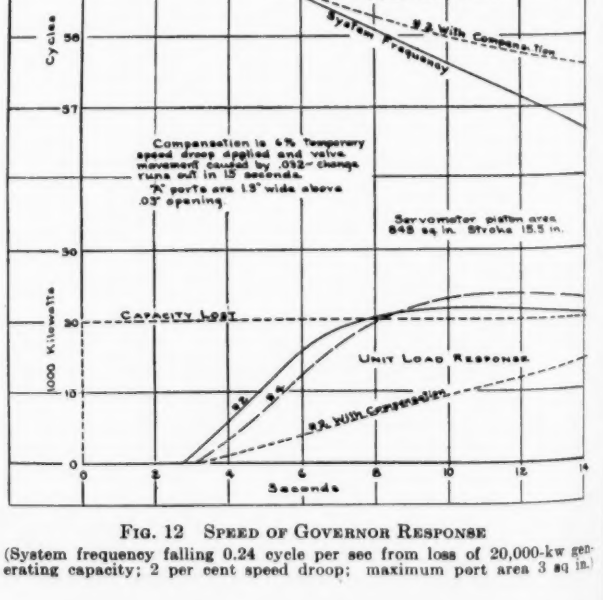

Fig. 12 Speed of Governor Response

(System frequency falling 0.24 cycle per sec from loss of 20,000-kw generating capacity; 2 per cent speed droop; maximum port area 3 sq in.)

shape of the valve ports, to control the time lag of gate movement behind speed. Square ports show much less time lag than do round ports of the same area. By using wider ports, the time lag is cut down further. Doubling the width of the ports results in half the time lag. Similarly doubling the movement of the regulating valve for a given speed change will give half the time lag. Doubling the oil pressure also will approximately halve the time lag. All this is true, if the restoring mechanism functions without lost motion. However, if the initial piston movement is made too rapid, lost motion in the restoring mechanism may leave the governor uncontrolled and "jumpy" or unstable on the small speed swings, particularly on the transient swings.

The A ports investigated are 1/3 wider than square ports above 0.03 in. opening and only about 1/4 the width of square ports below that opening. They were found to yield about the same time lag as square ports for the normal 10- to 20-sec speed swings which occur on our system. At the same time, they afford the advantage of slower movements on the very small speed changes, giving stability in the field of transient pulsations without sacrificing sensitivity to the slow swings of speed due to load changes.

Finally, the effect of adding compensation was studied. Compensation has the temporary effect of a large speed droop that is slowly removed as dashpot action runs out. With compensation, time lag can be reduced to a yet smaller amount and, at the same time, the amount of load picked up on normal speed swings can also be reduced to a figure more nearly comparable with that needed to correct the speed change, thus increasing the stability of the governor, provided there is no lost motion in the restoring mechanism and provided the timing of the dashpot action is suited to the speed swings which the governor is trying to correct. The adjustment of the dashpot is important because, while the best timing will reduce the time lag, short timing may increase the time lag seriously. Witness the two curves comparing 5- and 20-sec timing of compensation, shown in Fig. 11. Five-second timing showed a lag of 3 sec, while the 20-sec timing showed a lag of only 1.5 sec.

Fig. 12 shows the action of the governor on the system in an emergency with frequency falling 0.24 cycle per sec from the loss of 20,000 kw of generating capacity. The No. 2 governor with compensation will pick up load very slowly as shown, and the speed will drop to around 57 cycles before it is checked. Without compensation, the frequency is checked at 58.82 cycles within 6 sec after the gates begin to open. It was very apparent that to function properly as reserve capacity, compensation should be removed by some means when the speed falls below about 59.6 cycles. The line marked 4 shows the computed performance of another regulating valve with wide ports and a small movement of the regulating valve per unit of speed change.

Square ports obviously give quicker action than round ports, particularly at the smaller port openings. Apparently the advantage prompting the use of round ports is in making the governor slower and more stable on the small speed changes. But this slowness introduces more time lag and overtravel on the type of governing swings which occur on our system. Then too, round ports are a distinct loss in speed of operation when the governor is handling the gates for system reserve.

The studies made so far suggest the use of ports which have essentially the characteristics of round ports up to plus or minus 0.02 cycle speed change, the range within which transient pulsations occur. Beyond this point, it would appear that the ports should be rectangular and as wide as practicable, to reduce time lag and give quicker response in bringing on load as reserve. It also appears highly desirable to utilize the maximum movement of the regulating valve that can be obtained without measurable error or time delay, and with it, the smallest diameter of valve that will yield the required port area with the given valve movement.

It would seem that the best answer in a governor is a combination of high sensitivity translated into movement of the regulating valve, careful porting of the regulating valve to suit the location on the system, compensation to help reduce time lag, and the lowest speed-droop setting that can be used without hunting.

To this discussion, one important comment should be added. In speaking of system requirements and matters of design, we have tacitly assumed the governors to be in good mechanical condition. This is not always the case. It should be remembered that poor performance of a governor may be due entirely to lack of intelligent maintenance of the delicate parts of its mechanism, rather than to defects of design. The best governor this year may be the poorest one 5 years hence, if parts have become worn and lost motion has developed. Keeping governors up to a system standard of mechanical perfection is a very essential part of the problem of good governing.

It is realized that many of the foregoing statements are somewhat far afield. Yet such seemingly remote considerations have deep roots in system economy. The information is presented as suggestive of what may be accomplished by analysis and study. From what has been observed, there is plenty of room for investigation and improvement in the field of system governing.

Acknowledgments

In closing, the author desires to acknowledge his indebtedness to R. A. Garrett and to G. J. Vencill for much of the background material of this paper. Mr. Garrett made and analyzed most of the tests on individual governors. Mr. Vencill collaborated in the making of system tests, in developing the method of governor analysis by computation, and assisted in the preparation of this paper.

Discussion

P. W. Keppler.[2] The A.S.M.E. Committee on Industrial Instruments and Regulators (here abbreviated C.I.I.R.) has for several years sponsored study of automatic regulation. It has also accomplished much in standardizing terminology. It is hoped that a way may be found for this very active committee to give assistance to the excellent efforts of the author. This discussion is intended to help bring about such coordination of effort. First, however, it is necessary to clarify the terminology used in this discussion.

"Droop" is a well-understood term and is equivalent to "throttling range" of the C.I.I.R. terminology.

The conventional central-station steam governor without automatic frequency control is a "proportional" regulator (C.I.I.R. terminology). Its characteristics are conveniently made clear by imagining 2 jumps in frequency as shown in Fig. 13. These result in changes of governor position proportional to the changes in frequency curve No. 1, Fig. 13.

Next in importance is the "proportional speed floating" principle, sometimes called "automatic reset" (C.I.I.R. terminology). Automatic frequency controllers are based on this principle. It is illustrated by curve No. 2, Fig. 13. Rate of change of governor position is proportional to the total deviation of frequency, as shown.

The combination of these two most important principles gives the proportional plus proportional speed floating regulator, illustrated by curve No. 3, Fig. 13. This type of regulation, found in every steam central station if automatic frequency control is used by the system, has proved most successful in almost

[2] Assistant Engineer of Power Plants, Consolidated Edison Company of New York, New York, N. Y. Jun. A.S.M.E.

every field of automatic regulation, and basically all control problems are closely related.

The proportional speed floating regulator by itself is hardly suitable for frequency regulation, and need not be further discussed.

Before discussing the characteristics of the other two types, it

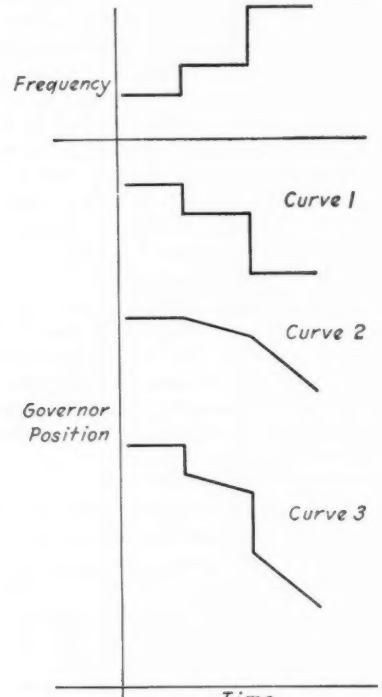

FIG. 13 MOTION OF THREE MOST IMPORTANT TYPES OF REGULATORS

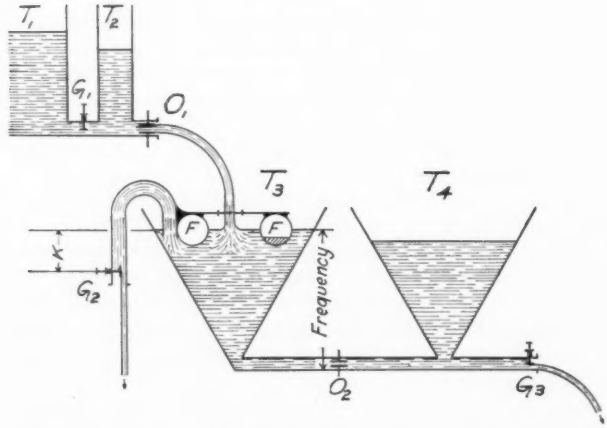

FIG. 14 HYDRAULIC ANALOGY OF ENERGY FLOWS TAKING PLACE DURING MODERATE LOAD CHANGE IN AN ELECTRICAL SYSTEM
Width of each tank is uniform

appears worth while to clarify the control problem by hydraulic analogy similar to that sponsored with great success by the C.I.I.R. In Fig. 14, tank T_1 represents energy stored in the boiler room and held at nearly constant level (constant steam pressure). This energy flows through the governor valves G_1. Straight-line or viscous flow is generally assumed where velocity is directly proportional to head, because it is sufficiently accurate for moderate changes and greatly simplifies visualizing and analysis. Energy cannot flow directly to tank T_3 which represents kinetic energy of the system and into which flows steam energy and from which flows electrical energy. First, the pressure and heat-energy content of the turbine must be raised before the increase in power can fully flow out of the coupling. Slowness or inaccuracy of the governor in obeying its own characteristic has the same effect. These lags are represented by tank T_2, Fig. 14. Time is lacking to determine if one tank is enough for representing this lag. Theoretically, every turbine stage should have a tank. Fortunately, where many small lag capacities occur in series, they may generally be combined into a few, and in our case even one tank is likely to be quite accurate. Tank T_2 cascades through the fixed orifice O_1 into tank T_3, the head of which is related to frequency. Cascading is here used because this frequency head does not appreciably affect energy flow out of T_2. In other words, with a blocked governor, the total useful work done by the steam is not likely to change with frequency.

T_3 represents the kinetic energy of all synchronous moving parts of the system, driving or driven, including machinery. Its head is frequency. Energy flows out at gate G_2 operated by the

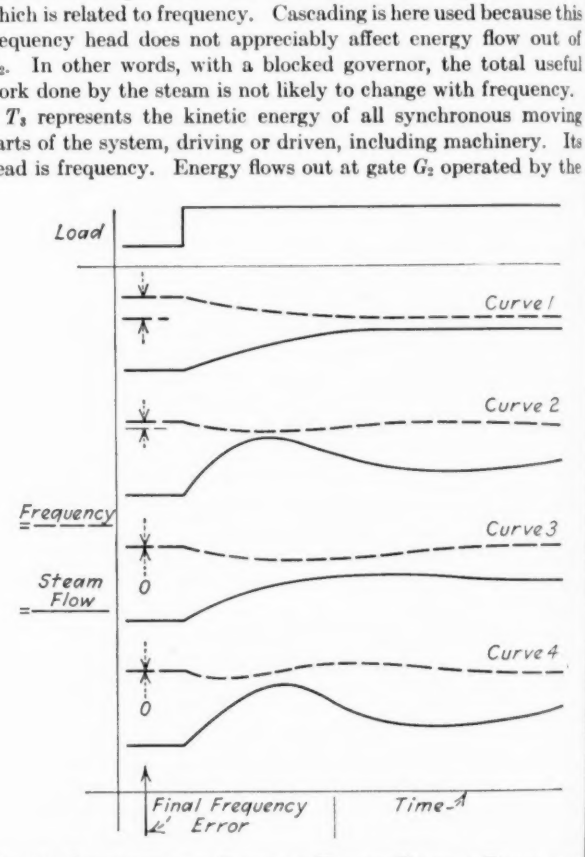

FIG. 15 CHARACTERISTIC CURVES OF VARIOUS TYPES OF REGULATION FOR AN ASSUMED JUMP IN LOAD

consumer, representing all output except a-c motors. This output is normally independent of frequency due to close voltage regulation. The float device F is therefore shown giving constant head K. Energy also flows through orifice O_2 into tank T_4 and finally leaves through gate G_3, again operated by the consumer. Tank T_4 represents the kinetic energy of induction motors and their driven machinery. Orifice O_2 is determined by slip characteristics of these motors. Both T_3 and T_4 vary in size but this may be assumed equal to the average value for any given moderate change of load. Their width is uniform so that, due to sloping sides, kinetic energy varies with the square of frequency. Fig. 14 represents the energy flows taking place during a moderate load change in an electrical system. Tank T_2 is an interference and should be kept small. The governor should respond quickly and accurately according to its proportional characteristic and the turbine should change its content of heat-and-pressure energy as little as possible with load. If both T_2 and T_4 could be

eliminated, then regulation would be ideally simple. But, while T_2 may be reduced, T_4 and O_2 can hardly be changed appreciably, and must be taken into account. It is entirely likely that mathematical analysis based on this analog is feasible and would result in optimum settings of governors for any given T_2, T_3, T_4, O_1, and O_2. At any rate, this analogy serves to clarify the problem. Of course the problem of governing, assuming this analog to be sufficiently accurate, is that of maintaining the level in tank T_3 as constant as feasible by adjusting gate G_1 smoothly, while G_2 and G_3 are being varied by the consumer.

The nature of the characteristics of various types of regulation for a "process" such as this is shown in Fig. 15, for an assumed jump in load. Curves No. 1 represent a "proportional" governor with sufficient droop and curves No. 2 with insufficient droop. Curves No. 2 are of course undesirable for the author's purposes of smooth regulation, due to excessive overtravel.

Curves Nos. 3 and 4, Fig. 15, illustrate the proportional plus proportional speed floating characteristics; curves No. 3 with optimum proportional characteristic and optimum floating speed; curves No. 4 without these. Curves No. 4 are again undesirable.

The "compensated" governor mentioned by the author is closely related to the foregoing one except that frequency is not brought back to its exact value but some residual droop is left in it. One advantage of this type is that any number of independent floating "heads" may be operated in parallel, although there is danger of some hunting. With true proportional speed floating, only one independent "head" device appears feasible, because with two heads in parallel, one would tend to go to full load, the other to zero load. Compensated governors should also be more stable for the same initial droop and floating speed settings, but they require manual or automatic elimination of the residual droop.

For steam central stations, the adoption of this type appears an unnecessary complication at least for the present. The "proportional" governor can be made very stable and smooth; its phase displacement with frequency ("time lag") may readily be made negligible, as witnessed by the author. If something better than a good proportional governor is desired, then careful application of automatic frequency regulation, giving zero final droop and eliminating manual interference, would appear a better step forward. Especially if load dispatchers were to change vital governor settings such as droop of "compensated" governors according to the load, as the author recommends, then regulation like curve No. 4, Fig. 15 would be likely to result.

The proportional plus proportional speed floating principle has proved satisfactory. Good regulator design plus careful setting is likely to produce accurate and smooth regulation.

Many steam governors are crude due to poor design or poor maintenance and this should undoubtedly be improved. But care should be used in writing specifications so that only essential values are asked for.

First, there should be a straight-line relationship between droop and output over the operating range as the author recommends. Otherwise, neither the governor nor the automatic frequency control can be given the optimum setting. To facilitate synchronizing, the droop at extremely low outputs may have to be made greater than that used in the operating range.

Second, there should be a sensitive "head," a minimum of lost motion, amply large oil pumps and pilot valves, rectangular ports without lap, in short the governor should come as close to its ideal (proportional) characteristic as possible. To make governors independent of harmonic-frequency pulsations is likely to affect their accuracy of motion and it would seem better to let them oscillate.

With improved governors, the optimum initial droop would become less, and optimum reset speed of frequency controllers would increase, resulting in improved accuracy and smoothness of regulation. Even with existing governors, however, these can be made quite good.

The writer wishes to commend the author, particularly for his excellent test work, and again express the hope that, by joint effort with the Committee on Industrial Instruments and Regulators, a substantial improvement in regulation may be brought about.

Regulation of System Load and Frequency

By HERBERT ESTRADA[1] and H. A. DRYAR,[2] PHILADELPHIA, PA.

This paper discusses the practices of the Philadelphia Electric Company system in the regulation of system load and frequency, including the scheduling and actual operation of generating capacity with regard to reliability and economy. A summary of the principles of economical load allocations on both steam and hydrogenerating stations is presented. The effect of changes in system load or generation on frequency, the self-regulation characteristic of the system, and the combined system governor action are discussed from the standpoint of the individual and the interconnected group of systems. The practices of the interconnection, of which the Philadelphia Electric Company is a member, in manually regulating the frequency and the incident problems thereto are considered. A discussion of governor instantaneous and average speed regulation, sensitivity, and response is given, with particular reference to their effect on frequency regulation.

THE problem of system regulation in its many phases has seemed to vary with the ever-changing operating conditions; it is probable in each instance that we have been satisfied with a partial solution of the existing problem. We may find the reason for such oversight, however, in the many other operating problems that were more persistently demanding a remedy.

Isolated Generating-Station Operation. When the system was supplied by a single generating station, the changes in load on the plateau of the curve constituted a large percentage of the total demand and, as a result, variations in the instantaneous frequency were such that industrial customers, particularly textile and paper mills, were subject to damage to their product. The average frequency was such that the production schedule of industrial plants, in quantity and quality, frequently could not be maintained. Frequency-measuring instruments of that day, however, were of such a broad scale that close average regulation was manually difficult.

Parallel Operation of Generating Stations. With the parallel operation of a number of generating stations, dependence on system inertia and governor response for system regulation seemed to provide a satisfactory solution. With this method, manual control was assigned to a single regulating station, the other generating stations maintaining their assigned output as an average loading, permitting the load to vary as the turbine governors responded to changes in speed. Aiding in the improvement of the system regulation was the diversity in the load swings which made the system load fringe a smaller percentage of the total load although larger in absolute magnitude.

Interconnected Operation of Systems. When interconnections were established and the problem of stability made its appearance, the settings of turbine governors were further damped and, in many instances, automatic frequency control was installed which tended to perform the normal function of the governors. If the tolerance of the controller was small, load variations on the regulating station were excessive and the station economy suffered. Electrical time service, however, was considerably improved and this was instrumental in the improvement of this type of service on systems having manual control.

Systems that favored that type of manual control, wherein dependence was placed upon turbine-governor response and the inertia of rotating equipment, to limit variations in frequency and to avoid burdensome changes in load on the regulating station, regarded the frequency indication as a guide in load regulation.

Limited Knowledge of Problems of System Regulation. In all these phases of system regulation, it would appear, as has been charged, there was a lack of sustained interest in this general subject, an interest that would apply itself to a complete solution of the problem rather than confining itself to a study of an existing phase and seeking a remedy for that.

Operating men favoring automatic frequency control as a remedy, regarded a narrow frequency band as essential as closely regulated voltage. Operating men who held to manual control of frequency objected to abnormal changes in load on a regulating station. The generating-station operating force was concerned primarily with economical performance. What ills there were in system regulation were regarded as inherent and system dispatchers "worried along" with them, striving to hold the frequency within reason and changes in station output to a minimum. The advent of interconnections may be said to have further postponed efforts looking to a solution, as continued interest in the problem was manifested usually by but one company of the group.

Scope of Study of System Regulation. In a study of system regulation, it is necessary to consider each of the following factors:

1 The scheduling of generating capacity
2 The actual operation of generating capacity
3 Load control
4 Frequency control
5 Governor characteristics.

Scheduling Generating Capacity

The two principal functions in the operation of an electric-power system, that of providing reliable service and attaining the highest efficiency of performance, demand that adequate generating capacity be scheduled for operation, based on the estimate of the system load, on the sum of the estimated loads of each area of the system, and the available transmission capacity. Fig. 1 is a schematic diagram of the main generating and transmission system of the Philadelphia Electric Company, indicating the distribution of the system load and the generating capacity which may be scheduled for operation.

Load Estimating. Service reliability and efficient operating performance demand accuracy in the forecast of the system load, in order that generating capacity, adequate to supply the system load and provide the necessary operating reserve, may be economically scheduled.

In the daily estimate of the system load, it is found that there is a base load for each day and for each hour of each day, the components of which are all the factors, with the exception of those affected by weather conditions, that may be considered as influencing customer demand and contributing to the diversity of such demand. When the components of the customer demand

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

FIG. 2 SCHEMATIC DIAGRAM OF LOAD DISTRIBUTION OF PHILADELPHIA ELECTRIC COMPANY'S POWER SYSTEM

that are the result of existing weather conditions are added to the base, the sum will be the system load. In making an accurate estimate of the system load, consideration should be given to the weather with the proper weight for degree of cloudiness, wind velocity, and temperature based upon the best available forecast.

Reliability. In the scheduling of generating capacity to supply the system load, the requirement of reliability of service is the first consideration. Reliability is fostered by maintaining the availability of the necessary generating capacity to each load center of the system. The degree of availability is deemed adequate if coverage is provided for the possible loss of the generating unit of largest capacity within a load area or the possible loss of the transmission capacity rendering available to the load area the largest amount of generating capacity.

Economy. In the scheduling of generating capacity to supply the system load and provide the necessary spinning reserve, economy as a factor in the operation of the system is secondary in importance only to that of reliability of service.

Economy in the operation of the generating system is effected when the cost per kilowatthour of the energy delivered to the bus of each load center is the lowest that may be obtained. Thus it is necessary not only to calculate the generating cost per kilowatthour, but to determine also the losses in transmission.

Spinning Reserve. The spinning-reserve requirement of an interconnected system is usually specified as equivalent to the capacity of its largest generating unit. This requirement, however, is an arbitrary measure and in some instances the reserve coverage provided is equivalent to the capacity of two or more generators.

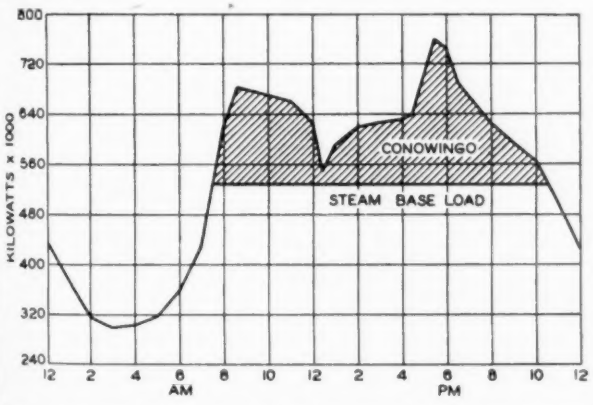

Fig. 3 Chart Showing System Daily Load With Portion Allocated to Conowingo

When systems are interconnected and the spinning reserve is pooled to provide coverage for the loss of the largest generating unit of the group, it will soon be evident that errors in the load estimates are much more frequently the cause of deficits in spinning-reserve capacity than the loss of generating capacity. Thus it has become necessary to provide spinning reserve as coverage for the loss of the largest generating unit or the possible load-estimating error, whichever is the greater.

Assuming that coverage on an interconnected group of three systems is to be provided for the largest unit or a 7 per cent load-estimating error, whichever is greater, it is seen that the reserve requirement will be based on coverage for the load-estimating error, if the capacity of the largest unit is less than 7 per cent of the load. The reserve requirement may be divided among the systems in accordance with some previously agreed upon formula.

When a system is uninterconnected, the hazard to reliability of a load-estimating error is obscured in the coverage for the largest unit of the system or in the number of units of smaller rating which provided an appreciable amount of reserve capacity above their efficient rating.

Actual Operation of Generating Capacity

Typical System Setup. To illustrate the actual operation of generating capacity on the system of the Philadelphia Electric Company, let us assume that the system load for which generating capacity has been made available is 760,000 kw, and the distribution of this load among the load centers as shown in Fig. 2 is:

Station	Load, kw
Chester	105000
Wilmington	37000
Paschall	19000
Schuylkill	163000
	324000
Delaware	87000
Richmond	145000
Westmoreland	87000
Plymouth Meeting } Barbadoes Island }	80000
Emilie	10000
Miscellaneous, including losses	27000
Total	760000

The capacity requirements to supply this system load and provide the necessary sectional and system spinning reserve would be:

Station	Capacity requirements, kw
Conowingo	245000
Richmond	255000
Delaware	60000
Schuylkill	135000
Chester	90000
Deepwater	54000
Total	839000

Coordination of Steam and Hydro. In determining how the load should be most economically allocated to the generating stations, it is necessary to know the performance characteristics of each plant in the system. However, the loading of Conowingo, a run-of-river hydro plant, supplying a large part of the system load, is determined first. Conowingo utilizes the full flow of the Susquehanna River for about 70 per cent of the year. During the remaining 30 per cent of the year, the river flows are in excess of what can be utilized by the present installed capacity of 252,000 kw. The plant generates approximately one third of the total energy output of the Philadelphia Electric Company system in a normal hydro year. It is highly important to allocate the load correctly to this station as it has much effect on the economy of the connected steam system.

Steam Base Load. Minimum steam-station costs are closely approximated by allocating to Conowingo a block of the system daily load, Fig. 3, of such proportions that the area of the block corresponds to the available energy to be generated, and the ordinate of the block corresponds to the economical hydro-plant capacity.

Referring to Fig. 3, the higher the position of shaded area, which represents the Conowingo energy output, the less will be the area of this block. The lower load limit of the shaded area, indicated as steam base load, increases as the energy output from Conowingo decreases. The steam base load may be defined as that system load above which Conowingo becomes the marginal station in system loading, taking all the variations in system load within the limits of its economical capacity. When the system load exceeds the steam base load plus the economical capacity of Conowingo, the excess must be carried as steam peak. When the system load is less than the steam base load, it is entirely carried by steam and Conowingo is shut down. By using the steam base load as the basis for loading Conowingo, advantage is taken of the Conowingo Pond in absorbing the variations which

occur in system daily outputs due to weather conditions and other factors affecting system load.

Determination of Steam Base Load. Corresponding to each value of Conowingo daily kilowatthour generation there is a definite steam base load for a particular day. This relation is utilized in determining the steam base load for each day by using the Conowingo loading chart for seven machines available at Conowingo, shown in Fig. 4. These curves determine the steam base load for a given daily Conowingo energy output and daily

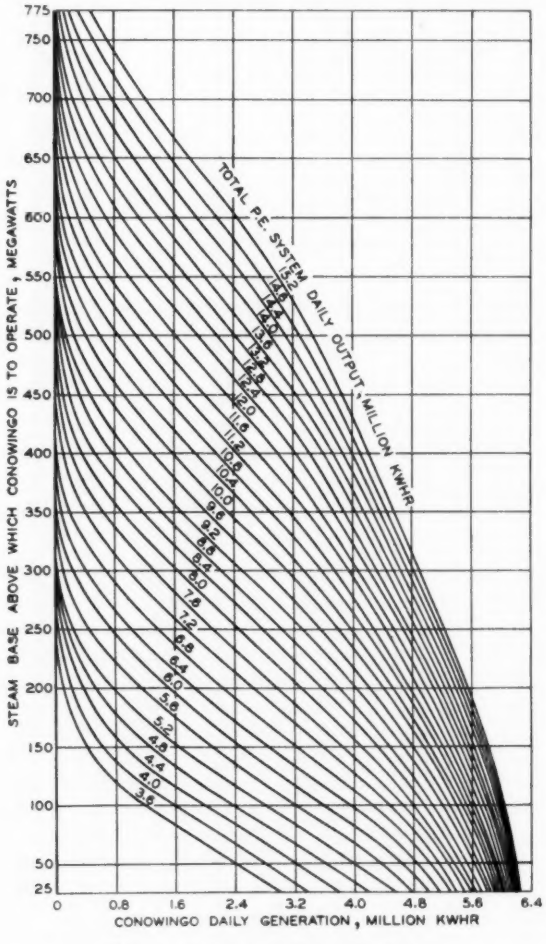

FIG. 4 CONOWINGO LOADING CHART

(Available peak prepared for = 259,000 kw plus steam base. If system peak is greater than this available peak, the steam peak prepared for must be increased to make up the difference.)

system generation. Similar charts are used if less than seven machines are available at Conowingo, one chart for each Conowingo capacity value. The curves are worked out from daily occurrence curves which show the generation in the load curve below each value of system load. The steam-base curves apply to the different seasons equally well in spite of the seasonal variations in the shapes of the daily load curve.

Variation in Hydro-Station Increment Rate. The foregoing relations have been based on substantially constant hydro-station increment rates. By hydro-station increment rate is meant the increase in station draft, or in rate of flow of water through the turbines, corresponding to a slight increase in hydro load divided by the increase in load. It can be conveniently expressed in terms of cfs per kw. Fig. 5 shows the variation in increment rate for Conowingo against station loading expressed in per cent of average hydro-station increment rate. The hydro increment rate remains practically constant up to the most efficient load for all hydro units on the line. Beyond this load, however, the hydro increment rate usually increases quite rapidly.

Economical Loading of Hydro. The principles of most economical hydro load allocations can be summarized generally as the utilization of the river flow so as to displace the maximum steam-station cost per cfs of river flow. The value of a small increment of river flow cfs is equal to the value of the corresponding small increment of hydro load Δ kw, in displacing steam generation.

The value of the river flow per cfs per hr $= \dfrac{I}{W}$

where $W = \dfrac{\Delta \text{cfs}}{\Delta \text{ kw}}$ = hydro-station increment rate

I = incremental cost of displaced steam generation

In order to load the hydro station in the overload region beyond most economical capacity, the value of $\dfrac{I}{W}$ must be equal to or higher than during the steam-base period of the day, as the total flow for the day is fixed and whatever extra water is used during

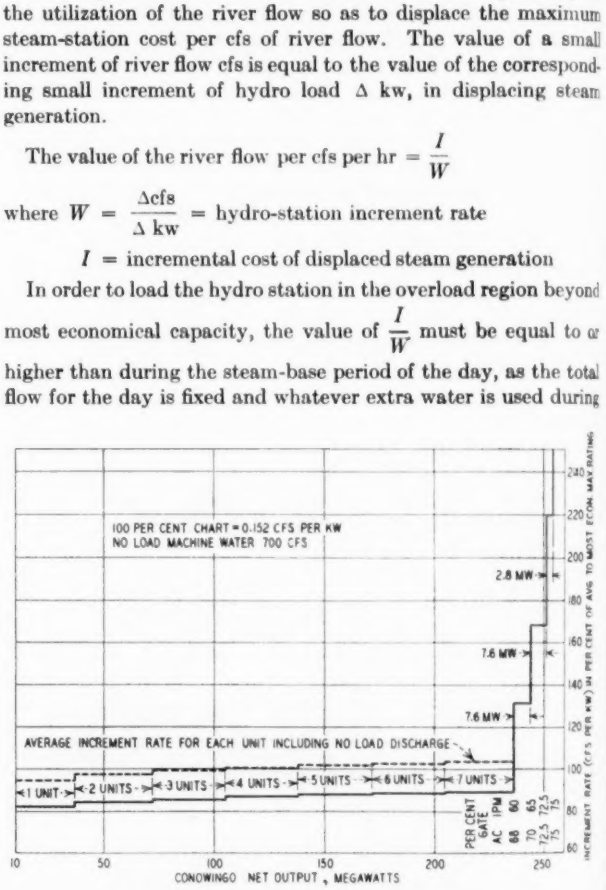

FIG. 5 CONOWINGO INCREMENT RATE

(To justify operation of hydro overload capacity the increment cost of steam stations, of energy displaced by hydro overload capacity, must be equal to or greater than steam-base increment cost multiplied by percentages on this chart.)

one period must be stored in the pond during some other period. Therefore, the hydro station is loaded incrementally beyond its most efficient rating in conjunction with the system to carry the peak portion of the load. In any case, however, the overload capacity of the hydro station, beyond most economical capacity, should be utilized as reserve on the system in order to reduce steam stand-by costs.

The incremental value of the hydro station in this region to be compared to the incremental cost of the steam is $I_B \dfrac{W}{W_B}$

where I_B = steam-base increment cost
W = hydro-station increment rate
W_B = average hydro-station increment rate

If W_B is taken as the average hydro increment rate up to the economical capacity, the curves in Fig. 5 then give the values of $\dfrac{W}{W_B}$ in per cent for the overload capacity.

Steam-Station Performance Curves. The steam-station performance curves are based on accurate performance tests of all

pertinent equipment, the tests having been conducted with the apparatus in the best possible operating condition. The heat-balance calculations, which are made by combining the tests of the individual equipment into station performance curves, are the same sort of performance calculations that are made in the design of a station. Daily performance curves are calculated from typical daily load studies by summating the individual hourly performances for the day, computed from the hourly plant performance curves. In working out the station performance curves, the most economical operating and loading schedules for individual equipment in the plant are developed.

Charts for Typical Station. Fig. 6 shows one of the plant-performance charts for a generating station having 2 turbogenerators and 12 boilers, giving the relation of hourly coal consumption to net kilowatt output for 32 F and 80 F condenser circulating water in injection temperatures, and for varying number of boilers under fire. The total coal consumption, based on coal having a standard heating value, is obtained from the sum of parts *A*, *B*, and *C* given by the curves. Part *A* gives the banking or no-load coal per hr for the number of boilers under fire. Part *B* gives the coal required per hr as a function of the net kilowatt output with all the boilers in the station under fire. Part *C* gives an adjustment for a less number of boilers under fire, the adjustment resulting from the decrease in boiler efficiency with increase in rating.

Increment Coal Rate. The heat-balance calculations for the station-performance curves are also used in obtaining the increment-coal-rate curves for the station. The increment-coal-rate curves greatly simplify the task of allocating properly the system load to the individual generating stations, and are also useful in determining increment costs of so-called economy power purchased from or sold to interconnecting companies.

The increment coal rate may be defined as the pounds of coal required to produce an increment of 1 kw in the net station output. It corresponds to the slope of the tangent at a given load on the hourly-coal-consumption curves shown in Fig. 6. The increment coal rate varies with station loading, condenser injection circulating-water temperature, and also with the number of boilers which are under fire.

In Fig. 7 are shown the increment-coal-rate curves for the generating station, the performance curves for which are shown in Fig. 6. The increment-coal-rate values expressed in per cent of average station coal rate are shown as a function of station load for 32 F and 80 F condenser injection circulating-water temperature. Adjustments are given below the main curves for the number of boilers which are under fire in the station. This adjustment is added to the value given by the main curves to obtain the total bogey increment rate. The main curves are for the maximum number of boilers under fire.

Increment Rate in the Overload Region of the Turbines. Sufficient turbogenerators are carried on the system at all times to maintain the load in the event of the failure of the unit of largest capacity. All machines, in general, are provided with overload capacity, where the increment coal rate is from 12 to 20 per cent greater than in the normal load region. This overload capacity should, therefore, be used as far as possible in providing reserve for the outage of the largest unit of capacity on the system. To make the increment-rate curves Fig. 7 more readable, the overload increment rate for the first main unit on the line has been omitted.

In other words, the curve is worked out on the basis that the next machine is put on the line just before the overload valves open on the machine already in service. The addition of the second unit on the line, Fig. 7, increases the coal consumption from 3100 lb per hr to 4400 lb per hr, depending upon the injection temperature. This increased coal consumption must be balanced against the increase in increment rate in the overload region to determine how much overload capacity should run before an extra unit is placed on the line in advance of reserve requirements.

Operating Factor. Inasmuch as the increment-coal-rate curves are derived from the same heat-balance calculations as the coal

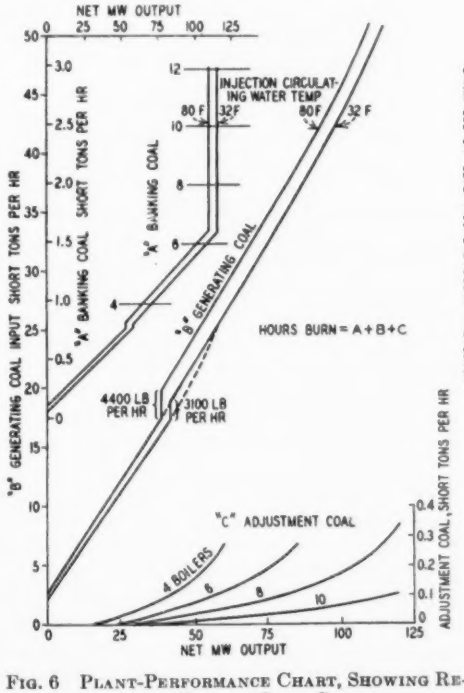

FIG. 6 PLANT-PERFORMANCE CHART, SHOWING RELATION OF TOTAL HOURLY COAL CONSUMPTION TO NET MW OUTPUT

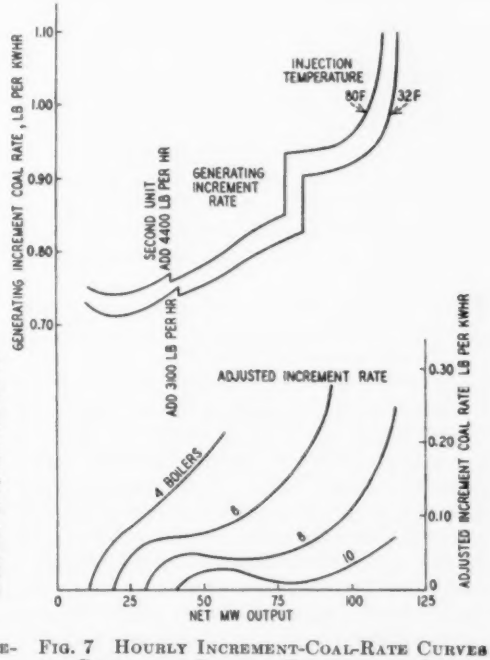

FIG. 7 HOURLY INCREMENT-COAL-RATE CURVES FOR GENERATING STATION; PERFORMANCE CURVES GIVEN IN FIG. 6

bogeys which are used to check the performance of the generating stations, the margin by which the actual coal consumption exceeds the bogey coal consumption should be used in correcting the bogey increment coal rate to actual conditions. This margin is approximately 2 per cent giving a factor of approximately 1.02 by which to multiply the bogey increment-coal-rate values in order to correct the actual plant conditions. The actual factor is known at all times from the check of operation in the plant.

Allocation of Load. The criterion for correct load allocation is that the load shall be increased on the steam-generating station having the lowest increment cost per kwhr. An important consideration with reference to load allocation is the number of main units to have on the line. At the lower loads, the number of units is determined by the amount of reserve for which it is necessary to stand by. In this case, the station increment-coal-rate value given by the curves in Fig. 7, corrected by the operating factor, is multiplied by the price of fuel giving the incremental cost of fuel per kwhr. To this is added the incremental maintenance cost to determine the total steam-station incremental cost which is used directly in determining the correct allocation of load. Assuming a river flow corresponding to a daily Conowingo output of 2,000,000 kwhr per day, and a daily system output of 13,000,000 kwhr, the steam base load corresponding to this is 529,000 kw. The most economical allocation of this steam base load to the individual steam-generating stations, Fig. 2, is as follows:

Station	Load, kw
Schuylkill	115000
Deepwater	54000
Richmond	250000
Chester	66000
Delaware	44000
Total	529000

With this steam base and the system load of 760,000 kw, Conowingo is loaded to 231,000 kw. As the system load changes, the load on Conowingo is varied to hold the frequency.

Regulation of Load

The system load is a composite function of the variable demands of the customers of a power company, the connected load or the maximum potential demand of which may be four or five times the actual diversified energy consumption, termed the system load. The continual change in the customer demand produces a fringe in the system load which is attended by a continual variation in the system speed. On an interconnected group of systems having a combined approximate load of 2,400,000 kw, the frequency variation because of this fringe may approximate 0.05 cycle. Accentuating this fringe and responsible for a greater frequency error are the swings of such loads as that of railroad or steel-mill demands.

These changes in the system load, however, should not cause the abnormal variations in frequency which, when corrective measures are applied, are sometimes reflected in extreme and continued changes in the output of the generating stations.

Frequency Variation a Guide to Load Change. A deviation from standard frequency under normal operating conditions generally may be considered as an indication of a change in system load. The major load changes, such as that of the morning pickup or the noontime drop, however, are anticipated from the normal shape of the load curve. Thus, in a system which regulates its load manually, the attention of the station operator is held to the frequency recorder in order that a sustained load change may be observed and the necessary change in station output made. Where the manual regulation is a responsibility of the load dispatcher, and the regulation is not assigned to a station, the allocation of the increased or the decreased demand will be made in accordance with the economic loading schedule. In this operation as in all regulating measures, attention of the station operator should be directed to the frequency, in order that errors in speed may be avoided.

Regulation of Tie-Line Loading. In the manual regulation of the load of an interconnected group of systems, it is usual to delegate to one company the responsibility of frequency control and to one or more of the other companies the duty of regulating the tie-line loading.

Regardless of the part in the general program of regulation that a company may be assigned, it should be recognized that control of the frequency is inherent in each regulating function. Slight changes in generation in an effort to return a tie-line loading to schedule, for instance, may improve the frequency or, if proper operating procedure is violated, may cause an abnormal frequency error.

Effect of Load Change on Frequency. The effect of a system load change on the frequency, when turbine-governor response tends to limit the variation, may approximate the following: Two per cent load change produces $^1/_8$ per cent frequency change or a system regulation of approximately 8 per cent.

These deviations in the frequency, with respect to system load changes, are those which remain after the turbine governors have responded to the initial frequency change and have partially corrected the variation in speed. These frequency deviations are, in themselves, responsible for an actual change in system demand. This change, when added to the change in generation effected by the governors, is equal to the initial load change at standard frequency. The correction of the remaining frequency deviation is effected by changing generation manually on the marginal station. Theoretically this manual change of generation should be comparable in amount to the change in load as the turbine governors of other stations act to restore their output to their assigned loading.

Frequently, however, there is little if any counteraction by governors and the manual change of generation on the marginal station to correct the remaining frequency deviation will effect a load change on all systems of the interconnected group in proportion to their respective system loads as the frequency is restored to normal.

Effect of Large Generating-Capacity Loss. If there were no turbine-governor response to a system load change, the variation in frequency for a given load change would be much greater in percentage deviation from standard. This deviation from standard frequency with respect to a system load change would be comparable to that which occurs when there is a deficiency of generating capacity with respect to the load at normal frequency.

The change in the system load as a result of a drop in frequency because of the loss of a large amount of generating capacity will approximate 2.5 per cent of the system load to 1 per cent change in frequency. In one instance, the system load at normal frequency was 720,000 kw and there was a loss of 230,000 kw generating capacity, the system load automatically reduced to equal the generating capacity remaining available. The generating capacity remaining available to the load was 580,000 kw and the reduction in load was 140,000 kw or approximately 20 per cent. The decrease in frequency was not quite 5 cycles, or approximately 8 per cent.

Effect of Frequency Reduction on System Load. The same relation between system load change and frequency variation, which exists in the event of the loss of considerable generating capacity, also applies when there is a reduction in system frequency. Reducing the frequency 0.6 cycle or 1 per cent on an interconnection having a load of 2,400,000 kw at normal frequency will reduce the combined load approximately 2.5 per cent or 60,000 kw.

Effect of Change in Generation on Frequency. This relation between load change and frequency variation is presented as forming a close approximation of the effect of the change of one factor on the other when there is no governor response to correct an error in the system speed. This same relation is also effective in the correction of frequency errors or the returning of tie-line loading to schedule. Where there are relatively small changes of

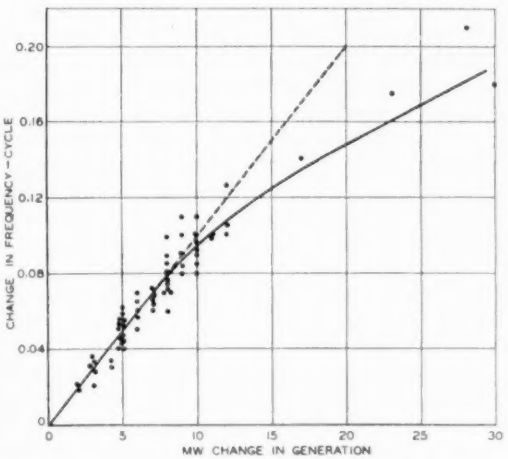

FIG. 8 EFFECT ON FREQUENCY OF CHANGE IN GENERATION
(Governor inactive; combined load of interconnected system = 2,400,000 kw.)

generation, there may be little if any counteracting effect of the turbine governors of other stations or systems. Thus it will be found on even large interconnections of approximately 2,400,000-kw load that a change of 10,000 kw in generation will frequently cause a change in frequency of 0.1 cycle.

Fig. 8 is a diagram of readings taken when the system generation was changed to note the effect on the frequency. These were approximately 40 per cent of the total number of readings taken. The other 60 per cent, which were not included as counteraction of governors or load changes on the system, were evidenced in the readings.

The company changing its generation 10,000 kw to correct tie-line loading may cause a frequency change of 0.1 cycle, and a company to correct an error of 0.1 cycle in frequency may have to change its generation only 10,000 kw.

Regulation of Simple Interconnection. Where only two systems are interconnected, proper operating procedure requires that manual readjustment of tie-line loading should be made as follows:

Generation should be increased or decreased first to correct any existing error in the frequency. Then, both systems must act together to complete the correction of tie-line loading, one system decreasing its generation as the other increases its output. In like manner, manual correction of abnormal frequency errors requires mutual action if "seesawing" of station loadings and of the frequency is to be avoided.

Interconnected-Group Systems. In the interconnected group of which the Philadelphia Electric Company is one, there are approximately fourteen operating companies. In the operation of the Pennsylvania-New Jersey Interconnection, of which the Pennsylvania Power and Light Company, Philadelphia Electric Company, and Public Service Electric and Gas Company of New Jersey are the member companies, instructions to change the generation are given by the interconnection load dispatcher who has the responsibility of maintaining the frequency. The allocation of the combined loading of the three companies forming this interconnection on the basis of economical performance improves the regulation of the frequency as the loading of the tie lines which are of ample rating may vary in amount and direction and requires no regulation. The Pennsylvania Water and Power Company and the Metropolitan Edison Company have the responsibility of regulating the tie-line loading.

Regulation of Interconnected Group of Systems. In the manual regulation of tie-line loading in an interconnected group of systems, proper operating procedure requires readjustment to be made in the following manner:

Generation first should be increased or decreased to correct any existing error in the frequency. The system to initiate this correction will be indicated by the relation of the tie-line loading to the schedule and the possible effect of the change on the frequency. Then, each system may have to change its generation, one or more decreasing its output as the others increase their output.

It can be said that correction of tie-line loading is not a duty

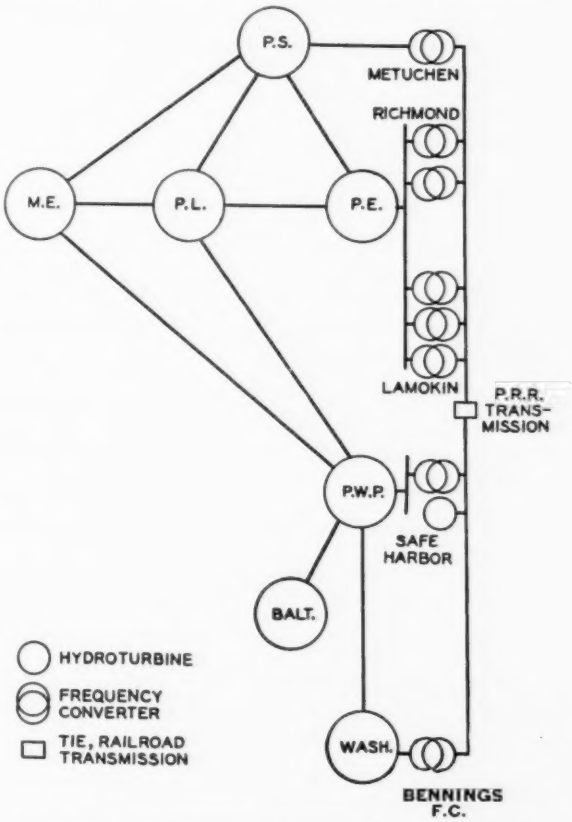

FIG. 9 REGULATION OF GROUP OF SYSTEMS, 60- AND 25-CYCLE LOOP; SIMPLIFIED DIAGRAM
(P.S., Public Service Electric and Gas Company; M.E., Metropolitan Edison Company, New Jersey Power and Light Company; P.L., Pennsylvania Power and Light Company; P.E., Philadelphia Electric Company; P.W.P., Pennsylvania Water & Power Company; Balt., Consolidated Gas & Electric Company; Washington, Potomac Edison Company.)

that may be performed by one system. Observance of the tie-line loading may be the responsibility of one system, but its regulation requires the cooperation of two or more systems.

In the same way, correction of abnormal frequency errors is a duty that may not usually be performed by one system. Mutual action by all systems of the interconnected group may be required to avoid "seesawing" of station loadings and of the frequency.

Attention to Frequency. In any adjustment of tie-line loading, it is desirable that the frequency be observed in order that an

existing frequency error is not aggravated, or a frequency error in the opposite direction is not induced, as subsequent correction of the frequency will again result in the tie-line-loading schedule being adversely affected and again requiring further adjustments.

In order that abnormal frequency errors may be avoided, it may be desirable that the application of corrective measures begin when the frequency departs more than 0.05 cycle from standard. This practice not only may reduce the number of abnormal errors, but will minimize the loading changes on stations and tend to prevent seesawing of station and tie-line loading.

Attention to Tie-Line Loading. Where a meter on the tie line is not available to the frequency-regulating system to indicate where a load change has occurred, the load dispatcher of this system must of necessity depend upon the dispatchers of those companies whose responsibility it is to observe and correct for tie-line loading. If there is a failure of companies to observe tie-line loadings, the burden is placed on the frequency-regulating system to ask for a check of the loading of these tie lines, and to await a report of these loadings before complete corrective measures may be taken to restore normal frequency. In the meantime, some changes in station output have been made and frequently these moves will be followed by changes in the opposite direction when correction by the tardy system has been made.

Interconnection Forming 25- and 60-Cycle Loop. Referring to Fig. 9, the load dispatcher of the Pennsylvania-New Jersey Interconnection, who supervises the allocation of the combined load of this operating group to each system (P.E., P.L., P.S.),[3] also has the responsibility of frequency control. The control of tie-line loading thus devolves on M.E. and P.W.P.,[4] with the greater part of this duty on the latter as P.W.P. must control the loading of the 60-cycle ties (P.W.P.-M.E. and P.W.P.-P.L.) and also the 25-cycle tie (P.W.P.-P.E.) formed by the frequency-converter supply to, and the transmission facilities of, the Pennsylvania Railroad.

Deviation from the scheduled loading of these ties frequently results from the frame shifting of the frequency converter at Safe Harbor or at Bennings. This operation may be performed to:

1 Regulate loading of 25-cycle tie
2 Increase the supply of power to Washington
3 Reduce overload on P.W.P.-Washington 60-cycle tie
4 Utilize output of hydro unit on 60-cycle system of P.W.P.

The movement of a converter frame, if necessitating the correction of tie-line loading by Washington and Baltimore, one counteracting the other in the effect on the frequency, should not cause an abnormal deviation in the system speed if the frequency is properly observed in the corrective measures.

[3] Philadelphia Electric Company; Pennsylvania Power & Light Company; Public Service Electric & Gas Company.

[4] Metropolitan Edison Company, New Jersey Power & Light Company, and Pennsylvania Water & Power Company.

Division of Railroad Load Swings. When there is an increase of the railroad load, regardless of the area in which it occurs, the supply of the increased demand will closely approximate the relative frequency-converter capacity in operation in each area, as the relative impedance of this type of equipment determines to a great degree direction of flow. In like manner, a reduction of railroad load will divide in approximate ratio to the frequency-converter capacity operating.

Regulation of Frequency

A frequency curve appears to have several components: A rapid, periodic variation of approximately 0.005 cycle of an approximate period of 2 sec; variations of approximately 0.03 cycle having a semblance of a periodicity of 30 sec; variations of 0.1 cycle or more from standard frequency that are irregular in occurrence. Fig. 10 is a copy of a high-speed Leeds and Northrup chart of the frequency of the Philadelphia Electric Company system for a 7.5-min period. The curve for this period is typical of the normal frequency curve.

Frequency Ripple. The rapid, periodic variation of approximately 0.005 cycle appears to be a rhythmic pulsation which may be ascribed to synchronizing power between generators and the load or between systems or parts of a system. The rapidity of the variation probably will not permit of regulation and the smallness of the variation does not warrant efforts to correct. This variation of 0.005 cycle follows the curve of the frequency as it responds to the other influences which cause changes in speed.

System Characteristic. Variations of approximately 0.05 cycle also are continuous. If the other causes of speed change were absent, these variations would probably be reflected in a curve which would be a succession of waves of an amplitude not exceeding 0.05 cycle that it would be inadvisable to regulate, because the load change on each generating station, as a result of the variation, is negligible, and any corrective measures might tend only to halve the periodicity of the variation without any reduction of the amplitude. This variation of 0.05 cycle also follows the trend of the frequency curve. As the deviation from standard frequency becomes greater, governors should respond to limit the changes in speed. If the governor regulation is 4 per cent and the frequency variation is 0.05 cycle or $^1/_{80}$ of the speed drop for 100 per cent load change, it may be possible that there will be no governor response.

This variation of 0.05 cycle in the system frequency may be ascribed to the change in the fringe of the load curve, which marks the great diversification in the use of appliances, lighting, motors, etc., throughout the day.

It is difficult to believe that these continual variations of approximately 0.05 cycle are a result of improper governor action as any erratic impulse from this source might be expected to cause an unevenness in the regulation that would render an average frequency of 60 cycles impossible.

That such average regulation may be considered as inherent

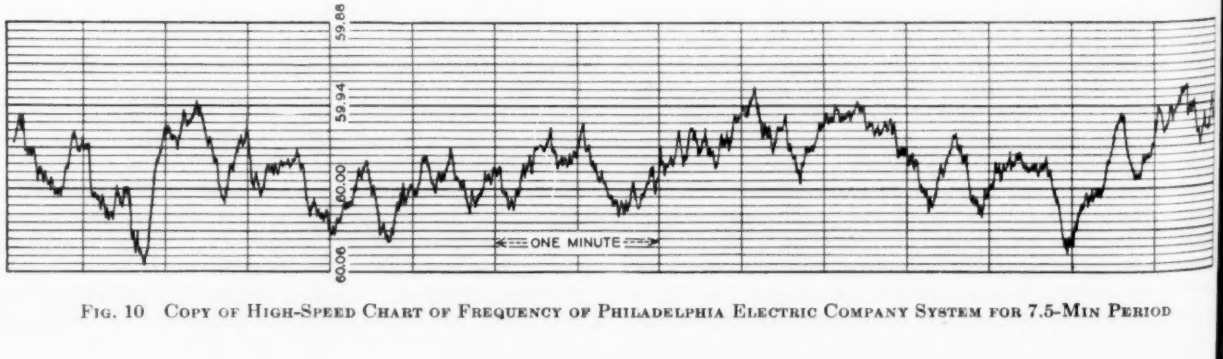

Fig. 10 Copy of High-Speed Chart of Frequency of Philadelphia Electric Company System for 7.5-Min Period

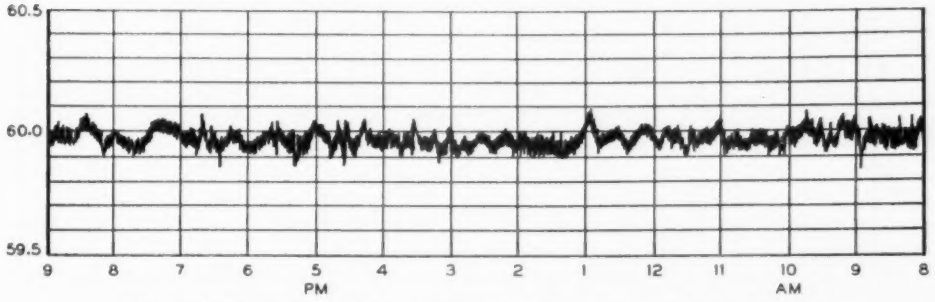

FIG. 11 FREQUENCY CHART OF UNINTERCONNECTED SYSTEM, MARCH 10, 1927

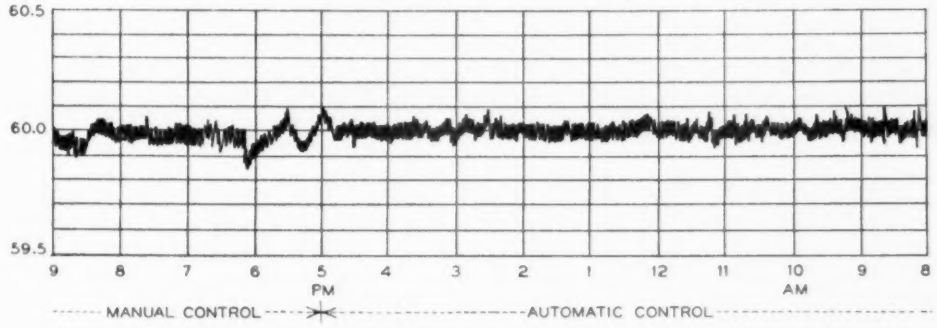

FIG. 12 FREQUENCY CHART OF TWO SYSTEMS INTERCONNECTED, APRIL 3, 1928

in a large system group is substantiated frequently in the operation of the combined system for intervals of several hours, during which periods there were no changes in generation to correct frequency deviations. This self-regulating property was evidenced particularly some years ago in an interconnection of systems having a combined load of approximately 4,000,000 kw. Frequency control on this group of systems had been automatic until 7:15 a.m. one day, when the regulating company transmitted a request to be relayed by telephone through six companies, to another company, which practiced manual regulation, to assume control. The message was not delivered and for more than 4 hr the frequency curve was similar to that of the previous hours when regulation was automatic. The lack of supervision of the regulation was discovered when the first regulating company asked the latter, "When did you install automatic frequency control?"

Similarity of Systems' Characteristic. Evidence of this component of the frequency curve is seen in the frequency chart of March 10, 1927, Fig. 11, when the Philadelphia Electric Company was operating as an uninterconnected system with a load of approximately 400,000 kw. This same variation is seen in the frequency chart of April 3, 1928, Fig. 12, when the system of the Philadelphia Electric Company was interconnected with that of the Pennsylvania Power & Light Company and in the frequency chart of October 14, 1929, Fig. 13, with Public Service Electric & Gas Company of New Jersey as one of the interconnected group. The similarity of the curves testifies to some one force that is inherent in the operation of a system or a group of systems, small or large, as productive of the variation. Such an impulse may have its source in the changing fringe of the load.

The chart of October 14, 1929, Fig. 13, indicates also the load of the regulating station, Conowingo. At that time the frequency control was always assigned to a generating station. As experience indicated that large interconnections with ties of large capacity were, to a great degree, self-regulating, the load dispatcher assumed direct supervision of the frequency and allocated sustained changes in load in accordance with the economic loading schedule. This practice may be observed in the chart of November 6, 1931, Fig. 14, which indicates the generated load of the marginal station which was directed by the load dispatcher to change its output when the change in frequency indicated a sustained load change.

Variations Demanding Correction. Also of interest in all these charts is the third component of the frequency curve which is irregular in occurrence. This component may be divided into two factors. One is the variation caused by changes in such load as the demand of railroads or steel mills. The other is the variation which is due to one of the following causes:

1 Loss of generating capacity
2 Units loaded regardless of frequency
3 Failure to anticipate system load changes
4 "Regulating" tie-line loading regardless of frequency.

Frequency variations due to such load changes as that of railroad or steel-mill demand may influence the setting of governors in order that governor action may maintain the frequency within reasonable limits for an appreciable change in load.

Variations in frequency which find their cause in departure from proper operating procedure may be said to be responsible for most of our present problems in regulation. It is probable that some improvement in governor performance would aid in limiting these variations. The improvement which would bring about closer attention of all operators to the frequency, however, would be fully as adequate. Maintaining satisfactory frequency then would be a matter of observing its trend and directing the necessary change in the output of the marginal station to correct deviation.

Nonobservance of Proper Operating Procedure. Of the failures to observe proper operating procedure, "regulating" tie-line loading regardless of frequency, appears to be the cause of approximately 75 per cent of abnormal frequency variations. The abnormal variations from this cause frequently occur on the hour or half hour or at the time readings are taken. Evidently, equipment loadings are then changed and, at times, regardless of the

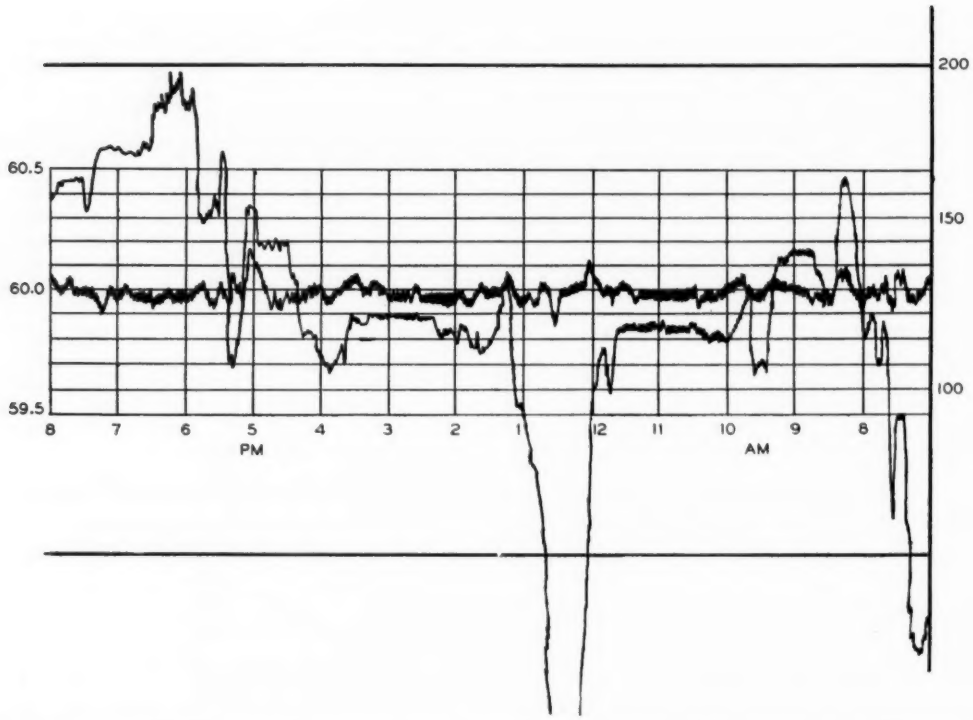

FIG. 13 FREQUENCY CHART WITH LOAD OF REGULATING STATION OF THREE SYSTEMS INTERCONNECTED, OCTOBER 14, 1929

frequency. It is commonly assumed that efforts in the correction of tie-line loading in its effect on the frequency will be counteracted by the action of the governors of units of other stations or systems, thus tending to maintain normal frequency. Often this is not the case, Fig. 8, and if the generation is changed without regard to the frequency, an abnormal frequency error may occur.

Speed Characteristic of Systems. In the regulation of the frequency and of tie-line loading, it is essential that this speed characteristic of the group of paralleled systems be known in order that the effect of changes in load and generation on the system frequency may be anticipated and the effect of variations of the frequency on the system load may be recognized.

On a group of systems, the combined load of which is 2,400,000 kw, this change of generation may be approximately 10,000 kw to effect a frequency change of 0.1 cycle. The reverse of this is also true. A change of generation of 10,000 kw, in an effort to correct tie-line loading, may cause a frequency change of 0.1 cycle.

Regulation of Tie-Line Loading Also Controls Frequency. Because of the appreciable effect on the frequency of a small change in generation, it is evident, if tie-line loading is to be corrected, that the creation of a frequency error must be avoided. Where this possibility is present, the system, which should counteract any adverse effect on the frequency, should be informed of the proposed action.

Frequently it happens that measures applied to correct frequency or tie-line loading have to be counteracted immediately afterward by measures of the same magnitude in the opposite direction. This type of operation constitutes the really objectionable problem in the regulation of the load and frequency. It evidences a failure to observe the trend of the load or of the frequency. It indicates that the remedy for the wide variations in frequency may be found in many instances in a minimum of applied corrective measures.

GOVERNOR CHARACTERISTICS

Governor Action. The action of the speed governors on the prime movers is a primary factor in maintaining the system fre-

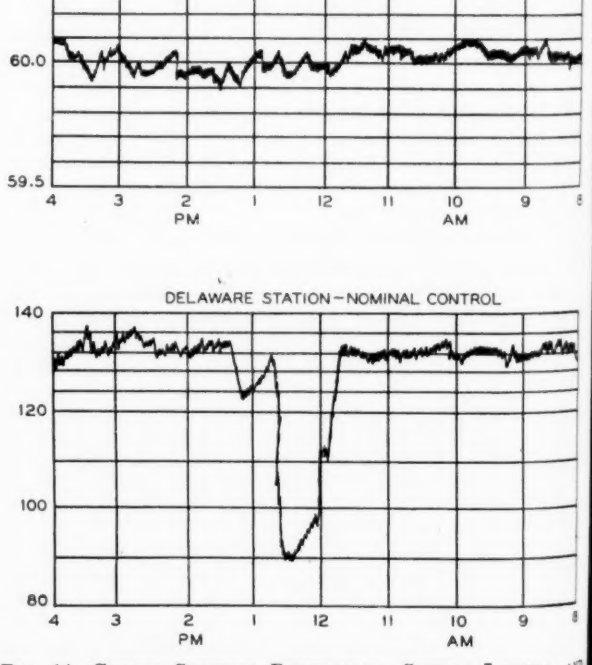

FIG. 14 CHARTS SHOWING REGULATION, SYSTEM INERTIA, AND GOVERNOR RESPONSE, NOVEMBER 6, 1931

quency within narrow limits. The governors should be sensitive to small speed changes and should hold the speed within narrow limits in accordance with their speed-regulation characteristic. The governors should do this without sacrificing stability, as it is part of the governor function to permit proper parallel operation of the prime movers.

Governor Sensitivity. The sensitivity of the governors is important for small changes in system frequency. If the governors do not respond to small changes in frequency, due to small load changes, the variation in frequency for small changes in load is then determined by the self-regulation of the system load. Fig. 8 shows the changes in frequency, resulting from changes in load less than 10,000 kw on a system with a combined load of about 2,400,000 kw. The average variation determined from the straight line in the illustration shows that the frequency varies 0.1 cycle for a load change of 10,000 kw, which on a 2,400,000-kw system is equivalent to 0.4 per cent load change for a change in frequency of $^1/_8$ per cent. This same approximate variation was obtained on several occasions when transmission-line failures resulted in a deficiency of generating capacity.

Theoretically it would appear that this is too large a variation in load for a given change in speed, but it is possible that a small percentage of the governors are acting to decrease the amount of speed change for a given change in load; it may also be that there is some slight variation in voltage which tends to contribute to the load change. By increasing the sensitivity of the governors, smoother operation of the governor function would be promoted and easier control of the frequency after load changes would result.

Governor Speed Regulation. For larger changes in speed, the variation in speed for a given change in load is determined by the speed-regulation characteristics of the governors. The speed-regulation characteristic may be defined as the change in speed in per cent of normal speed, which is required by the governor in order to vary the load from no load to full load. The governors on the system vary in speed regulation from two to eight per cent.

While the speed regulation over the range from no load to full load would indicate the frequency variation for a very large change in load on the system, the instantaneous speed regulation is a better indication of the effect on frequency of the load changes which are usually obtained on large systems.

Most governors have a wide range of instantaneous speed regulation for small changes in speed. This variation in instantaneous speed regulation is partly due to the difference in the amounts of steam admitted by a given movement of the control valve, depending upon the position of the valve. Other reasons for this variation are the changes in the efficiency of the turbine over the load range and on some governors the speed motor introduces a spring force which changes the speed regulation.

The position of the control valve has a large influence on instantaneous regulation. Thus, most control valves, which are just opening, will admit a large increment of steam for a given movement of the valve, while a valve which is nearly fully open will show a small increase in steam flow for a given movement of the valve. This is one of the reasons why as units approach full load, the instantaneous speed regulation is usually very high and these units participate very little in maintaining close frequency. The valve characteristics are sometimes changed by reshaping the ports, or by installing cams to control the movement of the valve.

Fig. 15 shows the instantaneous speed regulation plotted in relation to load for a turbine equipped with three overload valves. The instantaneous speed regulation is determined for each load point from the formula

$$\text{Instantaneous speed regulation in per cent} = \frac{C}{S \times \frac{\Delta \text{ kw}}{\Delta S}} \times 100$$

where C = turbine capacity
S = normal speed
$\frac{\Delta \text{ kw}}{\Delta S}$ = rate of change of load with speed

It is seen that the instantaneous speed regulation varies considerably over the load range and at full load is quite high. This turbine is equipped with cams on the primary admission valve, the secondary and tertiary admission valves, while the quaternary

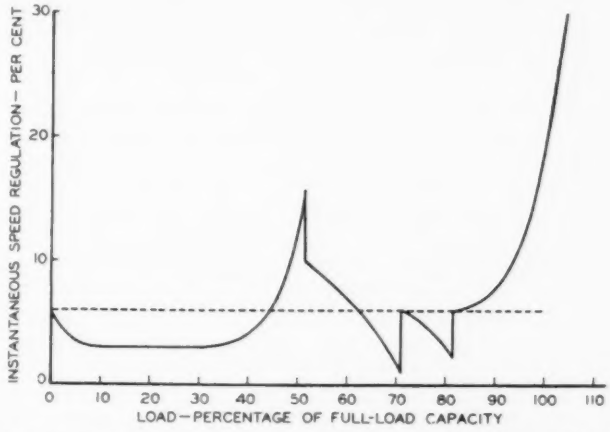

FIG. 15 GOVERNOR SPEED REGULATION; TURBINE EQUIPPED WITH FOUR ADMISSION VALVES

admission valve does not have a cam. On the valves equipped with cams, the instantaneous speed regulation is more uniform. Before the secondary valve has started to open at about 50 per cent load the instantaneous regulation is quite high and, if the machine is loaded at this point, there is less variation in load with a change in frequency. This may be desirable from an economy standpoint, as there is a sharp increase in the incremental heat rate of a turbine when the next admission valve is just opening. Any tendency to open the overload valve on load swings may result in loss of economy.

Combined-System Governor Response. The combined governor speed characteristic of the system results in a variation of 40,000 kw for a change in frequency of 0.1 cycle, which is about 2 per cent load variation for a change in frequency of $^1/_8$ per cent. This would correspond to a governor speed regulation of about 8 per cent. This regulation is obtained when the hydro units are on peak operation and their governors are assisting in the frequency regulation, although some of the governors on the steam-base-load units are more sluggish. When the flow on the Susquehanna River is at flood stage and the hydro units are operating wide-open with the governors against the stops, the speed variation on the system for a given load change is much greater, inasmuch as the governors are controlling speed on a smaller percentage of the generating capacity. This is especially apparent when the system load is a minimum and the hydro is maximum.

A governor with considerable inertia may become unstable and cause hunting if its speed regulation is made too small so that it tries to hold the speed within narrow limits, without sufficient dashpot action. It may also cause a swinging of the load at certain load points where the instantaneous regulation is too small. This hunting condition is usually self-evident in a steam-generating station where it occurs and may cause considerable trouble in the boiler plant. The operating forces in the steam-

generating station usually seek to correct such hunting in order to eliminate their trouble. Such hunting may be corrected by broader governor regulation and, from the system standpoint, it is better to eliminate such hunting even at the expense of broader regulation.

Effect of Governor Action on Tie-Line Loads. Where two large groups of systems are interconnected over a tie line, with a load change in one system, the governors on the other system will share in the load change in accordance with the variation in frequency and consequently cause a variation in the tie-line load. If the tie line is of relatively small capacity, the variation in tie-line load when superimposed on the normal tie-line load may cause the tie line to trip out due to overload or instability.

In some cases, the original variation in tie-line load caused by the governors may initiate a seesawing condition in attempting to correct manually the tie-line load. This additional variation may cause the tie lines to trip.

Effect of Governor Regulation on Economy. The regulating action of the governors on the base-load units would appear to result in an uneconomical allocation of system load if the frequency should change. For instance, if the frequency should increase, the most efficient base-load units in order to share in the frequency regulation would proportionately decrease in load, while theoretically for maximum economy the entire load drop should be taken by the marginal station. However, if all the units are sharing in the regulation, the change in frequency would be very small and the corresponding change in load on any station due to the governor operation would be very slight. Also, the more efficient units would in general be loaded nearer their maximum capacity and the control valves would be close to the fully open position where the governor regulation is much broader and the smaller change in load results from a given change in frequency. The frequency would then be restored to normal by repositioning the governors on the marginal station whose load should be changed in accordance with economic loading requirements. As the frequency is restored to normal, all the generating units with the exception of the marginal unit should return to their original loads before the load change occurs.

If an attempt is made to hold the frequency too close by regulating the frequency on a marginal steam station, all the load swings would be taken by the marginal station and would impose a heavy burden on the boiler plant of the station, with consequent loss in economy on the entire load carried by the station. If the marginal station is a hydro plant, the loss in economy would not be as great as on a steam plant.

Governor Load-Limiting Devices. Some governors on steam units are equipped with load-limiting devices which are used when the boiler capacity is less than the spinning-turbine capacity. Regardless of a decrease in frequency, the load-limiting device limits the loading on the turbine to any predetermined value corresponding to the setting of the load-limiting device. Should the outage of a boiler unit reduce the boiler capacity below the turbine capacity, the load-limiting device will prevent the possibility of water carry-over from the boilers to the turbine on a drop in frequency which would normally cause the governor to bring the turbine to full load.

Conclusions

1 The sensitivity of the governors should be increased as much as possible, in order to give smoother operation of the governors and provide a definite relationship between change in frequency and change in system load for small changes in load or generation.

2 The instantaneous speed regulation of the governors over the entire load range should be more uniform, in order to improve governor stability where the instantaneous regulation is lower and to limit the speed variation for a given change in load where the regulation is high. The instantaneous regulation, however, should be higher in percentage where sharp increases occur in the incremental heat rate of the turbine and at minimum loads on a plant where boiler-plant conditions may become unstable with extreme load changes.

3 The average speed regulation of the governors should be reduced as much as possible without, however, sacrificing stability of parallel operation. This measure should be applied generally throughout the systems of an interconnected group in order to limit the burden due to load variation on any particular station.

4 Where tie-line loads must be regulated, the regulation of frequency or tie-line loading is a mutual operation, requiring the cooperation of all system dispatchers. The regulation of the frequency must be performed with regard to the tie-line loading and the regulation of the tie-line loading must be performed with regard to the frequency.

5 Where interconnection tie lines require no regulation, frequency variations will indicate a change in system load and the interconnection dispatcher can allocate the load change on the basis of economical loading.

Discussion

Albion Davis.[5] Under the heading "Regulation of Frequency," the authors state: "A frequency curve appears to have several components: A rapid, periodic variation of approximately 0.005 cycle of an approximate period of 2 sec; variations of approximately 0.05 cycle having a semblance of a periodicity of 30 sec; variations of 0.1 cycle or more from standard frequency that are irregular in occurrence."

The variations of 0.05 cycle are referred to as a "system characteristic." It is stated that these variations are continuous and follow the trend of the frequency curve. The periodic variation of 0.05 cycle is ascribed "to the change in the fringe of the load curve, which marks the great diversification in the use of appliances, lighting, motors, etc., throughout the day." Such regulation is considered by the authors as inherent in the operation of a system or a group of systems, a self-regulating characteristic.

The writer believes that tests of the response of governors to these 0.05-cycle speed swings will disclose the fact that most of the governors are following these speed changes, picking up and dropping load on the swings, but not exactly in synchronism with the speed. It is believed that many governors will show a con-

[5] Chief Hydraulic Engineer, Union Electric Company of Missouri, St. Louis, Mo.

siderable time lag on the reversals of speed and, because of the time lag, will register considerable overtravel. Tests will probably show that the composite effect of overtravel of all governors is the underlying cause of the regular system hunting action, rather than the characteristics of the load.

It is for this reason the writer has urged that more systems get the necessary instruments to measure governor performance and find out, not only what individual governors are doing, but also what different governing combinations are doing to system speed.

R. W. McLaughlin.[6] An interesting point brought out in this paper is that in a typical large power system a $2^1/_2$ per cent load change will cause a 1 per cent frequency change if the governors do not function at all to counteract the change in speed. In other words, the system regulation with no governor action is equivalent to 40 per cent for 100 per cent load change. Of course, the term "regulation" as used here means the average regulation existing for a relatively small load change and, as used further in this discussion in order to make it possible to refer to regulation as being constant for any given machine, the fact that the regulation at various loads is considerably affected by valve design and valve-opening point is disregarded. Furthermore, in order greatly to simplify the discussion and assume a simple straight-line relationship between speed changes and load changes, we will not attempt to include the effect of lag caused by lack of sensitivity, which is in itself a variable for different loads on any given machine.

One of the most prevalent causes of complete lack of governor response to speed change of a few per cent is the increasing use of load-limiting devices. Under normal operating conditions, load limiters are set to allow the machines to carry a small margin of load above that which they are scheduled to carry, and governors are allowed to function normally. In case of a heavy rapid load increase on a system, it is possible that for varying time intervals the load limiters on several machines in a system may be holding the admission valves at a fixed position, preventing the governors from helping to control the frequency of the system. Thus, when a load-limiting device takes control away from a speed governor, the apparent regulation of the turbine immediately jumps to 40 per cent, based upon the load that the machine is carrying and, if the load limiter is set at 80 per cent of the capacity of the machine, the regulation referred to full capacity of the machine immediately becomes 50 per cent, as compared to a probable regulation of between 4 and 8 per cent when operating on the speed governor. Therefore, when a load limiter comes into effect, the apparent regulation of the machine immediately becomes so broad that it will have but slight influence on the frequency of the system, although a change in frequency will cause a slight change in load on the machine operating at its limit. The foregoing comments indicate that, although a load-limiting device may be of distinct advantage with respect to the operation of the boilers, it has an adverse effect upon the instantaneous regulation or frequency control of the system as a whole.

In order to calculate the average regulation for a power system with respect to gradual changes in load, assuming that the capacity and regulation of each machine serving the system are known, the following simple equation is useful

$$\text{Average regulation} = \frac{A + B + C + \ldots.}{\frac{A}{R_a} + \frac{B}{R_b} + \frac{C}{R_c} + \ldots.}$$

in which A, B, C, etc., are the rated capacities of the machines in operation, while R_a is the regulation for the turbine of capacity A, R_b is the regulation for the turbine of capacity B, etc. It may be noted that the denominator is equal to the total load change equivalent to 1 per cent speed change, while the numerator is the total rated capacity of the machines in service, and not the total load being generated. While the actual regulation at any given load varies somewhat from the average, the variation in regulation for different valve openings on modern multivalve machines is not of sufficient magnitude to be of particular importance.

Although some progress has been made in an attempt to minimize the importance of good speed regulation by the use of automatic frequency-controlling equipment, the continued importance of regulation is manifest by recent discussions between representatives of power companies and turbine manufacturers regarding the advisability of building governors with an arrangement whereby the regulation can be adjusted between certain specified limits while the machine is carrying load. While many of these devices have been built, the value of such a device depends upon whether the station operators are able to use it to its best advantage. It appears that the principal advantage of having variable regulation control is that the operators can vary the regulation of any machine in operation until they find the regulation which apparently gives the best average result. Thereafter, it is doubtful whether the bother of making frequent adjustments to this device will be justified by any real improvement in operation.

F. Oppenheimer.[7] At recent technical meetings, there has been frequent reference to designing and operating governors with speed droops at or near zero. This is, no doubt, due to a recognition of the fact that existing governors are on the whole operating at such high speed droops that poor frequency regulation results, which in turn adds to the difficulty of load and tie-line control.

The writer has pointed out the practicability of reducing immediately the general level of speed droop on a system step by step, unit by unit, a method which minimizes the risk of instability and mechanical difficulties. Power systems would thus take advantage of available, if limited, characteristics of existing governors without waiting for the possible remodeling which might be feasible, or waiting until older machines have been retired and replaced by modern governors, such as have been described. From certain tests made (for another purpose) on the interconnected system described by the authors, the writer has figured that for the whole interconnected system the speed droop is about 11.5 per cent (excluding hydro plants). This figure was obtained as follows. The total capacity of the interconnected system was 2,400,000 kw; Conowingo decreased its output 200,000 kw which caused the system frequency to decrease 0.53 cycle. The Holtwood governors picked up 13,000 kw on 61,000 kw capacity, Safe Harbor 30,000 kw on 96,000 kw capacity. Taking these three plants out of the computation gives

$$\frac{2{,}043{,}000}{157{,}000} \times \frac{0.53}{60.00} \times 100 = 11.48 \text{ per cent}$$

This is radically different from the speed droop attained by the governor described by Dr. White or the system described by Mr. Holden which dealt with droops of 0.02 per cent and about 0.5 per cent, respectively. It is obvious that the desire of steam engineers for large speed droop has been attained and with advantages in the way of steam economy and ease of operation of the steam plant. However, it is hardly necessary to point out that if the speed droop of all the units on a system is reduced proportionally, the load swings will divide as before but there will

[6] Turbine Engineering Department, Elliott Company, Jeannette, Pa.

[7] Pennsylvania Water & Power Company, Baltimore, Md.

be an improvement in system frequency. Also the frequency change of 0.1 cycle for each change in generation of 10,000 kw described in this paper will become proportionally less, and probably so small that an operator could make changes of 10,000 kw in generation with almost inappreciable effect on the frequency. This means he could correct tie-line loading without having to be concerned with its effect on frequency (except for large changes). This would be a great step forward in the operation of interconnected systems.

W. E. PHILLIPS.[8] Increasing the governor sensitivity, as stated in the paper, and decreasing the governor droop as brought out in the discussion, will undoubtedly improve the system frequency. This is a much desired objective. However, when all stations in an interconnected group are responding directly to frequency, it will cause greater swings in the interconnecting tie lines.

If we assume that the load comes on in the area of only one of the interconnecting companies, all stations will respond since there will be a drop in frequency. When the company in whose area the load comes on adjusts its generation to meet this new demand, it will be necessary for the other interconnecting companies to change their generation back to the value which existed before the change.

One generally accepted method of regulating an interconnection is to assign the control of the frequency to a centrally located company and to let the other interconnecting companies hold the tie lines toward the frequency-controlling station. If it were possible to make instantaneous changes in generation so that the tie line could be held absolutely constant, then the problem of the frequency-controlling station would be relatively simple, since generation changes would be required by it only to take care of load changes in its area. In actual practice, generation changes cannot be made instantaneously, consequently the tie lines swing and the load changes in the other areas are reflected in the frequency, the frequency-controlling or master station responding to them. This puts an added burden on the frequency-controlling station.

If, when the frequency deviates, all the interconnecting tie lines are made to deviate a small amount in a direction to help the frequency, then the burden of the master station is much less and the frequency is improved, since all stations are helping to control it. As the frequency returns to normal, all tie lines return to their normal scheduled load. The amount which any tie line deviates is definitely fixed for any given frequency deviation.

It may appear that the contribution made to frequency is essentially the same as that made when the governor sensitivity and droop are adjusted as indicated previously. However, the essential difference is that the amount contributed is not dependent upon where the units are operating on the speed-droop curve, Fig. 15 of the paper, or upon possible variations in governor sensitivity. The amount of contribution is definitely under control of the dispatcher. Thus the contributions of the interconnecting companies can be readily coordinated.

AUTHORS' CLOSURE

It is possible, in some cases, that the overtravel of governors may be responsible for a system hunting action that causes speed changes. However, a large number of tests that were made on the interconnected group of systems, of which the Philadelphia Electric Company is one, has indicated that governors frequently fail to respond to speed changes of as much as one-tenth cycle. It is apparent where the governor response is absent, that the speed changes are a result of changes in load.

[8] Engineering Department, Leeds & Northrup Company, Philadelphia, Pa.

Where these load changes are greater, and on the Philadelphia Electric system load swings of 50,000 kw are relatively frequent, governor response is more consistent. If there were overtravel of the governors in such cases the frequency would be extremely erratic, which is not the case.

Furthermore, the self-regulating characteristic of the systems, evidenced frequently for periods of several hours at a time, is difficult to reconcile with erratic governor action.

The following mathematical calculation indicates that the variations in frequency of approximately 0.05 cycle are due to changes in load demand. Let Δl = small instantaneous decrease in load demand; f_o = normal system frequency; f = system frequency at any instant; and L_o = system load. Then, the stored kinetic energy in system = Wf^2, where W is a constant.

Fig. 8 of the paper shows that for small sustained changes in load the frequency varies $^1/_6$ per cent for a load change of approximately 0.4 per cent. This indicates that the change in load demand in per cent is a little over twice the per cent change in frequency. The change in load demand due to frequency change $= 2L_o(f - f_o)/f_o$ approximately.

The small instantaneous decrease in load demand Δl results in an excess power input which is available for accelerating the system until the frequency changes sufficiently to absorb the excess power input. At any instant, Δl equals instantaneous power input for accelerating the system plus the increase in load demand due to increase in frequency. That is

$$\Delta l = \frac{d}{dt}(Wf^2) + 2L_o\frac{(f - f_o)}{f_o} \quad [1]$$

$$= 2Wf\frac{df}{dt} + \frac{2L_o(f - f_o)}{f_o} \quad [2]$$

For small changes in frequency f_o may be substituted for f in $2Wf(df/dt)$, or approximately

$$\Delta l = 2Wf_o\frac{df}{dt} + \frac{2L_o(f - f_o)}{f_o} \quad [3]$$

and

$$\frac{1}{2}\frac{\Delta l}{L_o}f_o = \left(\frac{Wf_o^2}{L_o}\frac{df}{dt}\right) + f - f_o \quad [4]$$

The solution for this differential equation is

$$(f - f_o) = \frac{1}{2}\frac{\Delta l}{L_o}f_o(1 - e^{-t/T}) \quad [5]$$

where $T = Wf_o^2/L_o$ kwsec per kw; T is the time constant in this equation and is equal to the stored kinetic energy in the system at normal frequency (Wf_o^2) per kilowatt of load. The approximate value of T for our system is 7 kwsec per kw, or 7 sec. In accordance with Equation [5], the change in frequency reaches about 63 per cent of the final sustained change in 7 sec. Portions of the curve in Fig. 10 of the paper have been reproduced on a large scale in Fig. 16. Section A refers to the last few seconds of the first-minute period, section B to the portion of the curve at 1½ min, and section C to 3½ min.

The exponential curve, Equation [5], was fitted to each portion of the system-frequency curve by measuring the frequency change at an interval of 7 sec after the beginning of the change. This increment is approximately 63 per cent of the total frequency change due to changed load demand. For example, considering section A, the values in Table 1 were obtained.

In this case the agreement was good during the first 8 sec of the change showing that the change was due to the inherent characteristics of the system rather than governor overtravel. The other two sections reproduced also show good agreement.

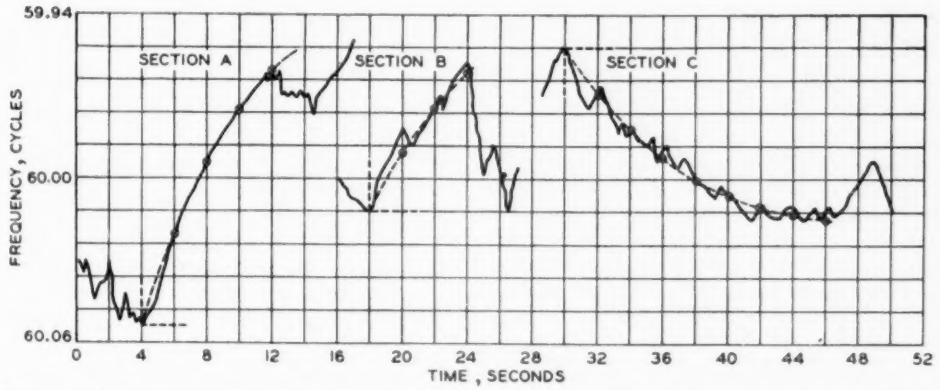

FIG. 16 HIGH-SPEED FREQUENCY CHART OBTAINED ON THE PHILADELPHIA ELECTRIC COMPANY'S SYSTEM

R. W. McLaughlin refers to the statements regarding the speed characteristic of the interconnected group of systems, of which the Philadelphia Electric Company is one. This characteristic is also evidenced in those instances of system trouble where there is a considerable deficit of generating capacity with respect to the normal system load.

Regarding the assertion that the paper has disregarded the fact that the regulation at various loads is affected considerably by valve design and valve-opening points, such effect was considered at some length in the body of the paper, and in the conclusions. In addition, Fig. 15 shows the variations in the instantaneous speed regulation throughout the load range of the unit.

TABLE 1 VALUES OBTAINED BY FITTING THE EXPONENTIAL CURVE TO SECTION *A* OF THE SYSTEM-FREQUENCY CURVE SHOWN IN FIG. 16

t, sec	$1 - e^{-t/T}$
2	0.243
4	0.436
6	0.577
8	0.680
10	0.760
12	0.821
14	0.865
16	0.899

$T = 7$ kwsec per kw

At 4 sec frequency, cycles..... = 60.054
At 11 sec frequency, cycles..... = 59.968
Frequency change, cycles..... = 0.086

Sustained change $= \frac{0.086}{0.63} = 0.136$

Points on the exponential curve:
At 2 sec, frequency change $= 0.136 \times 0.243 = 0.033$
At 4 sec frequency change $= 0.136 \times 0.436 = 0.059$

With regard to Mr. McLaughlin's comments on load-limiting devices, these devices in our system have been necessary to protect the boilers and also the turbines being supplied from these boilers in the event of a large change in frequency where the governor would normally cause the turbine to be loaded to its maximum capacity, which would be in excess of the available boiler capacity. However, where these devices are used as a stop on the maximum load which the turbine can carry, if the turbine is normally loaded at some point below this maximum load the governor should function in a normal manner for small changes in frequency, and it is only as a result of large decreases in frequency that the device becomes effective in limiting the load of the turbine.

In Fig. 8 it is shown that for small changes in frequency up to approximately one tenth of a cycle the per cent load change is two and one-half times the resultant per cent frequency change. Fig. 8 also shows that for load changes in excess of 10 mw, the frequency changes at a much slower rate, showing that the governors were responding when the apparent threshold of sensitivity of one-tenth cycle was exceeded. The fact that the governors respond for speed changes in excess of one-tenth cycle would indicate that load-limiting devices were not affecting the regulation.

Referring to W. E. Phillips' discussion, it may be said that whether governor sensitivity is increased proportionately throughout the interconnected group or remains as at present, the tie-line loading changes as a result of governor response should remain approximately the same.

Load changes occur in all load areas. Assuming a load change in one area, however, as this company makes the necessary change in generation, increased governor sensitivity will tend to more consistent automatic correction of the loading of the units of other companies.

Where the principles of interconnection operation as exemplified in the operation of such groups as that of the Pennsylvania-New Jersey interconnection are followed, tie-line loading, where the tie capacity is adequate, presents no problem.

Experiences in System Speed Regulation

By OTTO HOLDEN,[1] TORONTO, ONTARIO, CANADA

This paper describes operating conditions on four widely varying power systems. In one case, the means, adopted to reduce the wide variation in frequency of a small system serving two mines only, is discussed. The problems encountered in larger systems serving mines, paper mills, grain elevators, and municipal requirements are dealt with, concluding with the largest of the four, a system developing 1,400,000 hp at peak load, fed from nine generating stations. One plant of the system is assigned to regulate speed, the others conforming under instructions from a load supervisor. Automatic frequency-regulating devices are applied to some units at one plant, manual control being necessary at all others.

ILLUSTRATIONS of normal operating experience with regard to speed regulation in several of the systems of the Hydro-Electric Power Commission of Ontario, in which the results obtained vary greatly, are submitted in this paper. It is not intended to include details of the various phenomena or to offer any solution for the problems raised, but they are submitted in the hope that the description of the conditions prevailing may prove of interest. The paper considers only speed regulation as indicated by system frequency as this is affected by speed-controlling devices, inertia of rotating elements, and magnitude, diversity, and variation of loads. It does not deal with stability of the system, that is to say, its behavior under transient abnormal electrical conditions such, for example, as would be caused by short circuits.

The systems on which the regulation conditions are described are of various sizes and characteristics, ranging from one of small size, with one generating station supplying two customers, to one having a load of approximately 1,400,000 hp, supplied by nine or more generating stations with upward of 1500 miles of 110 to 220-kv transmission lines.

In each case, the type of load carried by the system, the relative magnitude of the sudden load changes, the generating and governing equipment, and various other factors, all have their effect on departure of system speed from its normal value. Comments on some of these factors will be found in the text. Sections of load and frequency charts reproduced supplement these comments.

The St. Joseph District

The St. Joseph District, the smallest of the systems considered, consists of a generating station with two units installed. The head is normally 16 ft, and one unit consists of a four-runner horizontal open-flume turbine, with a capacity of 1380 hp, connected to a generator rated at 2000 kva at 164 rpm and 6600 v. The other unit is a single-runner vertical propeller-type turbine of 1750 hp capacity, directly connected to a 1500-kva generator operating at 128.5 rpm and 2300 v.

A composite regulating constant for the plant, derived by adding together the product of WR^2 and square of the speed for each unit and dividing by the sum of their horsepower ratings, is 8,860,000. These units feed through banks of 6600/22,000- and 2300/22,000-v transformers to a 28-mile transmission line. The power supplies two gold-mining properties, after being stepped down at the local stations to 550 v.

Each of the mines has relatively large air-compressor and hoisting capacity. It is the operation of this particular equipment which gives rise to the large changes in load, with consequent wide variations in power characteristics. As both of these customers have been constantly increasing their production, the plant is at all times loaded to, or near, its maximum generating capacity.

When a relatively large increase in load occurs, due perhaps to the synchronizing of compressor operation and the starting of a hoist, the increased demand often exceeds the capacity of the plant. The speed of the unit is then reduced below normal, with consequent lowering of frequency, and a considerable period may ensue before normal speed is restored. Smaller changes in demand of, say, 25 per cent of the capacity of the plant are constantly occurring. The resultant frequency varies over a considerable range. The load and frequency charts shown in Fig. 1 indicate the conditions which obtain.

It is recognized that such regulation would not be suitable for other service but, owing to the fact that all the supply is used for mining operations, the conditions existing are more desired by the power customers than improvement at the cost of reduction in demand, with consequent lessening of production, since the operation of a high-speed automatic voltage regulator maintains voltage level within satisfactory limits.

Characteristics of motors used in mining practice and methods of reducing the load swings have been investigated. Discussion of these factors with manufacturers and operators has led to the readjustment of the time delays on the contactors controlling the motors, with some improvement in speed variation. On new motors being installed in the system, greater attention is being paid to the proper setting of the time delays in some instances and, in one case, a motor generator set with flywheel is being installed in conjunction with d-c motors on the mine hoists.

Load Conditions in the Abitibi District

In contrast to the foregoing are the conditions obtaining in the Abitibi District, a larger system, which also supplies, in the main, mining load. In this instance the generating station contains five units, the turbines being rated at 66,000 hp each, operating at 150 rpm under 237 ft head, and the regulating constant is 9,000,000. The turbines are supplied through 18-ft penstocks 262 ft long. The present 20-min peak load carried by the plant is approximately 135,000 kw, most of which, with the exception of some 30,000 kw used for steam generation, is mining load.

Transmission is at a normal potential of 110 kv. One large load of approximately 35,000 kw is located 250 miles from the generating station. Many loads of 2000 to 10,000 kw are connected. While the main load is derived from the operation of mines, a number of other important industries are also served. The ample generating capacity available, as well as the diversity in demand resulting from the large number of customers, particularly the large number of mines, results in power characteristics of the first order, which satisfactorily meet all requirements of service.

One of the turbine governors is adjusted to have zero speed droop, and the others a droop of 0.6 per cent. Stable operation

---

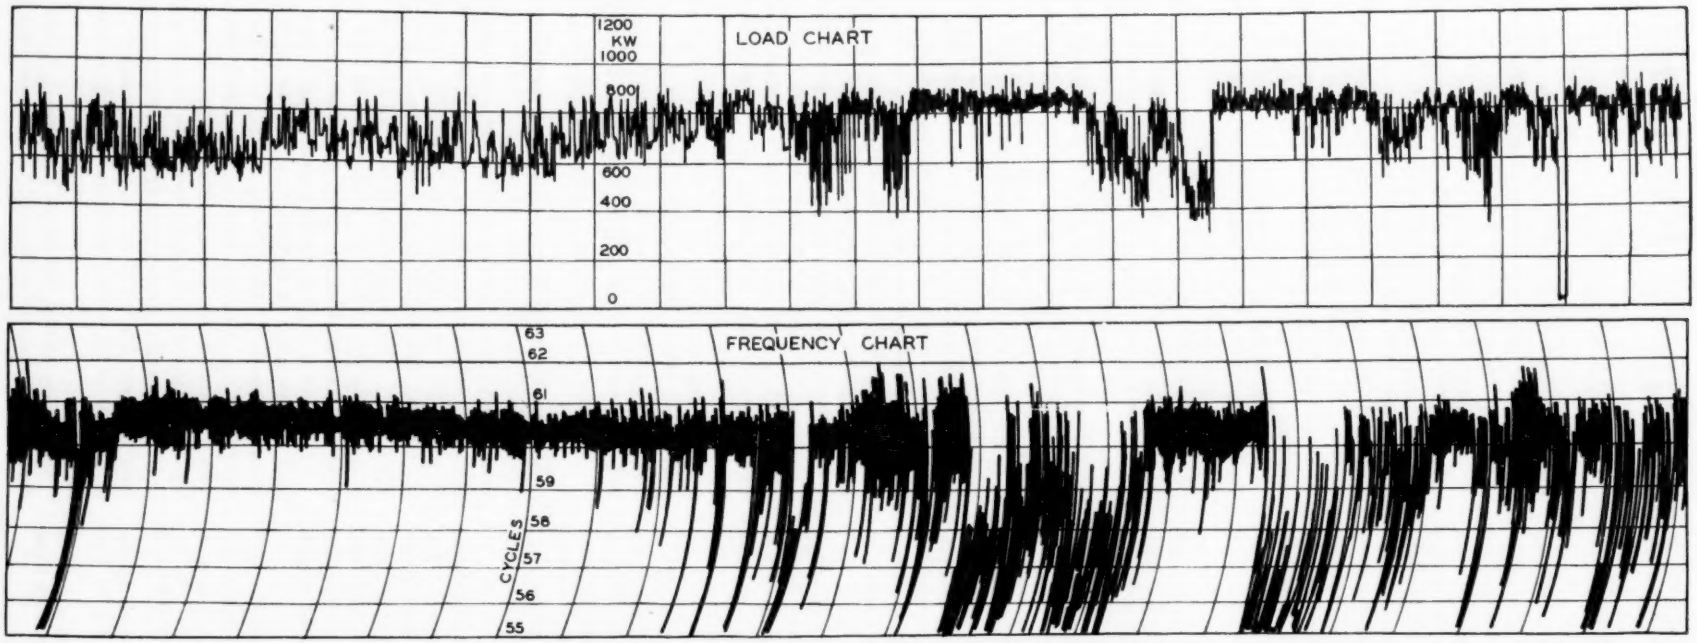

FIG. 1 TYPICAL LOAD AND FREQUENCY CHARTS; ST. JOSEPH DISTRICT

(The system load was approximately 2000 kw, all of which is for mining operations of two customers. Of this total a steady load of 1200 kw was being carried on unit No. 2, for which no graphic chart is shown. The average load on unit No. 1 was approximately 800 kw, variations from this being shown on the chart. Exceptionally violent fluctuations of frequency occur.)

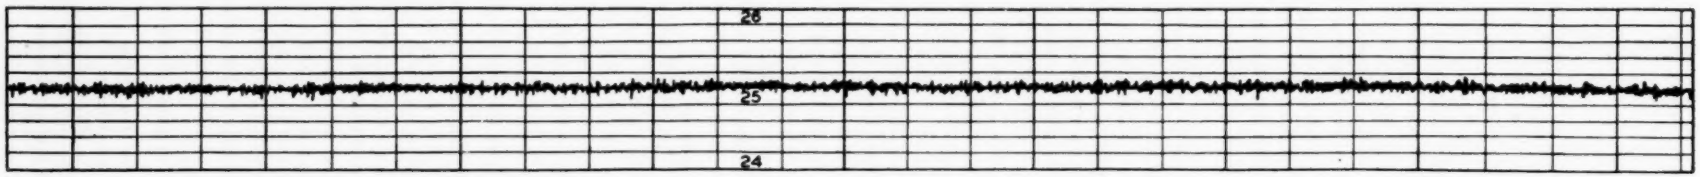

FIG. 2 TYPICAL FREQUENCY CHART; ABITIBI DISTRICT

(Power is supplied in this system to a large number of mines and other industries. The bulk of the load is mining load. The load for the selected hours was 90,000 to 100,000 kw.)

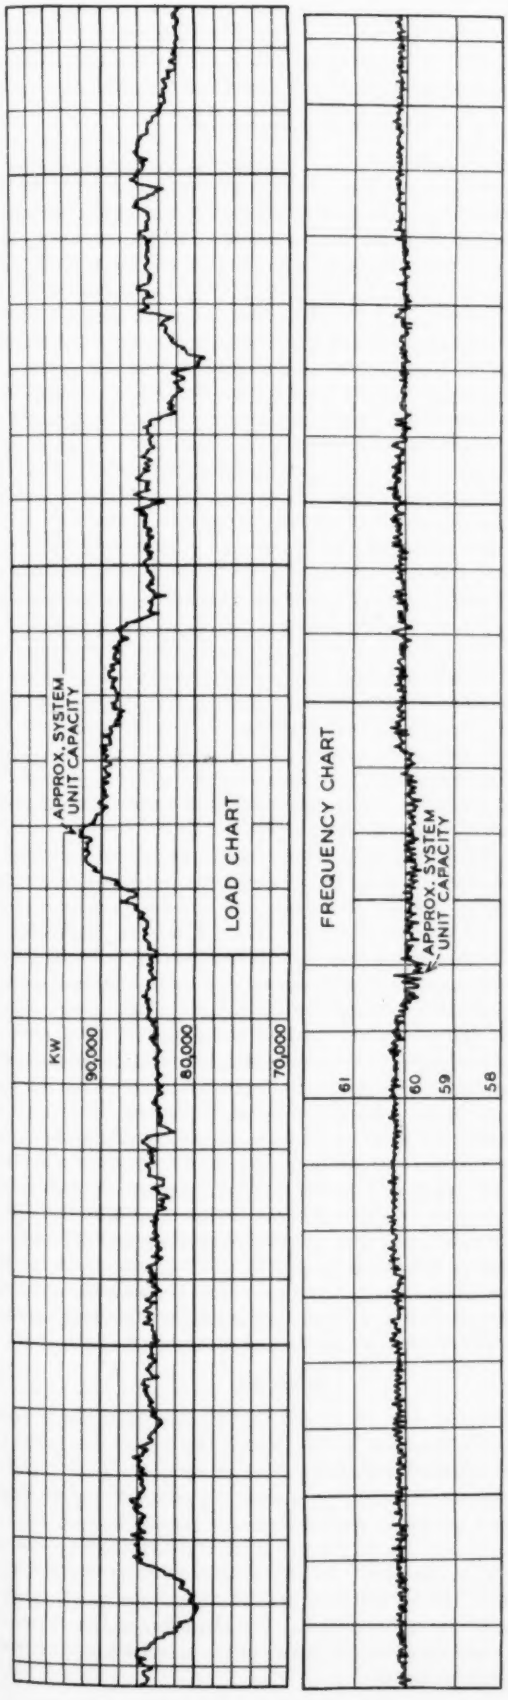

FIG. 3 TYPICAL LOAD AND FREQUENCY CHARTS; NIPIGON SYSTEM

(System load here is 80,000 to 90,000 kw, service being given to pulp and paper mills, grain elevators, municipalities, and mines.)

and satisfactory distribution of load among units are obtained with this arrangement. An examination of the frequency chart Fig. 2 indicates very little drift from normal frequency, although the momentary variations are quite similar in percentage to those in the following cases described.

CLOSE SPEED REGULATION NECESSARY ON NIPIGON SYSTEM

The Nipigon System provides an example where close speed regulation is necessary, but where difficulties in solution are introduced by the nature of certain of the loads.

Power supply for this system is secured from two plants on the Nipigon River. The first of these, at Cameron Falls, contains six units, each with a rating of 12,500 hp at 120 rpm under a head of 72 ft. The other plant, about 1 mile downstream, known as the Alexander Power Development, contains three units with a rating of 18,000 hp at 100 rpm, under a head of 60 ft. Composite regulating constant derived for nine units is 8,500,000.

The system peak has frequently exceeded the nominal rating of the power plants. The bulk of the power is transmitted at 110 kv to the cities of Fort William and Port Arthur, approximately 80 miles distant. Here, in addition to municipal and small industrial loads, there are several newsprint mills requiring, for satisfactory operation, speed regulation of a high order. At this point also are located the terminal grain elevators through which much of the grain grown in western Canada passes. In addition, at times a considerable block of power is used for steam generation, and the sudden fluctuation in this demand imposes additional duty on the regulating equipment. Transmission lines also reach out 90 miles northeasterly from the power plants to important mining districts east of Lake Nipigon and near Long Lake, where twelve or more mines use from 250 to 2500 hp each. Here, the effect of rapid changes in demand, which characterize mining loads, are offset somewhat by the number of separate customers and the relation that the size of the individual load bears to the total system load. In many instances the system load approaches within a few per cent the maximum capacity of the generating units. Under these conditions system speed is maintained within very narrow limits. Typical load and frequency charts are shown in Fig. 3.

NIAGARA SYSTEM REQUIREMENTS

Turning now to the largest system operated by the commission, the requirements to be met are of quite a different order; results are commensurate with these requirements. The Commission's Niagara System supplies power to the most populous part of Ontario, extending from Niagara Falls and Toronto on the east, to Windsor, Sarnia, and Goderich on the west, including 180 municipalities, 87 rural power districts, and a number of large industries supplied directly by the commission. The system extends beyond the easterly limits named, however, as a portion of its power supply is drawn from a power plant at Chats Falls on the Ottawa River, 200 miles east of Toronto, and from five others in the Province of Quebec, one of which is over 120 miles beyond Chats Falls.

Three power plants at Niagara Falls, having a combined capacity of 830,000 hp in 36 units, varying from 11,700 to 58,000 hp, supply the major part of the power for the system. The peak load in 1938 was approximately 1,400,000 hp, portions of which, however, are segregated from each other. The following comments apply to one portion of the system tied together electrically and having a peak load of about 800,000 hp. No value of the regulating constant is given for this condition, as power in large amounts enters the system from several power plants in the Province of Quebec, with varying numbers of units on this supply.

In such a system there are, of course, many industrial plants where very close speed regulation is essential and, because of

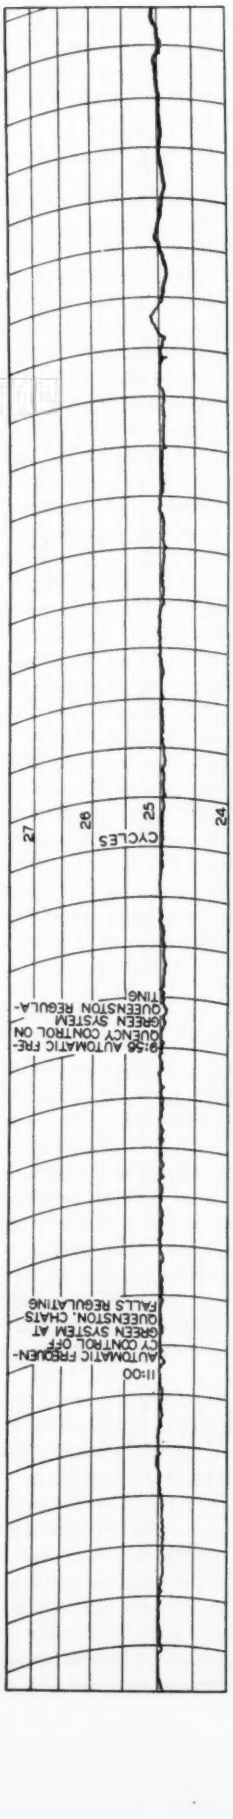

FIG. 4 TYPICAL FREQUENCY CHART; NIAGARA SYSTEM

(The load for which this frequency chart applies amounts to 500,000 to 600,000 kw, the power being distributed over a large area to many municipalities and industries. For the period from ten to eleven o'clock, automatic frequency regulation was in use.)

the size of the connected load and the diversity in demand, the requirements in this regard are readily met.

The system is of such size that variations in individual loads are of scarcely any moment. Even the sudden loss of the generating capacity of one of the large units, through some fault in the unit itself, would scarcely be noticeable throughout the system. The enormous amount of kinetic energy in the remaining units would prevent any material change in speed for the few seconds while other units were increasing their outputs to compensate for the capacity lost in the unit which had dropped out of service.

The problem in this case is one of sensitive and accurate governing to maintain at all times the normal frequency of the system. It has been the practice to assign speed regulation to one plant, other plants in the system increasing or decreasing their output in response to orders from the load supervisor located in a central office. Adjustment for minor variations in system load are automatically carried out by the governing equipment in the plant which at that time is responsible for speed regulation. The operators in this plant are required to give constant attention to the maintenance of correct frequency.

To improve the speed regulation further, devices to provide automatic frequency regulation have been applied to certain of the governors in the Queenston plant on the Niagara River. This equipment was built by the commission and is still in a state of development. A definite improvement has resulted from its use in the reduction of minor departures from the correct frequency, which otherwise would be unnoticed by the operator until the error had accumulated sufficiently to give an indication by comparison with whatever device is used to show constant frequency. It is significant that more nearly perfect uniformity of speed was experienced in operation of the coelostat controlling the telescope at the David Dunlop Observatory, north of Toronto, whenever automatic frequency control at Queenston replaced the manual control at other plants.

LOAD DISTRIBUTION

Procedure in distributing load among the plants supplying power to the system may be of interest at this point. As previously stated, power enters the system at the eastern boundary of the Province from five power plants in the Province of Quebec and from the Chats Falls plant on the Ottawa River. It is transmitted thence more than 200 miles at 220 kv to the Leaside Transformer Station at Toronto. Connection is made here to the 110-kv system extending outward from generating stations at Niagara Falls. There is no distribution of energy from the system between the eastern power sources and the Leaside Transformer Station. Apportionment of load among plants is determined by the load supervisor at Niagara Falls, who assigns to each plant the load that is to be carried at standard frequency, the amount carried by each plant being varied from time to time to suit the system-load curve, and various other circumstances.

In the portion of the system under consideration, two or three units at the Queenston plant may be in use, these usually being equipped with automatic frequency control. Operators at the eastern plants pick up the load assigned to their plant on instructions from the load supervisor, the load governors being set for the desired load at standard frequency. As normal variations in load in accordance with the daily load curve take place, all variations in output will take place on the regulated units at the Queenston plant connected in the system. As their maximum or minimum capacity is approached, as the case may be, suitable blocks of power are picked up or dropped by the eastern plants on instructions from the load supervisor.

Temporary disturbance in the system may cause the frequency to depart from normal. In such case, the load carried on each of the eastern plants may depart from that assigned by the load supervisor, but the operators at these plants are instructed to make no correction for changes in load caused by such temporary frequency departures. Restoration of system frequency will of course be made after the disturbance, but this is done by adjustments at the one plant then responsible for speed control. Usually, restoration of frequency redistributes the loads on the eastern plants to the amounts originally assigned by the load supervisor without action on the part of the local operators.

If disturbances in the system are of considerable moment, automatic frequency-regulating devices are disconnected automatically, and restoration of normal frequency accomplished manually.

At times, speed regulation is assigned to the Chats Falls plant on the Ottawa River, in which case manual control of frequency is necessary. The loads carried by other plants, including the Queenston plant, are in accordance with the assignments of the load supervisor. Fig. 4 shows that automatic frequency control is in use part of the time and manual control part of the time.

SUMMARY

The chart for the St. Joseph District illustrates a case where variations in frequency go far beyond the permissible limits for what is ordinarily known as satisfactory service. It accomplishes what is desired, however—it enables the mines served to obtain as great an output as possible from the available equipment.

The frequency charts for the other three systems provide an interesting comparison. In all cases satisfactory regulation is maintained, but certain peculiarities indigenous to the system are apparent in each instance. The character of the variations from constant speed are indicative of the peculiarities of the various controlling factors.

Two Years' Experience With High-Temperature High-Pressure Stations

The present review of operating experience with four typical high-temperature, high-pressure power-generating installations, among those originally presented in the "Power Panel Discussion" of December, 1937, deals principally with problems which have developed and means adopted for their correction. Great improvement in design has been accomplished and availability of both turbogenerator units and steam-generating units has increased materially. While in detail operating experience has varied largely, because of the variety of equipment involved, the composite picture presented of advance in the field of power generation, will serve admirably as a guide to designers of future equipment and to operators whose difficulties may have paralleled those contained in this joint discussion.

High-Temperature High-Pressure Superimposed Installations at Waterside Station[1]

By J. C. FALKNER,[2] NEW YORK, N. Y.

THERE have been very few changes in operating procedures at the Waterside Station since the installation of the high-pressure units two years ago. Such changes as have occurred have dealt mainly with the method of make-up, the method of watching water levels, chemical feed, sampling of boiler water, and the taking of steam samples.

Method of Operation Without Low-Pressure Boiler

It has not been possible, due to load conditions, to operate without some low-pressure boilers in service. A test of short duration with the high-pressure and low-pressure turbine units, running without low-pressure boilers, was made to check the operation of the back pressure regulator on No. 4 turbine and to familiarize the operating personnel with the difficulties to be expected when excessive swings occur. The tests proved very satisfactory. Loads were varied on both high- and low-pressure units without difficulty. An operating procedure has been worked out so that, as soon as conditions permit all low-pressure boilers will be shut down.

The distribution of load between the high- and low-pressure units will be made by the switchboard operators. In case of loss of low-pressure load, the back pressure regulator will automatically reduce the load on the high-pressure units but, in case load is lost on a high-pressure unit resulting in a reduction of low-pressure steam, the operator will reduce low-pressure load to a point where the low-pressure steam is normal.

High-Pressure Turbogenerator Units

Blade Troubles, Fouling Sources, and Cleaning Methods. Turbine generator No. 4, a 50,000-kw Westinghouse unit, was removed from service shortly after it was placed in operation September 10, 1937, in order to permit that company to remove the two rows of impulse blades. There were a few cracks in the shroud on the first row of impulse blades but in neither row were there any blade failures. These blades were removed on the advice of the company which had had trouble with other machines of similar design. With these blades out this machine operated without difficulty, except for a few shutdowns for inspection of the governor and bearings, until February, 1939.

On February 10, the turbine was taken out of service to examine bearings. Upon examination it was found that the bearing in the head end of the high-pressure turbine and the bearing near the flexible coupling between the main and feed-heating turbines showed cracking which necessitated their being rebabbitted at the Westinghouse Company's shop. When these bearings were replaced, the original shim positions were slightly changed.

In March, 1939, the unit was opened due to a rub being heard while the machine was being taken off the line. It was found that the coupling on the main-turbine side of the stub shaft between the main and feed-heating turbines had broken. The collar of the thrust bearing for the main unit is located on this stub shaft. The breaking of the coupling made the thrust bearing ineffective for the main unit and the spindle moved so that the high-pressure dummies rubbed and seized. One broken blade was found in the tenth stage and three pieces of shroud bands were found missing in the same row. The fact that the rotating parts of the high-pressure seal were integral with the spindle necessitated a complete new spindle for this unit. There is a difference of opinion as to the cause of the breaking of the coupling and as to whether the coupling broke before the rub appeared in the high-pressure dummies. The author is of the opinion that the coupling broke first, as there had been a slight change in alignment when the rebabbitted bearings were installed.

The new spindle with new blades, new dummies, and a new design of stub shaft coupling was installed in June, 1939, and the machine has run very satisfactorily since this change with the one exception of the governor which still has a hunting characteristic. This fact has necessitated the use of the load-limiting governor which has worked satisfactorily to date.

Until January, 1939, there was practically no evidence of blade fouling on either of the two high-pressure turbines.

Beginning in January, 1939, there was a capacity loss on the General Electric No. 5 turbine from 42,000 to 36,000 kw, taking place gradually over a 3-month period. The turbine was then taken off the line and allowed to cool for 12 hr, after which it was washed out with low-pressure steam from one of the boilers, without any water being admitted for desuperheating. This method of cleaning did not prove effective and on March 20 the machine was again taken out after provisions had been made to admit water with the steam. The washing lasted for a period of from 6 to 8 hr with a steam pressure of 15 to 20 lb per sq in., which was sufficient to turn the turbine. The steam temperature was 215 to 220 F. This method of cleaning proved satisfactory and the load on the turbine was increased to 42,000 kw. Ten days later the turbine again showed signs of fouling and it was again necessary to wash the turbine on June 10. After the third washing, the load was again brought back to 42,000 kw from 38,000 to which it had dropped.

[1] An Addendum to this paper appears on page 258 of this issue.

[2] Manager Production, Consolidated Edison Company of New York, Inc. Mem. A.S.M.E.

Contributed by the Power Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

No. 4 Westinghouse unit showed no sign of fouling when it was opened in March. It was first thought that the fouling of No. 5 General Electric unit was caused by the eliminator screens in the 5A and 5B boilers being plugged, thus allowing the solids to go out with the steam. Checks showed that the carry-over was less than 0.3 ppm which was as low as could be measured. A different method of blowing down the boilers has practically eliminated the fouling which proved that it is necessary to wash out lower waterwall headers and mud drums, while the boiler is off the line at intervals of not over two weeks.

Vibration Problems. On No. 4 unit there was a double frequency vibration on the generator end which was caused by the two-pole field of the generator. This trouble was eliminated when the machine went back into service as the field has been provided with slots to compensate for the lack of pull on the sides 90 deg from the field coils. No vibration has been experienced on either of the high-pressure turbines.

Protection Against Overheating With Loss of Load. There is a by-pass connection around the throttle valve of No. 4 unit which will pass a quantity of steam sufficient to keep the blades partially cool in case the throttle valve is closed and the generator is on the line operating as a motor. A steam gage in the high-tension control room gives indication to the switchboard operator of loss of steam at the boilers and, in case a throttle valve trips and the load starts down on the unit, the operator will trip out the generator in either case when the load has dropped to 2000 kw thus protecting the turbine rotor against overheating.

Consumption of Hydrogen. The Westinghouse unit uses an average of 10[3] cu ft of hydrogen per day, and the General Electric unit uses an average of 30 cu ft. There has been no trouble due to the use of hydrogen in either machine. The hydrogen was not used in the Westinghouse generator until July, 1939. A load of 45,000 kw at 0.9 power factor could be carried on this generator using air as a cooling medium.

Methods of Starting and Stopping High-Pressure Units. Both high-pressure units are started up integrally with the boilers; that is, as soon as there is a pressure of 200 lb in one of the boilers, the turbine is gradually brought up to 200 rpm, where it is held for approximately 1 hr. The exhaust from the turbine is used in the station auxiliary steam line at 5 lb back pressure. The pressure is then brought up and, when it reaches 600 lb, the exhaust steam is cut into the 200-lb header. From this point, 1 hr is allowed to bring the machine up to full speed.

In stopping the unit, no special precautions are taken other than those used on any low-pressure unit, with the exception, however, that the machine is kept on the turning gear for a period of time varying from 24 to 48 hr when stopping the Westinghouse machine and 24 hr for the General Electric machine.

Rise in Exhaust Temperature During Shutdown. There is a rise in the exhaust-casing temperature immediately after shutdown up to 670 F. This temperature has caused no trouble to date.

High-Pressure Boilers

Both sets of boilers for Nos. 4 and 5A units have operated successfully at 1300 lb and 450,000 lb of steam output, but to date it has not been possible to operate at the rated load of 500,000 lb per hr, without dissociation of water due to hot tubes in the top boiler-header sections or excessive carry-over.

Changes in baffle and washer designs in the drums have been made and it is expected that in a short time the guaranteed output will be obtained.

Trouble with refractory at the burner has been experienced and new carborundum blocks and refractory are now being tried out.

No trouble with slag-screen tubes has been experienced to date. The chrome ore over the slag-screen tubes has to be replaced every time the boiler comes off for cleaning.

Steam-Temperature Control. The temperature of the steam is 900 F and is controlled with a flue-gas by-pass around the superheater. This control has worked satisfactorily and it has been possible to maintain the desired temperature over all ranges of load. The outlet temperature of the exhaust steam leaving the turbine governs the steam temperature entering the turbine as the low-pressure units now installed in Waterside Station are not built to use steam at a temperature much over 525 F.

Influence of Ash Composition and Fluid Temperature on Cleaning Problems and Capacity. The ash composition and the fluid temperature have a great influence on the cleaning problems of the high-pressure boilers. Coal that has an initial ash-deformation temperature of not less than 2200 F has been determined upon after 2 yr of operation. At present, the cleaning of boilers is done by hand lancing and by taking the boiler off the line for a few hours, about twice a week, thus allowing the slag formation on the tubes and side walls to cool and fall off.

An experiment on the problem of cleaning the side walls of the high-pressure boilers by the use of a hand lance of special design, which has been used successfully at the East River Station for many years, is now being conducted. Also a nozzle to use water on the steam-generating tubes is being made up for trial.

Three men per watch of 8 hr each are continuously occupied in keeping slag off the boiler and superheater tubes. Soot blowers are used on the economizer tubes with good results.

Experience With Lighting Devices. Illuminating gas from the street mains is used in bringing the boilers up to pressure and also to ignite the pulverized fuel. A period of 5 to 6 hr is taken to bring the boiler up from cold. The gas is ignited by an electrical "glow bar" which is located directly in the path of the gas. The glow bars have burned out quite frequently, but as there are four burners per boiler, no trouble whatsoever has been experienced with the ignition of the coal. The induced-draft fans are always in operation before the gas is turned on the boiler.

Performance of Mills, Power Consumption, Life of Parts, and Sensitivity to Various Coals. The performance of the mills has been uniformly good. They give a fineness of 80 per cent through 200 mesh, 96 per cent through 100 mesh, and 99 per cent through 60 mesh. The mills run very quietly, and very little trouble has been experienced outside of the replacement of mill rollers after their normal expected life. The average life of the rollers is 85,000 tons; scrapers, 18,000 tons; and bull rings 85,000 tons. Only two grades of coal have been used on these mills, namely, Coleman "Colver" and Weaver "Revloc." As these two coals are the only coals used, the data on the sensitivity are rather limited.

Flame Stability at Varying Loads. The flame stability has been satisfactory at all loads above one third of the rated capacity of the boiler. A pulsation in the furnace has been experienced, the cause of which the boiler manufacturer is attempting to ascertain. A new primary fan inlet is being tried out as tests show that the initial pulsation starts at that point.

Feedwater Treatment, Boiler Concentration, and Internal Cleanliness. The Hall treatment is used in these boilers and consists of the following chemicals:

An average of 86 lb of disodium crystallized phosphate is used per 24-hr day for two boilers.

An average of 21 lb of sodium hydroxide is used per 24-hr day for two boilers.

The phosphate is introduced directly in the boiler drum by means of high-pressure pumps, while the sodium hydroxide is added by gravity to the boiler feed between the deaerator and the boiler-feed-pump suction.

Samples of boiler water are taken three times per day and ana-

[3] This system has been in operation for only a very short time.

lyzed for sodium hydroxide, sodium chloride, and sodium phosphate.

The boiler concentration is held at 450 to 500 ppm, but it is thought that by the use of boiler-drum baffles, which have now been installed, the boiler concentration can be carried as high as 800 ppm without excessive carry-over. Small amounts of scale were found in the boiler tubes, while the drum was free from scale, and very little deposit was found on the side-wall tubes.

Experience With Loss of Feedwater. There have been several cases where the lack of feedwater has necessitated the shutting down of the high-pressure boilers. On two occasions, the side waterwall of one boiler ruptured, and as the feed lines for both boilers for one unit come off the same header, the pressure dropped, thereby necessitating the immediate removal of the other boiler from the line. Another shutdown of the boiler due to the loss of feedwater occurred when the automatic valve, controlling the feedwater level in the drum stuck, and the water tender, while endeavoring to put the valve on hand operation, jammed the valve in such a manner that the valve closed, and the boiler had to be taken off the line. No shutdowns due to loss of feedwater to the boiler feed pumps have occurred.

Control, Availability, and Maintenance of Boiler Feed Pumps. Four of the six boiler feed pumps now in use at Waterside are motor-driven; the remaining two being driven by steam turbines. The two steam-driven pumps are so designed that they can be brought up to speed almost instantaneously. The motor-driven pumps are driven by constant-speed motors. The boiler feed pressure drop is taken across the boiler feed valve, there being no excess pressure valves used.

The availability of the Worthington boiler feed pumps has been 97.6 per cent. There has been practically no maintenance on these pumps other than the normal packing of the glands.

One of the difficulties experienced with steam-driven pumps has been the leakoff valve from the outlet header to the suction header, which failed on several occasions. The trouble was caused by an excessive drop across the valve and this was finally overcome by putting two valves in series with a pipe made with labyrinth orifices in it, in order to help in building up a resistance to the water flowing through the valves. The pump manufacturers asked that the steam-driven boiler feed pump always be operated with the by-pass valve partly cracked so as to permit some water to pass through the pump at all times.

Air Heaters

Means of Preventing Condensation During Starting on Light-Load Operation. There has been no means of preventing condensation in the air preheaters during the starting up of boilers or while operating at light loads, and this has caused considerable fouling of the air preheaters with the consequent loss of boiler capacity until the air preheaters were cleaned or washed. Due to load conditions one of the four boilers had to be taken off every night.

An experiment was tried using a movable air jet, which blew down from the air-inlet side of the air heater. The nozzle was so adjusted that it would move in and out so that all parts of the surface were blown every 2 or 3 hr. Compressed air at 125 lb pressure was used for this blowing. Steam-jet soot blowers originally installed with the air preheaters operated partially satisfactorily. A by-pass around the air preheaters has been installed on Nos. 4A and 4B boilers and, if it proves successful, a similar by-pass will be installed on Nos. 5A and 5B boilers.

Methods of Cleaning. The most successful method of cleaning air preheaters is by washing them with boiler feedwater which usually restores the draft drop through the air preheaters to its original figure.

Effect of Fouling on Capacity and Economy. Several times during the life of the boilers, it has been necessary to reduce the capacity of the boilers due to the lack of secondary air, because of the dirtiness of the air preheaters. When this condition occurs it is necessary to take the boiler off the line at the earliest opportunity and wash the air preheaters.

Deaerators

Effectiveness of Deaeration, Steam-, and Water-Flow Control. It has been found that, when the steam pressure in the deaerator is kept above 2½ lb, the deaerator will give almost 100 per cent deaeration. If, however, the steam pressure is allowed to vary for any reason, there will be a certain amount of oxygen fed into the boiler.

The steam to the deaerator is controlled by a regulating valve at the feed-heating tubine. The operation of this valve has been investigated and it was found that there is an intermittent flow of steam from the feed-heating turbine to the deaerator with this type of control. A new control valve will be installed at the deaerator to insure sufficient steam at all times for complete deaeration.

The water flow to the deaerator is controlled by a float valve which is actuated by the water level in the deaerator. Some trouble has been experienced in maintaining the water level in No. 4 deaerator, while no trouble has been experienced on No. 5. A new control valve, the same as on No. 5, will be installed at an early date.

Condenser-Hot Well Deaeration. The feedwater is deaerated in the condensers of the low-pressure turbines before being sent to the deaerators of the high-pressure units, but there is equipment through which some air may come in contact with the feedwater; such as leakage through the packing of the hot well pump, etc., which necessitates the use of a deaerator.

Deaeration of Make-Up Water. The deaeration of make-up water takes place in the condensers of the low-pressure units, and the make-up water comes over mixed with the condensate from the unit to which it was admitted.

Since the installation of the high-pressure units in Waterside, it has not been possible, due to load conditions, to cut out the low-pressure boilers. The supply of all make-up water needed in the station is fed to the low-pressure boilers, so that the high-pressure boilers have 100 per cent condensate.

Effect of Filling Idle Boilers on Deaerator Performance. On

TABLE 1 PERFORMANCE OF HIGH-PRESSURE INSTALLATION AT WATERSIDE STATION

High-pressure turbine generators	Unit No. 4	Unit No. 5
Date in commission	Sept. 10, 1937	June 29, 1938
Kilowatthours generated	325,909,000	258,260,000
Maximum kw load on generator	47000	52000
Service hours	11377.4	8250.6
Total available hours	12379.1	8980.3
Idle hours[a]	1001.7	729.7

[a] Hours available but not in operation due to conflicting outage of dependent equipment.

several occasions an idle high-pressure boiler was filled too fast and thereby drained the deaerator to such a point that make-up had to be put into the deaerator from the city water connection, thus adding to the work imposed upon the deaerator, with a resulting decrease in deaerator efficiency. The boiler operators are cautioned against filling the boilers too rapidly, and also against a too rapid heating of boiler tube and drum surfaces.

High-Pressure Heaters

All of our heaters are of the vertical type with a floating head.

Tube Materials, Cleanliness, and Leakage. The only trouble experienced with cleanliness of the tube has been that of oil coming from the exhaust steam, necessitating the washing of the tubes.

Some trouble has been experienced due to leakage of the heads of the heaters. Due to the location of these heads in the boiler room, the work of removing leaking heads is very difficult. There have been 43 tube failures in the No. 5 heaters and no tube failure in the No. 4 heaters. As two heaters are operated in parallel, it is possible to take one heater out of service to make the necessary repairs without excessive drop in feedwater temperature.

Table 1 gives the performance record of the two 53,000-kw topping turbines and the four high-pressure boilers at Waterside Station, covering the period from the date of installation to July 31, 1939.

Fisk Station Topping-Unit Operation[1]

By A. E. GRUNERT,[2] CHICAGO, ILL.

THE FISK STATION high-pressure topping plant has at this time completed nearly two years of operation. The first two months of its operation have been previously outlined.[3] That discussion was largely a disclosure of operating difficulties which invariably reveal themselves with initial operation of new developments of this nature and of defects in design which caused these difficulties.

The Fisk Station topping unit was the first capacity addition to the Chicago system following several depression years during which no new generating equipment was installed. It naturally followed that the basic trend at that time toward higher steam pressures and temperatures influenced design. The installation is not particularly different in design when compared with those contemporary to it but, being an early topping installation, it is representative of development. The topping installation was first put into service on October 8, 1937, by a plant personnel having no previous experience with this type of equipment.

The period, following that covered in the previous discussion[3] and extending to the present time, is one in which early operating and design difficulties were largely overcome. In the following discussion an endeavor is made to log the various trials and tribulations experienced in the course of this operating period. It is felt that efforts made to correct conditions which caused difficulties, have been successful to a degree that future operation may now be viewed with confidence. It is consequently believed that subsequent availability and performance records will compare favorably with those of any installation of this type and of this kind.

[1] Covering the period October, 1937, to August, 1939.

[2] Superintendent of generating stations, Commonwealth Edison Company. Mem. A.S.M.E., Melville Medalist, 1931.

[3] "Discussion of Preliminary Operations of the Fisk Station Topping Unit of Commonwealth Edison Company," Power Panel Discussion on New High-Temperature High-Pressure Stations, Trans. A.S.M.E., vol. 60, FSP-60-13, July, 1938, p. 413.

Details of Installation

In brief, the installation consists of a 30,000-kw 1200-lb per sq in. 900-F turbine generator, supplied with steam by two 375,000-lb per hr boilers. All auxiliaries are electrically driven except boiler feed pumps. Turbines for these three pumps take steam from the high-pressure header and exhaust to the low-pressure header in parallel with the topping turbine. The capacity of this topping installation was so chosen that the exhaust would supply the steam demand of two 25-cycle horizontal units. This combination forms in effect a flexible and efficient 90,000-kw cross-compound unit. More detail of the equipment in the installation is contained in Table 1. Figs. 1 and 2 are, respectively, cross-sectional views of the steam generators and turbine that are used in the topping installation, and Fig. 3 is a flow diagram of the topping plant.

Fig. 4 shows graphically the record of availability of each of the two high-pressure boilers and of the turbine generator, which together comprise the topping plant. The cause of each case of outage is briefly stated and those cases which may be considered as forced outages, due to conditions of the particular boiler or the turbine generator, are specially indicated. The monthly production economy of the combined plant under the actual conditions prevailing in each month is also shown. A more detailed analysis of the thermal performance appears in Table 2. It will be noted that the normal indicated production economy of the combined plant will be approximately 12,800 Btu per net kwhr. Some reduction in this figure is anticipated when certain contemplated alterations in the low-pressure system are completed. The plant was originally designed for an actual performance of 12,500 Btu per kwhr and it is expected that this performance will eventually be attained. It should be noted in this connection that the low-pressure equipment in this plant is of a rather old type and design.

Turbine-Generator Operation

The turbine-generator unit itself had an availability factor of 85.7 per cent for the three months' operation in 1937, 90.7 per cent for the year 1938, and 100 per cent for the first six months of 1939. The outage chart extends one month beyond this period to August, 1939, and indicates the fact that at that time the topping plant was out of service for scheduled inspection and overhauling. During the 22-month period covered by the chart there were nine outage periods with but three attributable to the turbine itself. The two longest periods from July 24 to August 23, 1938, and July 6, 1939, through the remainder of the month, were for general inspection and overhauling. During both of these periods repairs to spindle blading were necessary as will be explained subsequently. The generator, since installation, has had a perfect availability record.

Referring to the outage chart for the turbine, Fig. 4, the outage between October 8 and October 13, 1937, was necessary for adjustment of a throttle-valve bushing and for minor adjustment and tune up of the governing gear. Further checks were made of the thrust bearing and shaft seals, and the dummy clearance was adjusted on October 23. The next outage which started on October 27, 1937, is not attributed to the turbine as it was caused by boiler carry-over deposits which caused the second inlet valve to stick. Heavy deposits of boiler carry-over were also found in the valves of the header system and these deposits were removed by flushing the header with water. The three subsequent outages of January 7, January 25, and May 20, 1938, are likewise not attributable to the turbine, as is indicated by the causes which are shown on the outage chart. The July 2, 1938, outage was necessary, however, when the first and second admission valves were found to be sticking. Upon removal and inspection of the valves the head of a $^3/_4$-in. cap screw was found lodged between the seat

TABLE 1 GENERAL DATA, FISK STATION HIGH-PRESSURE PLANT

STEAM GENERATING UNITS:	
Manufacturer	Babcock & Wilcox Co.
Number	Two
Max.Continuous Output (each)- lb/hr	412,500
Normal Max. Rating " "	375,000

and disk of the second inlet valve. Upon inspection of the throttle valve it was found that this cap screw head had broken from one of the screws which held the throttle-valve seat to the throttle-valve body. The sticking of the first inlet valve was caused by valve-stem packing which had lost its plastic qualities and had caused excessive friction. A combination die-formed resilient metal-ring and soft asbestos-ring packing was substituted but this packing lasted only three weeks.

As the first general inspection of the turbine was scheduled to occur soon, the date of the inspection was advanced to July 24, 1938, because of the failure of this packing. It was found that the metal-foil packing rings had disintegrated under high temperature and particles had adhered to the valve stems. To ease the duty of the packing the leakoff was changed from 225 lb per sq in. to approximately 4 lb per sq in. Soft packing in die-formed rings was then installed and the number of rings was decreased to that required by the new pressure. This change proved satisfactory.

The inspection made at this time showed that stellite seat facings were in perfect condition. Three broken $3^1/_4$-in. cylinder studs, which were judged to have failed due to defects in material or machining, were replaced in the bolting that is used for the turbine cylinder joint. The admission-valve operating mechanism needed correction where clearances did not correspond to design dimensions. Lapped admission-valve-cover joints made up without gaskets held tight under high pressures and temperatures. Crane ring-type joints on all admission inlet bends were found to be in good condition. The trip-gear mechanism, which on several occasions had operated sluggishly, was fitted with an Alemite lubricating system during this outage. This change has materially improved its operation.

During the inspection, it was found that the lock washer which had been released from under the head of the broken cap screw, mentioned previously, had gone through the valves and nozzles and had lodged in one of the steam passages of the second moving row of impulse blading. The inlet edges of the first moving row of impulse blading were damaged by the passage of the lock washer but the relatively slight damage done was corrected by local grinding.

The blade elements of the turbine consist of a 45-in-mean-diam 2-row impulse wheel, followed by 34 rows of reaction blading. Nozzle blocks for the impulse blading are built up of a series of blade elements in which steam passages are completely machined before the elements are welded together as a single nozzle-block unit. The first row of moving blades is $2^1/_2$ in. wide as shown in Fig. 5. Proportions of these blades illustrate the massive construction used to resist the heavy intermittent forces encountered. All blades are made of a standard alloy known as "Cyclops No. 17-A," a 19 per cent nickel, 8 per cent chromium alloy.

The integral shrouds of the first moving row of impulse blades were originally welded together in groups of five. During inspection it was found that many of the welded joints had cracked, although the welding between several pairs of blades still remained sound. The strength of the original welding, however, had been somewhat reduced during manufacture in securing a smooth cylindrical surface by turning down the blade tips after welding. The blades of the first impulse row were rewelded in pairs during overhauling and a much heavier welding bead was used than in the original assembly. The full section of the welding bead was left in place for strength in this repair.

A slight looseness was noted in the blades of the first moving row on the impulse wheel. The manufacturer did not feel that

this looseness was harmful as the massive dimensions of the blades are such that tightness is assured by centrifugal force when the unit is up to speed.

The shrouding of the second moving impulse row was found cracked in a number of places and a short piece of shrouding had broken off completely. One blade of this row was broken off where the shroud section failed and the tenon of the adjacent blade was injured. These two blades were replaced.

The shroud sections originally installed on the blades of the second moving row of the impulse wheel were of sufficient length to include six blades. These shroud sections were punched to receive blade tenons, the shrouding being applied by riveting of the tenons. It was concluded that cracking of the shrouding was caused by high stresses set up during riveting, and that harmful stresses would be avoided by carefully fitting new shroud sections so that they could be assembled in place without initial stress, the new shroud sections being held by welding around the projecting ends of the tenons. This shrouding was designed to group three blades instead of six as in the original design, because of the temperature range through which this blading must operate. As a result of the failure of the original shrouding on the second moving row of impulse blading, it was decided that a replacement row of blades with integral shrouding should be designed and held in

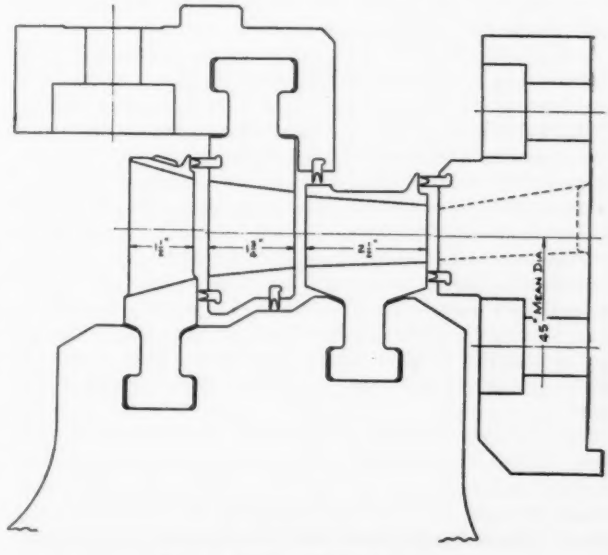

FIG. 5 IMPULSE-BLADE ASSEMBLY

readiness for installation should further difficulty be experienced in this section of the turbine.

The reaction blading was found to be in good condition on this inspection. A slight looseness was noted in some of the assembled segments toward the center of the spindle, but this looseness was not considered harmful as the blade segments become tight when up to speed. There were a few shrinkage cracks found in the silver soldering of the reaction-blade shrouding toward the low-pressure end. These were resoldered.

Following this overhauling period in August, 1938, there was no further outage for repairs of the turbine-generator unit during 1938 or the first six months of 1939. During March, April, and May of 1939, however, the steam rate of the topping turbine showed gradual increase. This was particularly noticeable in the first part of May when the steam rate of the turbine had increased to a corrected rate of 26.9 lb per kwhr at 23,000 kw load. This was reflected in the division of load between the topping turbine and the low-pressure turbines to which steam was supplied. During the same period, a reduction of capacity had been experienced in the auxiliary turbines driving the boiler feed pumps. Fouling of nozzles and blading of these small turbines was suspected and successful washing restored their capacity.

The foregoing experiences led to the washing of the topping unit. The washing was to be accomplished with saturated steam supplied at a rate slightly above no-load full-speed requirements with the unit electrically tied to the system. Saturated steam at full pressure was to be obtained by reducing the steam temperature as far as possible with boiler regulation and then removing the remaining superheat by injecting desuperheating water into the steam header at a point as far removed as practical from the turbine. A suitable nozzle was installed in one of the boiler risers for this purpose and thermoelements were inserted in existing wells at the turbine inlet and exhaust for accurate steam-temperature determination during the washing procedure. A steam-sampling outfit was set up which permitted checks to be made of conductivity of a continuous sample of condensed steam from the turbine exhaust.

With but one boiler in operation at reduced steam flow, steam-temperature reduction by means of boiler control was started at 11:00 p.m., June 3. Adhering closely to a temperature-reduction rate of 50 F per hr, a temperature of 650 F was reached at 3:00 a.m., June 4. This steam temperature represented the lower limit obtainable by means of boiler control. At 3:15 a.m. water was gradually injected into the header and by 5:00 a.m. a steam temperature of 590 F was reached.

At this point the conductivity of the exhaust-steam sample rose suddenly from 5.6 micromhos to 32,000 micromhos. As the washing progressed the steam-sample conductivity decreased to a value of 1000 micromhos after $3^1/_2$ hr of washing. During this period several samples of condensed exhaust steam were taken for chemical analysis. Analysis showed the blade fouling to consist of approximately 40 per cent soluble sodium silicate, 23 per cent sodium hydroxide, and 23 per cent sodium chloride. Other soluble inorganic salts made up the remainder of the deposit.

After the foregoing washing period, the temperature of the steam was gradually restored to normal and load was applied to the unit. At a load of 27,000 kw, the corrected steam rate of the topping turbine was found to be 24 lb per kwhr. The conditions existing during the washing operation are shown graphically in Fig. 6.

After a month of continuous operation subsequent to washing of the turbine, the topping plant was taken out of service for scheduled inspection on July 6, 1939. When the turbine was opened 26 blades in the second impulse-spindle row were found broken. The only evidence of this failure, noticeable while the unit was in operation, was an increased steam rate which had not returned fully to normal after completion of the washing procedure. Blade failure, however, was not definitely expected as the unit ran in good balance before the inspection.

As mentioned when discussing the July, 1938, turbine inspection, two blades and the shrouding of this second moving impulse row were replaced. The new blading, designed with heavier sections and integral shrouding made up for replacement following the 1938 inspection, was installed during the August, 1939, overhauling. The integral shrouding of these new blades was welded together so that groups of three blades are formed.

The shrouding on the spindle reaction blading was originally of pure nickel. Failure of this shrouding, due to cracking, required its replacement with new shrouding made of stabilized 18 per cent chrome, 8 per cent nickel material. This shrouding was arc-welded in place with 25 per cent chrome, 12 per cent nickel weld rods.

Four $3^1/_2$-in-diam cylinder bolts were found broken on this inspection. As a result of this and of the bolt failures found in the previous inspection, all of the larger studs for the turbine joint were replaced. The new studs will be made of Triplex No. 3

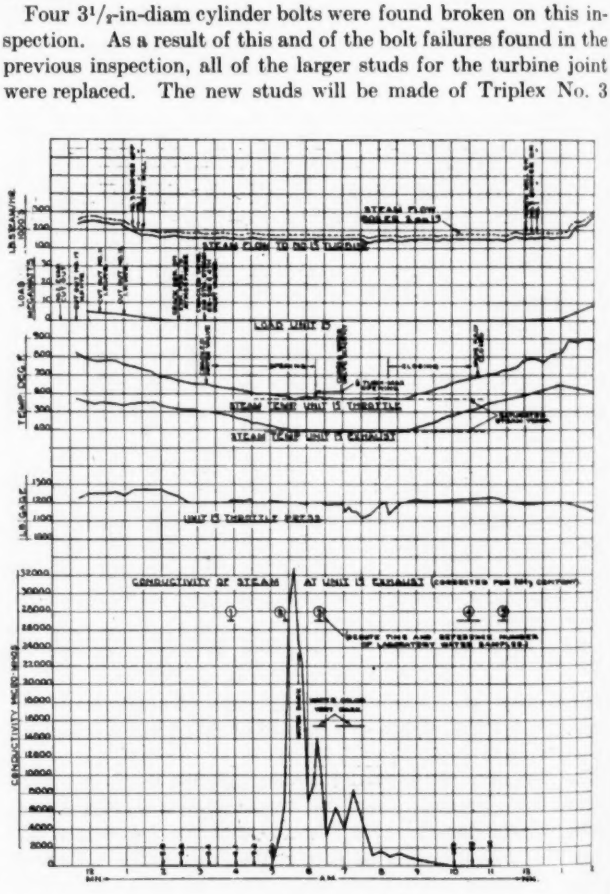

FIG. 6 DESUPERHEATING OPERATION FOR HIGH-PRESSURE TURBINE WASHING

bolt steel, a material which is now believed to be more suitable than the material originally used for this high-temperature-bolting service.

Although blading difficulties have been found in each of the two inspections of the turbine so far made, it is felt that the improvements accomplished will be found adequate, and that improved performance will result. Based on observed conditions and performance of the first impulse-spindle row, the changes made should limit future blading maintenance to minor repairs. It is expected that availability records with subsequent turbine operation will be further improved by shorter overhauling periods which possibly may become less frequent.

Steam Generators

The availability of the two steam-generating units of this topping installation has not equaled that of the turbine generator. This is apparent when the turbine and boiler outage charts in Fig. 4 are compared. The steam generators had an average availability factor of 61.2 per cent for their operation in 1937, 80.2 per cent for the year 1938, and 87.6 per cent for the six months of 1939. Steam supply, however, has been available from one or both steam-generating units during all except two short periods in the first four months of operation of the installation.

As the steam generators are similar in design, the major operating difficulties encountered with one were either indicated or experienced in the operation of the other. As a result, the improvements made in the boiler installations were made on each of the units in about the same sequence.

Steam was supplied to the high-pressure-header system on September 18, 1937. After preliminary adjustments were made to the feed pumps and other auxiliaries, operation was continued, the steam produced being passed through the pressure-reducing and desuperheating equipment to the low-pressure header, Fig. 3. In the early operation of the boilers, joint leaks developed where recirculators entered headers of the side-wall screens and also where economizer tubes entered the steam drums. Rerolling of these joints failed to prevent the recurrence of leaks during further service, and it was necessary to seal-weld the joints for tightness. Inability to hold rolled economizer joints tight was attributed to strains due to variable economizer temperatures. Recurring leakage of rolled recirculator joints was attributed to excessive joint strains set up by unequal expansion of recirculators and screen wall tubes. Seal welding, where necessary, has prevented joint leakage but strains at the joints persist. These strains have to the present time caused no apparent difficulty other than the leakage before joints were seal-welded.

During the initial operation of the installation, carry-over deposits were found to be accumulating in header valves and control valves of the turbine unit in quantities which were sufficient to interfere with valve operation. Tests for steam purity, made when units were steaming at the rate of 230,000 lb per hr, indicated that excessive carry-over was present when total solid concentrations in boiler water were maintained at 425 ppm. Lowering of the water level resulted in carry-over of less than 1 ppm at this rating but, when ratings were increased to 310,000 lb per hr, carry-over again became excessive. As 375,000 lb of steam per hr is required from each boiler for designed operation of the topping installation, improvements for better steam purity were necessary. With a changed drum baffle and steam-scrubber arrangement,[4] satisfactory steam purity has been attained at normal boiler ratings when total solids in the boiler water were maintained at 400 ppm. Operation was continued with this steam-scrubber arrangement in 1938 and the first six months of 1939.

As ratings were increased, difficulties with furnace slag accumulations on the sloping portion of the secondary-furnace wall were experienced. The original design provided for operation of the secondary furnace as a dry-bottom furnace, the slag falling through the opening across the bottom of this furnace, in a dry state, and being removed by a hydrojet system installed beneath the opening. This arrangement proved impractical as slag built up on the sloping secondary-furnace rear wall in thicknesses of 4 to 12 in. and at times avalanched down in quantities and sizes so large that removal by the hydrojet installation was impossible. During boiler outages in December, 1937, the secondary-furnace bottoms were changed, as shown in Fig. 1. With this arrangement all furnace slag is readily removed through the slag-drip holes of the primary furnace in liquid form.

[4] Reference (3), Fig. 4, p. 416.

Through this period difficulties were also experienced with failures of vertical slag-screen tubes and ruptures of tubes around the slag-drip openings in the primary furnace floor. The several changes necessary to correct these conditions required outages shown on the chart during January and February of 1938. The changes made consisted first, of the addition of 12 recirculating tubes between the upper slag-screen header and the lower distribution header to the screen; second, of offsetting alternate groups of 2 slag-screen tubes into the secondary furnace as shown in Fig. 1, instead of into the primary furnace as originally designed; and third, of moving the burners 2 ft 10 in. forward in the primary furnace. These changes had the effect of improving circulation and reducing the duty imposed on the tubes which previously had ruptured. A better balance in circulation between the screen-tube and floor-tube circuits also resulted. Further changes that were made to improve conditions in the floor-tube sections consisted of increasing the radius of tube bend in tubes around the slag-drip holes and the installation of water-cooling coils at these slag openings to retain a deeper protecting layer of molten slag over the floor tubes. These changes resulted in improved performance of these sections of the boiler installation.

During the outage of the steam-generating units shown in April, 1938, lancing doors of improved design with added insulation, improved hinges, and latching devices were applied in place of the original doors. It was necessary also to apply additional insulation about the boiler setting to reduce the temperature at lancing galleries and in other localities about the boiler where operators must work.

Repeated leaks from economizer-tube joints at the headers necessitated the completion of seal welding on all joints in the economizer sections at this time. During previous outages some seal welding of economizer tube joints had been accomplished.

On May 20, 1938, an outage of the entire topping installation was necessary to remove pieces of straightening vanes which had come loose from their position in the topping-turbine exhaust line. These straightening vanes had originally been installed to direct steam flow for more accurate metering through a topping-turbine exhaust orifice. As a result of the failure of this set of vanes, all straightening vanes in the header installation were removed to prevent a recurrence of failure, and possible resulting injury to turbine blading.

During the outage of the topping turbine for inspection and overhauling, the boilers were alternately taken out of service for inspection, cleaning, and repairs. At this time 9 economizer-tube sections at the boiler drum, which had been seriously eroded by spray from a joint leak, were replaced in the economizer of No. 2 boiler.

Difficulties with blistering and rupturing of tubes in the vertical slag screen, and in the primary-furnace floor and upper generating-tube sections, had caused questioning of the adequacy of boiler-water circulation and of the water treatment used in the installation. Apparently some of the tube failures were aggravated by more or less loose deposits which had accumulated at the points of tube rupture. These deposits had settled out of suspension in such quantities as to be evidence of sluggish circulation. Water lines in the interiors of the top-row tubes in the generating section were also evidence of inadequate circulation. In an effort to improve this latter condition, the top row of generating tubes was replaced with a changed design of tubes during outages of No. 1 boiler early in July, 1938, and of No. 2 boiler from August 27, to September 10, 1938. The original top tubes were parallel to the remainder of the tubes in the bank, while the new tubes were bent as shown in Fig. 1.

Soot-blower position changes were made during these boiler outages for more effective cleaning of the heating surface. The

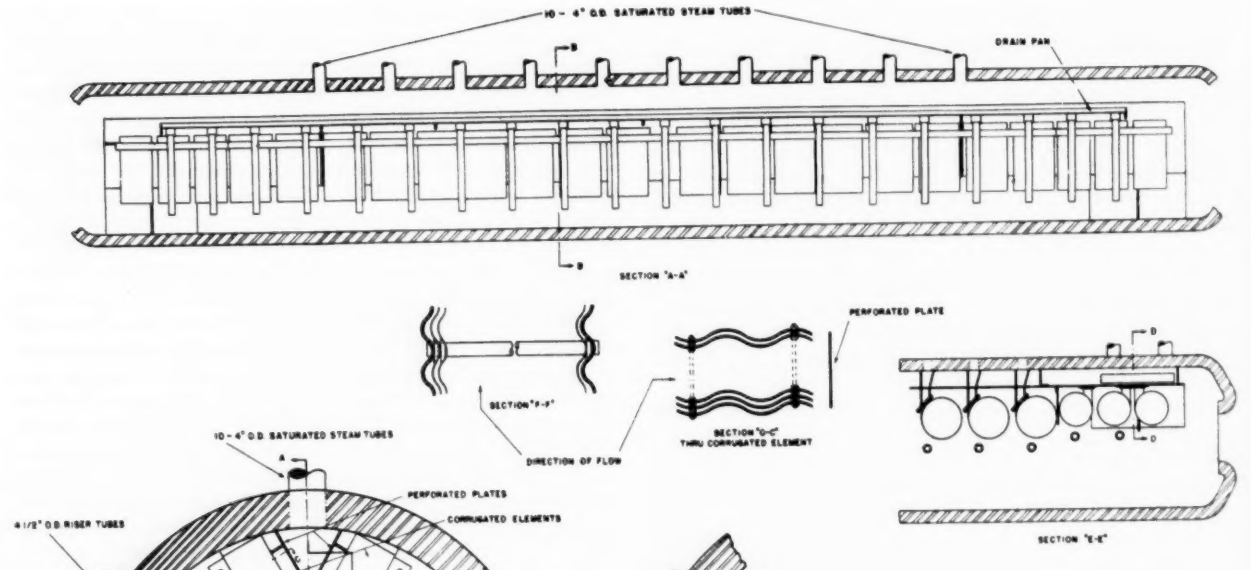

FIG. 7 IMPROVED STEAM-SCRUBBER ARRANGEMENT

soot-blower supply-header piping was also changed to secure higher pressure at the blower heads, resulting in higher jet velocities for more effective cleaning.

Operation of the boilers during the period from October, 1938, to February, 1939, was interrupted with several outages taken to clean tubes and make changes to improve circulation in the generating section. Restrictor plates in the uptake headers of this bank of tubes, altered design of top-row generating tubes mentioned previously, discontinuation of Akon treatment, and installation of tube cores in the upper ends of the top two rows of generating tubes were tried in efforts to prevent tube failures. These alterations failed to produce the desired result.

During the outage of No. 2 boiler between January 29 and February 6, and of No. 1 boiler between February 10 and February 17, 1939, distributor tubes made up of 1-in. tubing with a cone attached at the bottom were inserted in each of the uptake headers of the generating-tube section. The cone is arranged to divert the intense circulation of the bottom-row tubes through the 1-in. tube, while the 1-in. tube terminates near the top of the header and flow through it tends to induce circulation in the remaining tubes in the header. Sufficient equalization of circulation has been attained with this arrangement to prevent further tube failures in the generating-tube section.

With the changes mentioned, both boilers have operated for three-month periods and were taken out of service during May, 1939, only for inspection. No condition was found in these inspections which would have interfered with a longer service run on either boiler.

Due to difficulties experienced in other high-pressure-boiler installations with cracking of drum metal at joint seats, across which excessive variations in temperature occurred during operation, a changed design of economizer-tube joint at the drum and method of introducing feedwater were recommended by the manufacturer. The changed position of economizer-tube entry to the steam drum resulted from a decision to change the drum baffling and steam-scrubber arrangement from that shown in the previous paper,[4] to the cyclone-separator arrangement developed by the manufacturer. These drum changes were accomplished during the August, 1939, outage of both boilers, while the topping turbine was inspected and overhauled. The improved economizer-tube joint at the boiler drum and drum-cyclone arrangement is shown in Fig. 7. The installation of cyclone separators and changed scrubber arrangement is not expected materially to improve steam purity over that secured with the previous arrangement, but was adopted primarily to assure a maximum density in water supply for boiler circulation.

During the August, 1939, outage, the boilers were thoroughly cleaned externally, and the tubes in the generating sections and screen and wall circuits were turbined. The turbining was not considered necessary to remove deposits but was performed to make certain that the boilers would be in optimum condition for an extended service run.

In general it appears that the tube failures experienced during these correction and development periods have been largely due, directly or indirectly, to sluggish circulation. While there are many factors in operation and design which may contribute to this condition, it would appear that the matter of solid-water downcomer supply is particularly important as is also the matter of ample return-circulating-tube area. It would also appear that where relatively high heat transfers occur, parallel circulation with unequal flow resistances should be avoided as far as practical design will permit. The several changes in these boiler units have largely been made with the intent to improve one or the other of these conditions. The records of improved availability indicate that efforts along these lines have been sufficiently successful to regard regular boiler-operating periods of six or more months' duration as a reasonable expectancy. Turbine availability in this topping installation has exceeded this performance in previous operation. With these improvements a very desirable plant availability performance is anticipated.

Logan Operating Experience

By PHILIP SPORN,[1] NEW YORK, N. Y.

BEFORE beginning a review of the approximately two years of operating experience at the Logan Station of the Appalachian Electric Power Company, a brief description of the major equipment installed in 1937 will be of help as a background. The superposed extension consists of a 40,000-kw, 3600-rpm, water- and hydrogen-cooled generator supplied with steam at 1250 lb per sq in., 925 F, from a single boiler of 1,000,000 lb per hr capacity and exhausting at 200 lb per sq in. 510 F to five low-pressure turbines totaling 50,400 kw. The details of the equipment comprising the plant and the underlying design considerations have been published in various technical journals.[2] However, mention should be made that, at the time of its purchase in 1935, the 40,000-kw turbogenerator was the largest-capacity, 3600-rpm topping unit that could be proposed and the first hydrogen-cooled generator placed on order. It is also, so far as is known, the only water-cooled generator stator. The boiler is still the largest built to date.

Initial operation of the high-pressure boiler was started in October, 1937, and trial operation of the turbine, November 2, 1937. Operating experience during this initial period up to December 2, 1937, was reported as part of the Power Panel Discussion at the Annual Meeting of the Society, December 8, 1937.[3] The rather limited experience of one month of operation available at the time of that discussion justifies further comment on operating experience as the second year of operation nears a close.

Since the starting date until August, 1939, comprising 15,638 hr of elapsed time, the high-pressure section of the plant was available 8956 hr or 57.3 per cent of the time, while the service hours were 8750 or 56 per cent of the time. With a gross generation of 255,527,000 kwhr, the capacity factor for this period has been 40.8 per cent. The availability of the high-pressure turbine alone was 86.4 per cent and the service hours 56 per cent of the elapsed time. The single high-pressure boiler, which is used for the low-pressure section of the plant through the pressure-reducing and desuperheating system when not supplying the topping turbine, had service hours equal to availability amounting to 71.8 per cent of the period. Details of the outages on the high-pressure turbine and boiler will follow later. Since July, 1938, when the last major turbine difficulty was remedied, the record is more pleasant to report. Fig. 1 shows a graph of the maximum hour output of the high-pressure turbine since that time. The availability of the high-pressure section of the plant increased to 81.5 per cent, the service hours to 80.2 per cent, and the capacity factor to 61.8 per cent. For the turbine only the availability at 97.2 per cent and the service hours at 80.2 per cent have been quite satisfactory. The high-pressure-boiler performance is encouraging with availability and service hours increasing to 84.7 per cent in this recent thirteen-month period.

During the thirteen-month period, the station heat rate of 14,400 Btu per kwhr compares favorably with the design expectations, remembering of course that a serious shortage of circulating water in the summer months, necessitating spray nozzles and recirculation, is an uncontrollable influence on over-all plant economy. Under such conditions the condenser pressure attains as high as 3.4 in. Hg, and the additional large auxiliary power consumption to operate the spray-pond pumps amounts to 8 per cent of full-load generation.

Although the high-pressure turbine is rated 40,000 kw and the five low-pressure turbines aggregate 50,400 kw, making a station rated at 90,400 kw, much higher loads have been consistently possible because of hydrogen cooling of the topping unit and nozzle changes on the low-pressure units. Under favorable winter conditions, with ample circulating water, a gross station load of 103,000 kw has been attained, involving 48,500 kw on the 40,000-kw topping unit supplied with 1,000,000 lb per hr of steam from the single high-pressure boiler. This high load represents a reserve capacity available of 12,600 kw or 14 per cent over the name-plate rating of the units.

Operating procedure, as originally set up for this station at the time of initial operation late in 1937, has proved to be entirely satisfactory and no major modifications have as yet been found necessary. Basically, the system of starting and stopping is one in which the low-pressure boilers, the low-pressure turbines, the high-pressure boiler, and the topping turbine are treated as separate divisions, each of which is operated separately but in sequence. Whenever the high-pressure boiler is out of service at least two of the low-pressure boilers and two of the five low-pressure turbines are operated. The desired load on these units is maintained by backing down on the low-pressure boilers while steam flow is increased through the reducing valve as the high-pressure boiler is started and loaded. The high-pressure boiler could not be started without at least one of the low-pressure boilers in service because induced-draft fans are turbine-driven. Then the topping turbine is warmed through a manually operated atmospheric exhaust. When ready, the topping turbine under control of the speed governor is synchronized, then put under control of the back-pressure governor, and loaded while flow through the reducing station decreases. The reverse order is followed when taking the high-pressure equipment off the line. Under running conditions, the reducing valves are closed, the load is varied on the low-pressure turbines which, in turn, control the steam flow and load on the topping unit through the medium of the back-pressure regulator on the topping turbine.

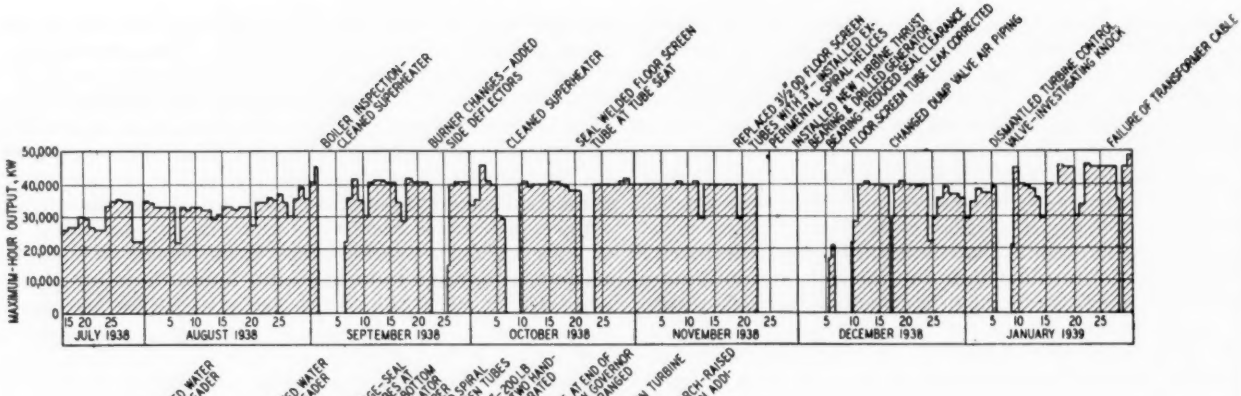

FIG. 1 MAXIMUM HOUR OUTPUT FROM JULY, 1938, TO AUGUST, 1939, LOGAN HIGH-PRESSURE TURBOGENERATOR

There have been several interesting experiences which indicate the flexibility of the station. On one occasion a test trip-out of 15,000 kw and an accidental trip-out of 36,000 kw of low-pressure unit capacity created no disturbance beyond control of the boiler operator and without popping of safety valves. There was an occasion when one of the induced-draft fans was lost and another, when a forced-draft fan was lost, both times with full load on the high-pressure boiler, but recovery to stable operation was accomplished without difficulty. Any system disturbance affects the load less on the topping unit than on the low-pressure units.

A most interesting incident occurred once when the entire station load was lost. The pressure in the 200-lb steam header, supplying the low-pressure units, dropped to as low as 60 lb, but this was sufficient to keep in operation the turbine-driven induced-draft fans on the high-pressure boiler supplied from this header without resorting to firing the low-pressure boilers.

HIGH-PRESSURE TURBOGENERATOR

The major outages on the high-pressure turbine have resulted from failure on two occasions of the first-stage shroud band. With the second shroud-band failure, the turbine manufacturer gave proper consideration to the extreme combinations of stress to which the first-stage blading is subjected, involving intermittent stress from partial peripheral admission and stress from centrifugal force coupled with high-temperature effect. Since the second repair was completed and the turbine placed on the line on July 15, 1938, it is gratifying to be able to report that no further trouble has resulted to date from the first-stage shroud band. It is to be noted that the turbine admission-valve system at Logan, shown in Fig. 2, continues to be, as it was initially, a partial admission system, the sequence being 1, 2, 3, 4, 5, 6. The only other serious difficulty occurred when the thrust bearing let go, but since its repair there has been no recurrence.

Overheating of blades in the topping turbine, caused from motoring of its generator with insufficient steam flow, when low-

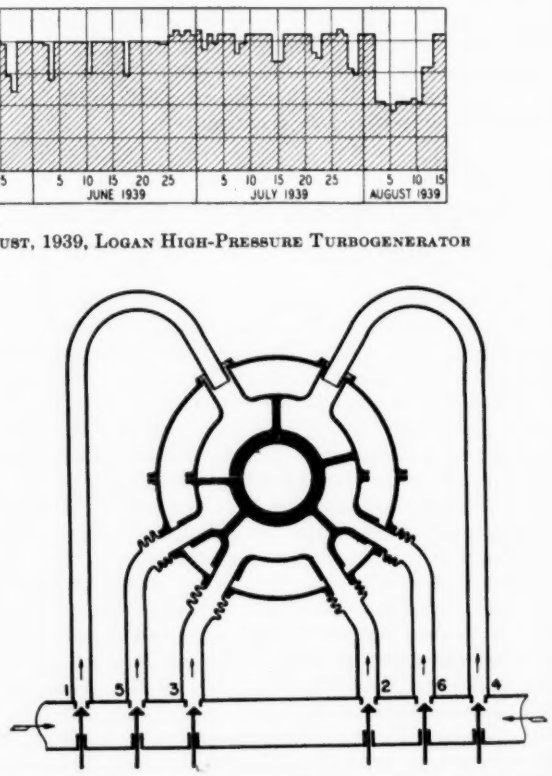

FIG. 2 DIAGRAM OF ADMISSION-VALVE SYSTEM, LOGAN HIGH-PRESSURE TURBINE

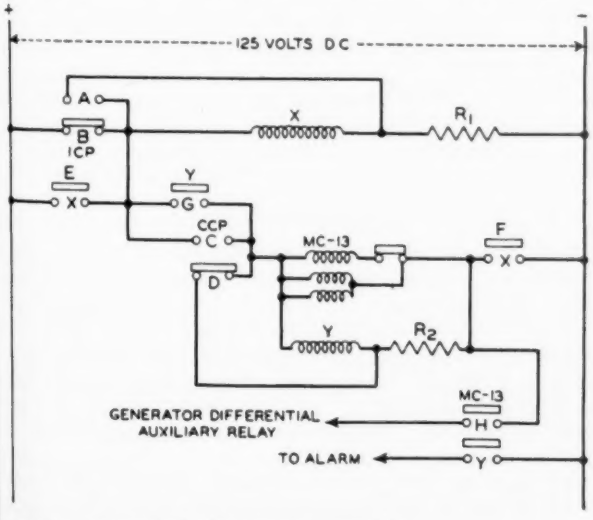
pressure units have tripped out, is prevented at Logan by a somewhat special reverse-power relay which the author helped to develop.

The scheme consists of a sensitive reverse-power relay calibrated to operate on power component only and to close its contacts to trip the generator off the line in case the power flow is from the bus bars into the generator with a magnitude of $\frac{1}{2}$ per cent of the kilowatt rating of the generator after a time of 1 min. In addition to this reverse-power relay, a timing relay is provided to give the desired time of 1 min. A single current transformer is employed with a ratio of approximately full-load rating of the generator to give 5 amp secondary current. Furthermore, a lockout, single-phase, reverse-power relay is provided to make the above sensitive reverse-power relay inoperative, provided the generator



is supplying power to the bus bars of an amount equal to or greater than 40 per cent of its kilowatt rating. The installation of this lockout relay is provided to insure that the generator will not trip off the line unnecessarily due to improper operation of the sensitive reverse-power relay on surges or otherwise. In addition, an alarm circuit is provided to operate at the instant the generator starts motoring, so as to inform the operator that the generator is motoring and permit him to correct conditions within the period of 1 min before tripping occurs, if possible.

The detailed operation of the scheme may readily be understood from Fig. 3, which is an elementary control diagram of this system.

Under normal conditions, with the generator supplying power to the bus bars in excess of 40 per cent of its rating, contacts *A* of lockout reverse-power relay *ICP* are closed, short-circuiting coil of auxiliary relay *X*, causing contacts *E* and *F* of relay *X* to open, thereby removing negative supply to contacts of timing relay *MC*-13, preventing the operation of generator differential auxiliary tripping relay, regardless either of the operation of the sensitive reverse-power relay *CCP* or of the timing relay *MC*-13.

In case the generator is supplying power of less than 40 per cent of its kilowatt rating to the bus bars, contacts *B* of the lockout reverse-power relay *ICP* close, energizing auxiliary relay *X*, causing its contacts *E* and *F* to close. Due to the power flowing into the bus bars, contacts *C* of the sensitive reverse-power relay *CCP* are open, preventing energization of the timing relay *MC*-13. Also, contacts *D* of the sensitive reverse power relay *CCP* are closed, short-circuiting coil of auxiliary relay *Y*, causing contacts *G* and *H* to open, preventing the operation of the alarm circuit.

Under motoring conditions, power flow being from the bus bars into the generator, contacts *B* of lockout reverse-power relay

ICP = lockout single-phase reverse-power relay
CCP = sensitive motoring three-element single-phase reverse-power relay
MC-13 = d-c timing relay
X = type HGA d-c auxiliary relay
Y = type HGA d-c auxiliary relay
R_1 = resistor for *X* auxiliary relay
R_2 = resistor for *Y* auxiliary relay

Fig. 3 Elementary Control Diagram of Special Reverse-Power Relay, Logan High-Pressure Turbogenerator

ICP close, energizing auxiliary relay *X*, causing its contacts *E* and *F* to close. In addition, contacts *C* of the sensitive reverse-power relay close, energizing coil of auxiliary-relay *Y*, causing its contacts *G* and *H* to close. Then timing relay *MC*-13 starts to operate and, at the same instant, alarm circuit operates. After timing relay *MC*-13 has operated for 1 min, its contacts close, energizing generator differential auxiliary relay, tripping generator off the line.

During the last year there have been two occasions when the low-pressure units have tripped out from failure of the group excitation for these units. On both occasions the high-pressure unit was prevented from motoring by the successful functioning of the special reverse-power relay.

When the topping turbine is being shut down, the rise in exhaust steam temperature is negligible before the exhaust is opened to the atmosphere, but in bringing the turbine on the line after

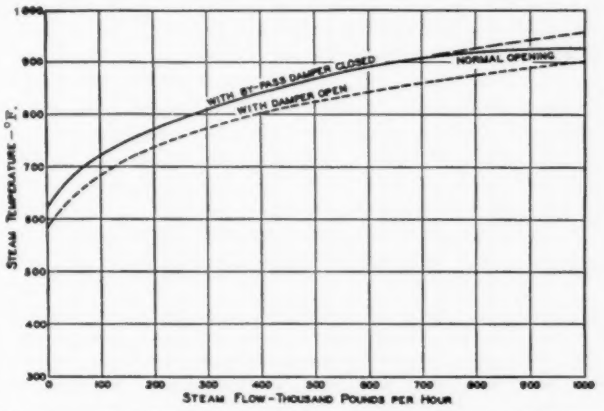


Fig. 4 Steam-Temperature Range With By-Pass Damper Control, Logan High-Pressure Boiler

a short shutdown period the stored heat raises the exhaust steam approximately 175 F until loaded and under control of the governor.

There have been no vibration problems with the topping turbine and the use of vibration and eccentricity recorders have proved helpful during starting periods. There is also no noise problem whatever.

The hydrogen-cooled generator has functioned most gratifyingly even under capacity load with the adverse condition of high cooling-water temperature. Although this generator is designed for a gas pressure of 15 lb per sq in. and has had test runs at this pressure, during which the shaft sealing and gas consumption were satisfactory and lower temperature of windings realized, day-by-day operation has been confined to a pressure of 0.5 lb per sq in. Even with cooling water at 90 F, a higher gas pressure was not needed to effect proper cooling of the windings. Hydrogen purity is easily maintained at 99 to 100 per cent, and gas consumption, averaging less than 40 cu ft per day, has been costing less than $300 per year.

Regarding the pad cooling arrangement for direct water cooling of the stator, outside of the original difficulty with the removal of air from the system, satisfactory performance has been obtained. There have been no signs of water leakage either in the pads or in the piping of the system. It has not been necessary at any time to remove and replace the condensate used as make-up for this pad-liquid system. Two heat exchanges are provided for the cooling of the pad liquid both of which are used during the warmer months but only one of which is needed during most of the year.

High-Pressure Boiler

The 1,000,000-lb per hr, dry-bottom, pulverized-fuel boiler has, of course, been subject to some outage—more outage than the turbine. Ash-screen tube failures resulting from impaired circulation and excessive heat input required replacement. To

remedy this difficulty, smaller-diameter tubes having spiral circulating strips and an increased slope were substituted and burner angles adjusted with satisfactory results.

West Virginia bituminous coal from four different seams near Logan with ash-fusion temperatures ranging from 2350 to 2700 F has been burned without difficulty. Slagging has not been serious and cleaning of boiler tubes by soot blowers and lancing has been easily accomplished. Load swings of 10,000 to 15,000 lb per hr are readily handled and, on occasion, it has been possible to drop load from 900,000 to 540,000 lb per hr momentarily. Steam temperature has been controllable within the prescribed range shown in Fig. 4 with the remotely operated by-pass dampers. With tangential firing, a minimum boiler load of 300,000 lb per hr can be attained without loss of flame stability. However, it is interesting to note that, with a fuel combination of gas and coal, a load of 175,000 lb per hr has been carried successfully for a 2-hour period. Four auxiliary natural-gas burners are used for starting with the aid of a kerosene torch and together are capable of carrying a boiler load of 50,000 lb per hr. The four Hardinge mills each of 15 tons per hr capacity have been rendering satisfactory service with a power input of 16 kw each at full capacity. To date these four pulverizers have handled a total of over 350,000 tons of coal. Experience indicates that exhauster blades made of boiler plate require replacement after a mill has handled 35,000 tons, and the wear on the ball charge amounts to 0.086 lb per ton of coal. The two Ljungstrom air heaters when cleaned once each shift with steam soot blowers have maintained their capacity and have exhibited no tendency to fouling. However, the exit flue-gas temperature, leaving the air heaters, remains about 30 or 40 F higher than the manufacturer's performance guarantee.

Feedwater make-up is supplied from an evaporator whose feed is coagulated river water in which temporary hardness usually predominates, forming a scale in the evaporator not readily susceptible to cracking. To offset this, approximately 0.2 ppm of tannin is added to the evaporator feed for 1 ppm of hardness. Total dissolved solids in the vapor leaving the evaporator is confined to 2 ppm or less. A pressure-type deaerator located midway in the feedwater-heating circuit, using exhaust steam from the turbine-driven induced-draft fans, has consistently maintained the dissolved oxygen of the feedwater at 0.005 cc per liter or less. Scavenging of final oxygen is obtained by continuous feeding of ferrous sulphate and caustic soda at the deaerator outlet in proportion to the dissolved oxygen in the feedwater. At no time does the boiler water show the presence of ferrous iron. Orthophosphates and caustic are fed in shots into the feedwater at the discharge side of the regulator for maintaining a pH value of 9.6 and a phosphate concentration of 10 to 25 ppm as PO_4. Boiler-water total solids range between 100 and 250 ppm.

The saturated steam from the boiler has a specific conductivity averaging from 0.5 to 0.7 micromhos. Even so, some fouling of turbine blades, as evidenced by increasing first-stage pressure, has been experienced after long periods of continued operation, suspected to be attributable to iron from the oxygen scavenger not detectable by conductivity determinations because of being too slightly ionized. Only recently the oxygen-scavenger feed was temporarily discontinued to determine the effect on first-stage pressure drop. Fortunately the deposit on the turbine blades seems to be removed or greatly reduced following a turbine shutdown. The only reason assignable to this is that the condensation on the blading during the subsequent turbine warming-up period is responsible for washing off the deposit.

Boiler Feed Pumps

Three identical 3600-rpm feed pumps are installed, one of which is motor-driven and two turbine-driven with the exhaust steam absorbed in the feedwater-heating cycle. Ordinarily, the turbine-driven pumps are used with the motor-driven as stand-by. These pumps have horizontally split cases and handle water at 350 to 390 F. Their performance has been satisfactory in every way except for failure of ring gaskets involved with the removable head at the discharge end of the pump where the balancing disks are located. Apparently, it is a question of slightly warped castings and selection of suitable gasket material. But this is a minor matter.

Reducing Valves and Desuperheaters

The two steam reducing valves for supplying the low-pressure section of the plant from the high-pressure boiler have been practically free of vibration and noise since the initial changes reported two years go.[3] When the station is operating normally with exhaust from the topping unit supplying the low-pressure units, motor-operated shutoff valves ahead of the reducing valves are kept closed. This is believed to be favorable to the life of the reducing valves. The automatic desuperheating equipment, though somewhat complex, has functioned very satisfactorily, and has maintained the steam temperature within narrow limits.

Heaters

In the feedwater-heating cycle, there are no heaters on the discharge side of the boiler feed pumps. Following the deaerator on the suction side of the feed pumps are two vertical surface heaters of the floating-head type, both handling water at 450 lb per sq in. and using steam at 100 and 200 lb per sq in., respectively. Admiralty tubes in the 100-lb heater and arsenical-copper tubes in the 200-lb heater have both functioned satisfactorily thus far without leakage or tube dirtiness. After some experience with various head gaskets, the toroidal type was definitely unsatisfactory, but copper and corrugated monel have proved to be much superior. Drain subcoolers built into heaters are not used at Logan. However, a separate drain cooler, used in conjunction with the 100-lb heater, has performed up to expectations with control of the drains on the outlet side so that no flashing can occur in drain piping between the drain cooler and the heater being drained.

Electrical Features

It will be recalled that the entire output of the Logan topping unit, as well as substantially all that of the five low-pressure machines, is taken care of by a single, 4-winding, 100,000-kva transformer bank with windings operating at 4000, 11,000, 44,000, and 132,000 v. Further, the larger station auxiliaries are fed through a newly developed magnetic air-type circuit-beaker switchboard. Both of these large and/or new developments have worked out most satisfactorily. No trouble has been experienced with the load-distribution or regulating characteristics of the multiwinding transformer. The air breakers showed their rating capability in an elaborate series of acceptance tests and have since functioned with a complete absence of any difficulty.

In a discussion of this kind there is only time for covering the high spots but there are, of course, many interesting detail problems which have been solved or remain to be solved. As a general conclusion it may be said that the selection of 1250 lb pressure, 925 F temperature for a topping extension to this station and the equipment designed for use therewith have proved a design, operating, and financial success. If we had the job to do over again, the experience gained of course would enable improvement in many details, but basically the design would be the same.

Superposed Installation at Omaha Station of Nebraska Power Co.

By LOUIS ELLIOTT,[1] NEW YORK, N. Y.

INFORMATION was presented two years ago before the Society concerning the high-pressure high-temperature superposed extension at the Omaha Station of the Nebraska Power Company.[2] At that time equipment operation aggregating 5700 hr was discussed. The present statement covers the period from initial operation in February, 1937, to May, 1939, and includes operating data and experience in addition to or differing from that detailed in the previous paper.

In brief, the extension includes one 10,000-kw 0.8-power-factor turbogenerator, designed for 1200-lb, 900-F operation, and one 265,000-lb per hr bent-tube boiler with economizer and regenerative air heater, fired by a 570-sq ft traveling-grate stoker. The high-pressure turbine is superposed on a 15,000-kw 200-lb condensing unit, with a nonautomatic reducing and desuperheating station discharging to a 325-lb header. Division of load between high-pressure and topped units is determined by maintenance of constant back pressure on the former. The station is operated normally with at least one 325-lb turbine and one or more boilers on the line, in addition to the superposed combination.

Operating time of boiler and turbine to May 1, 1939, has aggregated about 15,000 hr, equivalent to 78 per cent of elasped time since initial service. Availability (practically equal to "demand availability") of the high-pressure-turbine unit for the entire period has been 82 per cent, and for the last 7300 hr, since latest overhaul, 94 per cent. The unit was opened up in February, 1938; the next overhaul is scheduled for February, 1940. High-pressure boiler availability has been 87 per cent for the entire period, and 94 per cent since the latest general overhaul. Generation by the high-pressure unit has been at 78 per cent unit output factor (based on 10,000-kw rating) for the entire service period. Operation of the topping combination has been practically continuous since the early part of this year, and reliability is considered as substantially on a par with that of the 325-lb section of the plant.

Load on the combined unit is determined by consideration of over-all station costs, of service reliability, and of certain operating and maintenance difficulties experienced. As examples, loading is influenced by economy characteristics of the 325-lb units operated, by the formation of deposits on the blading of the 1200-lb and 200-lb turbines and on the tubes of the cross-over heater, and by slagging of boiler heating surfaces.

During 7300 hr ending April 30, 1939, generator had averaged 7050 kw, and heat rate of combined high-low-pressure unit averaged 13,700 Btu per kwhr net output with 84 per cent boiler efficiency and 60 F average deficiency in throttle temperature.

Design heat rate at 7500 kw (gross) load with 84 per cent efficiency and 900 F steam temperature is 13,050 Btu per kwhr net output, or 13,600 Btu with correction applied for actual steam temperature prevailing. It is therefore to be expected that when steam temperature is brought up to that originally intended, performance of unit will be substantially equal to design value.

High-Pressure Turbine

Reduction of turbine capacity from blade deposits was experienced prior to the February, 1938, overhaul, at which time blading was cleaned by blasting with fly ash because silica content and temperature conditions prevented removal by washing. Subsequently, boiler-water concentrations were reduced, and leakage of the low-pressure unit condenser is now checked regularly; stage pressures and load tests now indicate no appreciable scaling of blading, so that further ash-blasting may not be necessary.

The turbine unit originally showed some vibration, but with adjustments, made from time to time, conditions are now much improved and are quite tolerable.

As at first installed, the turbine water rate was 2 to 3 per cent high at lighter loads, caused in part by excessive high-pressure packing clearances, but largely by turbulence of steam in the space between the first-stage-wheel exit and smaller diameter nozzles of the second stage. A dam or baffle was installed in the first-stage shell space, extending from the inside of the shell to the rotor and attached to the second-stage diaphragm and to the inside of the upper half of the casing. This improvement eliminated much of the loss and permitted the turbine to meet its expected performance.

No automatic devices have been installed, or other provision made, to protect against overheating of the turbine with loss of load. The smaller turbines are less vulnerable in this respect than the larger.

Starting-up procedure has been modified as compared with the method reported two years ago. The 200-lb turbine is now started first, taking steam through the 325-200-lb reducing valve. The exhaust valve of the high-pressure turbine is also opened to admit 200-lb steam to the turbine casing. The high-pressure boiler is brought up to 600 or 800 lb pressure, passing 75,000 to 100,000 lb of steam per hr through the 1200-325-lb reducing valve. The high-pressure turbine is then started, exhausting to the 200-lb turbine. As the load is picked up, the 1200-325-lb reducing valve is closed, and the boiler pressure is raised to 1200 lb. This method obviates loss of steam to the atmosphere, inherent in the original starting method. Starts and stops have been relatively infrequent—only as occasioned by maintenance requirements.

High-Pressure Boiler

There is little occasion to make rapid changes in load on the combined unit, and the boiler output is maintained steady, except as the daily load curve calls for adjustment at certain hours.

Deficiency in total steam temperature persists, correction having been delayed. On account of this temperature condition, there has been no need for control of steam temperature, for which a manually operated by-pass gas damper is provided.

Slagging of boiler-unit heating surfaces must be fought continually, the Kansas coal burned having relatively high sulphur content and low ash-softening temperature; samples show initial deformation at 1850 F and a fluid condition at 2100 F or below. Because of these ash characteristics, difficulties of cleaning boiler and air-heater surfaces increase rapidly as maximum boiler capacity is approached. The boiler is now normally operated during the day period at an output of approximately 225,000 lb per hr, as slagging difficulties increase above 230,000- to 240,000-lb per hr output. It requires 14 man-hours per day for cleaning of the heat-transfer surfaces.

Relatively few large stoker-fired boilers have recently been installed in utility plants, and the question may arise as to comparison with pulverized-coal firing for conditions such as encountered at Omaha. At time of selecting firing method, no experience was available with burning of Omaha's basic coals in the pulverized form, under a boiler operating at high steam pressure and temperature. On the other hand, experience in this plant over a period of years with relatively large traveling-grate-fired boilers had been quite satisfactory, combustion

[1] Consulting Mechanical Engineer, Ebasco Services Inc. Mem. A.S.M.E.

[2] "Superposed Extension to Omaha Station of Nebraska Power Company," by Louis Elliott, Trans. A.S.M.E., vol. 60, FSP-60-13, July, 1938, pp. 418–419.

losses and stoker maintenance being low. Investment for a stoker-fired unit was estimated as lower than if powdered-coal equipment had been used, particularly considering that the dust-collecting problem for the latter would have been more difficult.

The slagging troubles that have been experienced with this steam generator, and especially with the superheater, have been more severe than on the older equipment, probably because of higher steam, gas, and metal temperatures required. However, while opinion might be held by some that these slagging troubles would have been less if pulverized coal had been used, there is as yet no experience to assure such a difference, particularly considering the much larger weight of ash carried up through boiler and superheater.

No circulation troubles have been experienced in boiler or furnace walls or arches, and the traveling-grate stoker has developed no operating or maintenance difficulties, notwithstanding its great size. Boiler water is conditioned to maintain an average pH value of 10.7, while keeping total solids at 250 ppm and total alkalinity at 75 to 100 ppm. A ratio of 0.5 between sulphates and carbonates is normal.

Air Heaters—Feed Pumps

Corrosion and plugging of the air heater at the top of the inlet side of the rotating element results from the sulphur and moisture content of coal. This necessitated installation of a by-pass around the air heater to permit cleaning. The upper 4-in. portion of the regenerative surface has been modified and is now made up of elements with corrugations designed to give a freer gas travel, and bound together in groups so as to permit ready removal of a corroded or fouled surface and substitution of new or cleaned sections.

The shaft of one of the 3600-rpm steam-driven feed pumps failed completely. The majority of opinion is that this resulted from imperfections in shaft material.

High-Pressure High-Temperature Superimposed Installations at Waterside Station

By J. C. FALKNER, NEW YORK, N. Y.

ADDENDUM[1]

FOR the last 2 years, high-temperature high-pressure equipment has operated at the Waterside Station. One Westinghouse 53,000-kw unit went into service September 10, 1937, and one General Electric 53,000-kw unit went into service June 29, 1938. Both units operate at 1200 lb pressure 900 F temperature, 3600 rpm and have hydrogen-cooled generators. Both units have a feed-heating turbine attached to the main-turbine shaft. Four Combustion Engineering Company boilers of 500,000 lb of steam per hr capacity are used; two boilers per turbine. There is no cross connection between the steam lines at the boilers or turbines; however, the boiler-feed-pump discharge headers are cross-connected.

At the present time, 52 old 650-hp 200-lb boilers are operating. These boilers are necessary for load on the station and also to supply the demand steam to the New York Steam Corporation. The heat rate on the station for both high- and low-pressure boilers taken from the weekly station-performance records for the months of October and November, 1939, shows an average Btu rate of 13,676.

Operating Record of Turbogenerators

There has been considerable trouble with the high-pressure equipment and many changes were made to the original installations before finally arriving at a satisfactory operating condition. With reference to the turbines, two rows of impulse blades of the Westinghouse unit were removed after a few weeks of operation at the request of the Westinghouse Company because of trouble on other machines. This unit operated as a straight reaction turbine from the time the impulse blades were removed until it was rebuilt in July, 1939, with practically no operating trouble. This turbine had to be completely rebuilt after the breaking of the coupling attached to the shaft on which is located the main thrust bearing. This break allowed the turbine rotor to change its position so that the high-pressure dummies rubbed and seized,

[1] Presented in connection with the contribution appearing on page 241 of this issue.

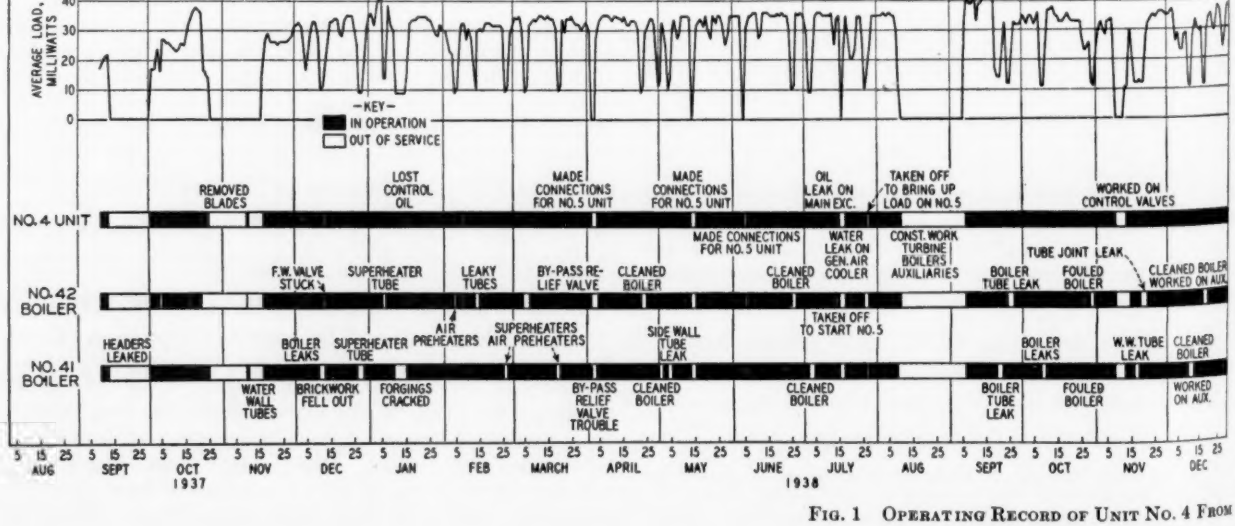

FIG. 1 OPERATING RECORD OF UNIT NO. 4 FROM

causing an outage from March 11 to July 4, 1939. The General Electric unit has not been opened since it was installed.

The Westinghouse unit has generated 420,000,000 kwhr and has an availability factor of 78.5 per cent. Since this machine was put back into service for regular operation on July 4, 1939, the availability factor has been 99.1 per cent.

The General Electric unit has generated 355,000,000 kwhr and has an availability factor of 95.7 per cent. Since July 1, 1939, the availability factor has been 99.2 per cent.

Both units have steam admission at full periphery. The Westinghouse unit has carried a maximum load of 49,000 kw; the General Electric unit 51,000 kw. At present, these units operate at 48,000 kw due to a high back pressure at the turbine exhaust. This is a temporary condition caused by pipe-line changes necessary for the addition of two high-pressure units, one to be installed in 1940 and the other in 1941.

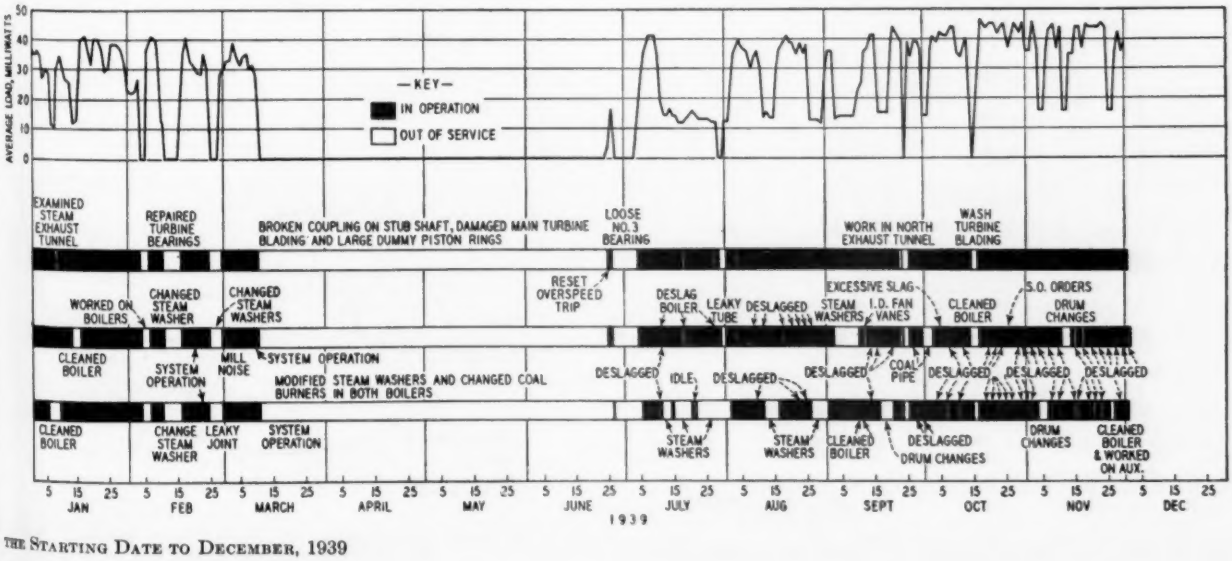
The hydrogen-cooling equipment on both generators has given no trouble to date.

Figs. 1 and 2 show the operation of units Nos. 4 and 5 from their starting dates to December, 1939.

Performance of High-Pressure Boilers

Two of the four Combustion Engineering Company boilers went into service September 10, 1937; one on June 29, 1938; and one on July 25, 1938. The availability factors for these boilers have been as follows:

No. 4A boiler	79 per cent
No. 4B boiler	81 per cent
No. 5A boiler	82 per cent
No. 5B boiler	88 per cent



There has been circulation trouble on these boilers in the sectional headers, side-wall and superheater tubes. During the first few months of operation there were two side-wall-tube failures; this trouble was cured by welding sectionalizing plates in the intermediate waterwall headers. No trouble has been experienced with these tubes since the sectionalizing plates were installed. One superheater tube in No. 4A boiler ruptured; it was found that the trouble was caused by improper alignment of the superheater. The trouble was eliminated by reducing the space between the superheater tubes and the boiler side walls by the use of Fahrite plates.

Circulation trouble in the sectional headers developed as soon as the boilers were brought to full rating. These sectional headers are made up of 4-high and 3-high sections placed alternately across the boiler. Trouble developed on both the 4-high and 3-high header tubes, the failures being due to the overheating. Because of load conditions, it was impossible to make changes at that time so that the boilers were operated at 1150 lb pressure with a maximum rating of 450,000 lb of steam per hr, at which rating no circulation trouble was experienced.

Later, there were many experiments made by installing orifices or restrictors in the sectional headers and tubes; and changes were made to the baffling in the drum. These changes consisted of removing the screen-type washers, Fig. 3, which were originally installed in the boilers for the Westinghouse unit, and installing bubble-type washers in their place. Another change consisted of a scoop kicker baffle over the 3- and 4-high sectional header downcomer tubes in the drum. Another change was a partition baffle.

Several of these arrangements are illustrated in Figs. 4, 5, and 6. The present arrangement in the drum, Fig. 7, which was made about 2 months ago, consists of separate straight kicker baffles in front of the downtake tubes to the sectional headers. These kicker plates make use of the velocity head as well as the static head of the water in the drum, at the same time the steam is released upward. Also, three additional screens were placed in the drum ahead of the six original drying screens in order to help in the elimination of carry-over. Tests indicate that a total solid concentration of 800 ppm can be carried without excessive carry-over. The boilers are now operated at full load, full pressure, and full temperature, with a total solid concentration averaging 450 ppm.

Extensive tests were made on these boilers after each change was made in the drum, and thermocouple readings were taken on each of the top tubes of the 3- and 4-high sectional headers. These thermocouple readings showed many variations. At times there were no hot tubes but an excessive carry-over and vice versa. Temperatures as high as 850 F were shown, the saturation temperature being 580 F. Hydrogen readings checked the high tube temperatures, indicating that dissociation was taking place. Also the carry-over was checked by the steam-temperature-recording chart and by a sensitive cell placed at the turbine exhaust; density readings were taken by measuring the head of water from the boiler drum to the mud drum. Unless further circulating trouble develops no further changes will be

The Starting Date to December, 1939

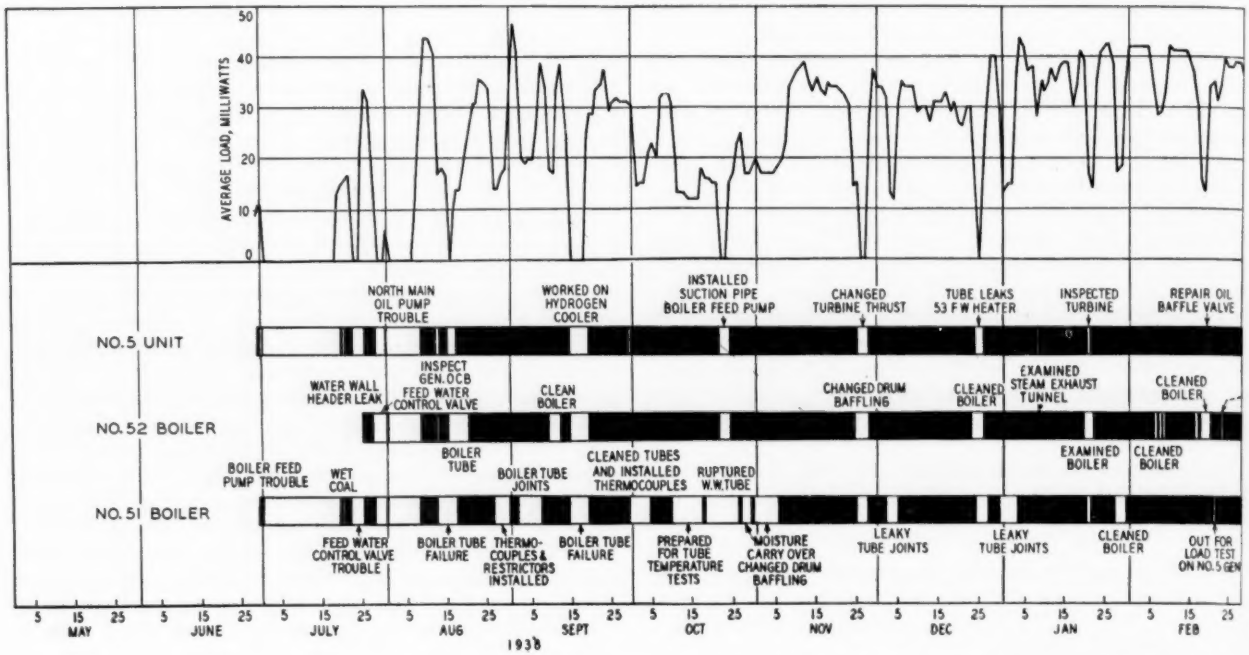


FIG. 2 OPERATING RECORD OF UNIT NO. 5 FROM

made in these boilers, although there are several schemes which have been advanced.

Considerable rerolling of tubes has been necessary since these boilers were put into operation, but the number is gradually diminishing so that at the present time it is seldom necessary to reroll a tube.

A continuous blowdown system is used on these boilers so that any desired concentration can be held within close limits.

Trouble has been experienced with burner tips. This trouble has been partially eliminated by decreasing the drop through the mill classifier from 2 to 3 in. which increases the primary air to the burners. This reduced the fineness of the coal from 80 to 76 per cent through a 200-mesh screen. It is felt that this reduction of fineness will not cause an increase in slag troubles and that the increased primary air will reduce burner maintenance. This change also reduces milling costs.

No trouble has been experienced with the use of gas for starting the boilers except in the case of the electric glo-bars used in igniting the gas. They have been a continuous source of trouble

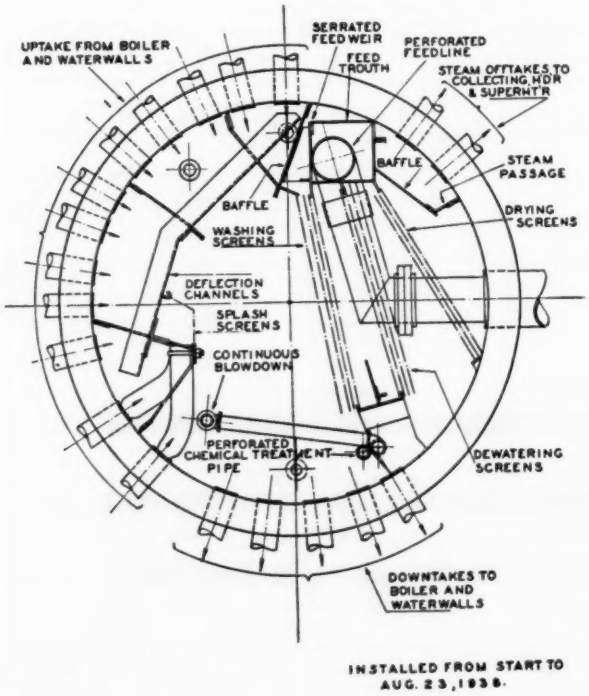

FIG. 3 ORIGINAL ARRANGEMENT OF DRUM STEAM WASHER

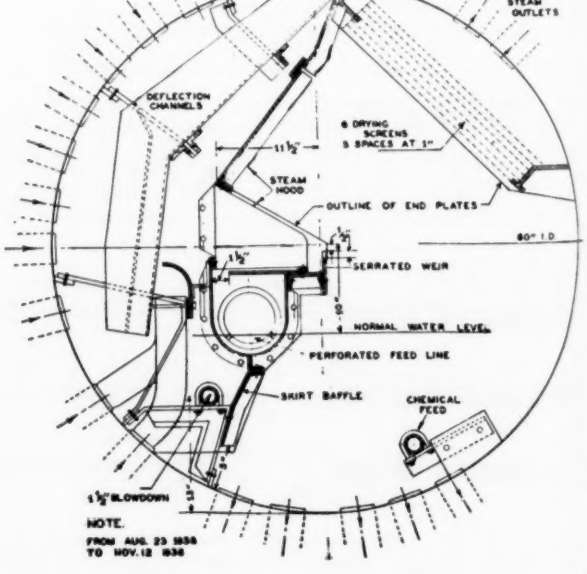

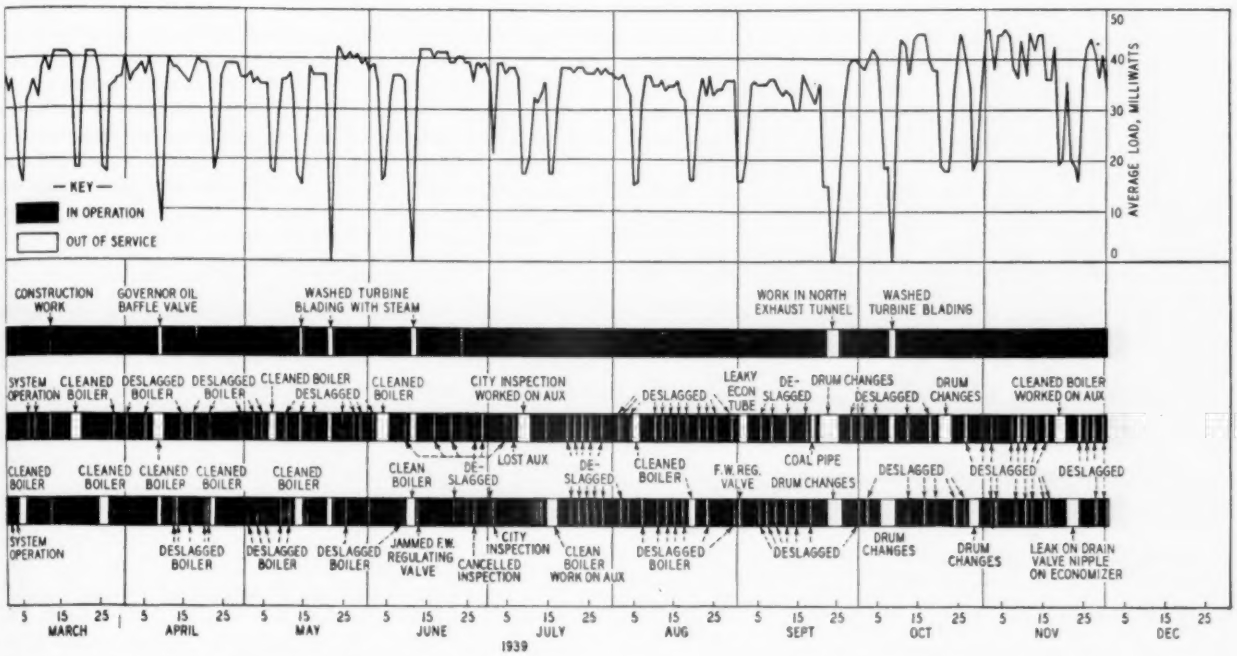

FIG. 4 TYPICAL ARRANGEMENT OF DRUM STEAM WASHER IN AN EARLY INTERMEDIATE STAGE

THE STARTING DATE TO DECEMBER, 1939

and an engineering study is being made to remedy this condition.

The continuous slag-tap arrangement has given very good service. There have been a few instances, however, where due to a change of coal, a great quantity of slag suddenly poured over the slag spout which necessitated taking the boiler off the line on two occasions, and only quick action on the part of the operator prevented another shutdown.

The cleaning of the boilers, superheaters, and furnace walls has developed into quite a problem and it is found necessary under present operating conditions to take one of the four boilers off the line for a 2-day period of cleaning every 4 weeks. In addition, there are three men per watch of 8 hr each who are continually occupied in keeping slag off the boiler and superheater tubes. An engineering study is being made for the installation of retractable soot blowers to aid in the elimination of slag formations.

In addition to the Bailey meters, gas-sampling lines for each boiler were run to a central point on the operating floor whereby the operator can take snap samples of CO_2 in the boilers. It has been necessary on a few occasions to reduce the load on

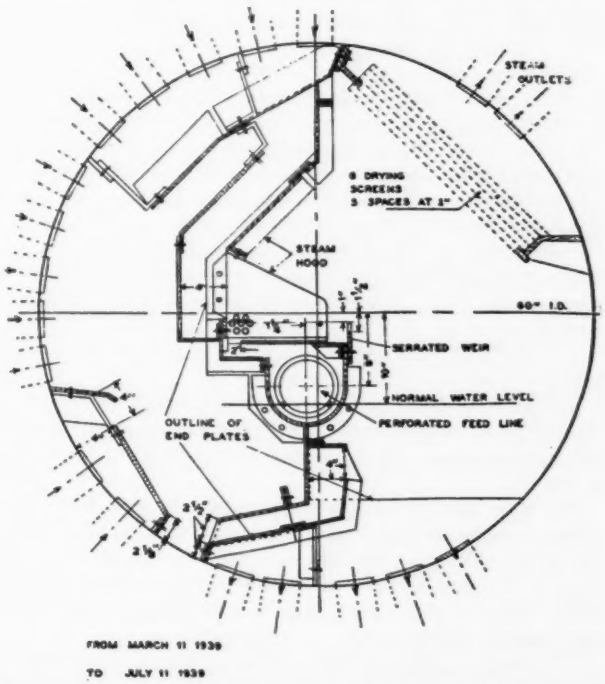

FIG. 6 TYPICAL ARRANGEMENT OF DRUM STEAM WASHER IN A LATER INTERMEDIATE STAGE

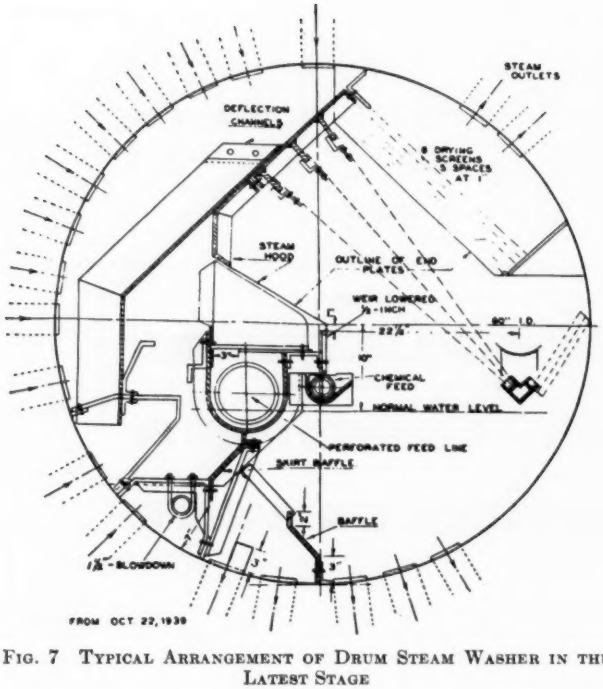

FIG. 7 TYPICAL ARRANGEMENT OF DRUM STEAM WASHER IN THE LATEST STAGE

boilers from time to time when it was found that the CO_2 was increasing to a point where the temperature would further aggravate the furnace conditions. At the boiler outlet, CO_2 is held at 14½ per cent.

The carry-over from the boilers is relatively small and cannot be read accurately on any meter but, over a period of months, there is a gradual fouling of the turbines which necessitates washing. This washing is done by admitting 200-lb saturated steam to the turbine and operating it for a period of several hours, care being taken not to cool the turbine down at a rate of more than 100 F per hr. These washings have resulted in bringing the machine back to normal.

Preliminary tests have been made on the quick pickup of these boilers and additional tests will be made to see what effect a sudden swing on this station will do to the boilers, particularly the water level. Preliminary tests indicate that no trouble will be experienced. The tests were made by running the General Electric turbine on one boiler and reducing the steam output of the boiler from 500,000 to 400,000 lb of steam per hr and then increasing the load on the turbine by rapidly operating the turbine control governor to the load corresponding to 500,000 lb of steam on the boiler. This test was repeated at 400,000 and 350,000 lb of steam per hr. An increase of not over 1 to 1½ in. water level in the boiler was experienced which is not considered dangerous. Additional tests will be made.

The pulverized-fuel mills have operated satisfactorily and no trouble has developed other than the usual maintenance, such as the replacement of mill rollers and rings after their normal expected life.

The other auxiliaries, such as air preheaters, fans, boiler feed pumps, precipitators, etc., have given some trouble, but nothing out of the ordinary. The slag conveyer from the pit under the boiler to the slag hopper has had a high maintenance, and another method of slag removal will be installed on the boilers for No. 3 and No. 4 high-pressure turbogenerators.

A Zeocarb system for water softening, having a capacity of 600,000 lb per hr, was put in service 2 months ago. This system is used for make-up to the high-pressure boilers when steam from the exhaust of the high-pressure turbines is sold to the New York Steam Corporation. This water has amounted to as much as 25 per cent of the total water to the high-pressure boilers.

On the whole, as indicated by the availability factors on the turbines, boilers, etc., even with the trouble as indicated, the high-pressure equipment at Waterside Station has operated in a satisfactory manner and it is felt that, since the boilers can now be operated at full capacity, an even better operating record will be made.

Discussion

E. G. BAILEY.[1] With respect to boiler operation, the papers and discussion have repeatedly developed three general points as being troublesome in the case of some of the units covered in the operating experiences of the last two or three years. The design of these units dates back to 1936, when a diversity of topping units was purchased, many for limited space conditions and other requirements beyond the experience of either engineers or manufacturers.

The three points most frequently mentioned are boiler circulation, carry-over in the steam, and slag. While the principles of circulation have been well known for a long time, there were many limitations in certain specific cases, such as a strong urge for a cheap unit and cramped space conditions, which resulted in unsatisfactory installations. These, however, have been rectified in situ, and some units, installed simultaneously with those, have been free from any circulation difficulties. We feel that the designs which are now being installed will definitely be free from circulation difficulties.

There are times when impurities in the water and the formation of scale are the cause of failures. It is believed that users and manufacturers will be able to distinguish between the different causes, and each will be able to meet satisfactorily the requirements and prevent outages due to tube failure in waterwalls and boilers.

The second point, impurities in the steam, is also well along toward a much improved solution, through the use of improved baffling and steam cyclones in the steam-and-water drums. These have been installed in a sufficient number of places, under enough conditions, with different water analyses, to assure us that the steam can be made quite clean and, furthermore, that the steam can be separated from the water, as well as the water from the steam.

The third point, slag, is one which cannot be so quickly summarized, because there is a diversity of coal and ash, with as widely varied characteristics. However, a great deal has been accomplished in the last 2 years toward surveying this condition more accurately and critically. It is believed that the improvement in furnace design is along the direction in which the slag problem will be kept within limits for satisfactory operation, at a minimum of cost for initial design, slag-cleaning equipment, steam consumption, and man-hours.

C. C. BALTZLY.[2] The high-pressure installation at our Schuylkill Station consists of two Combustion Engineering Company, 600,000-lb per hr tangentially fired boilers, supplying a Westinghouse 50,000-kw 3600-rpm high-pressure turbine at 1250 lb gage pressure and 900 F temperature, which exhausts into a low-pressure header at 230 lb per sq in. gage pressure and 550 F temperature, supplying low-pressure units having a combined capacity of 85,000 kw.

[1] Vice-President, The Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

[2] General Superintendent of Station Operation, Philadelphia Electric Company, Philadelphia, Pa. Mem. A.S.M.E.

Boilers. Initial operation of the two high-pressure boilers began in September, 1938, and during the first year operated approximately 80 per cent of the total time. Considerable trouble was experienced with the bunker-C fuel-oil burners installed for starting purposes, but this was finally corrected by installing a burner which has a fan-shaped spray employing either air or steam for atomization. Firing rings with directional air vanes are used with this burner. The boilers are fired with pulverized fuel, but the oil burners were used for a period of 1 month with an operating economy within $1^1/_2$ per cent of that obtained with pulverized fuel. The maximum rating obtained with 8 of these burners per boiler was 420,000 lb of steam per hr. No detrimental effects were noticed throughout the boiler system.

Leaks in the economizer-tube bends have been encountered, caused by faulty fabrication. These leaks were repaired by gas welding.

Leaks in the water-column connections to the drums and flanged joints on the superheater-outlet headers were found to be due to improper bolting materials. These were replaced with chrome-molybdenum-tungsten A.S.T.M. 193 Symbol B-13, which have proved satisfactory.

One floor tube failed due to erosion of iron in the slag and impingement of flame on the tube. The burner angle was changed, and no more trouble has been encountered.

On both boilers the fins on the floor tubes around the slag spout burned off, allowing the slag to come in contact with the tubes. A water-cooling coil was installed around the slag spout, and the slag level was increased from 2 in. to 4 in. over the entire furnace floor.

After about 2 months' operation, the beams supporting the economizer in both boilers were found cracked and broken. These beams were made of Fahrite material and were replaced with beams of the same material, but were heat-treated for less brittleness. No more failures have occurred.

Difficulty was experienced initially in maintaining the steam temperatures below the maximum operating limit of 925 F, at ratings over 500,000 lb of steam per hr. The following steps were taken: (1) Removed kicker baffles between the superheater and first bank of generating tubes; (2) lowered the front baffle 24 in.; (3) removed every other tile in the top row of the baffle below the superheater by-pass damper. However, it is still necessary to water lance the furnace walls and air lance the front bank of generating tubes daily to keep the steam temperature within the controlling range of the by-pass damper.

Trouble was experienced with the carry-over when injecting a chemical solution at a rapid rate into the rear drum. This trouble was overcome by injecting a more dilute solution over a more extended time. Expected performance on the screen-type washers was not to exceed 2 ppm carry-over at 600,000 lb per hr with 500 ppm drum concentration. Boiler concentration is now being held below 300 ppm for total dissolved solids and the carry-over is running around 1 ppm. In an additional effort to improve the carry-over condition, 37 of the steam-circulating tubes between the two upper drums were removed.

The Raymond bowl mills, each of 15 tons per hr capacity, based on 72 grindability coal, have given satisfactory service.

The fan blades, however, have to be changed after about 15,000 tons of coal. Different kinds of material were used, but it was found that the soft-steel blades have proved most effective.

Considerable trouble has been experienced with the cast-iron burner boxes, which have the Fahrite material tips. Two boxes have recently been installed made of steel plate having the plate extending through the Fahrite casting so that if the joint between the Fahrite and the box becomes loose there would still be no leakage through the joint. These were installed only a short time ago, so we are unable to say how successful they will be.

No. 3 Turbine. The high-pressure turbine was operated initially on September 14, 1938, without the impulse blading and the generator was cooled with air. The maximum load with these conditions was 42,000 kw.

Shortly after the initial operation, a severe rubbing was noted during the starting-up period. The turbine was dismantled and the spindle returned to the manufacturer's shop. The radial seals were found to be worn about 0.05 in., and the low-pressure shaft seals were worn and pitted. New radial and shaft seals were installed at that time. Considerable trouble has been experienced in the operation of the various governing devices. The machine is now operating satisfactorily on the back-pressure control and load-limiting device. The speed-governing mechanism is not yet functioning satisfactorily.

On two occasions, outages were caused by thrust-bearing failures, necessitating the installation of new thrust blocks. Changes in the design of the oil circulation were made to correct this condition.

In February, 1939, the unit was dismantled for installation of the impulse blading with full peripheral steam admission. The axial and radial sealing strips were found badly worn, 3 first-stage nozzles were found broken, seals were damaged, and several valve seats were found loose. The unit was returned to service on April 27, 1939. Hydrogen cooling was installed at that time and the machine was loaded to 50,000 kw.

The internal inspection at that time disclosed a heavy chemical deposit on the last 6 stages. Water-spray nozzles have been installed to permit washing of the blading with the turbine in service. Tests had indicated that the deposit could be removed by hot water or saturated steam.

In order to determine any indication of further fouling of the blading by chemical deposit, a daily check has been maintained on the drop in pressure from the impulse chamber to the turbine exhaust for any given load, and is compared with a prepared curve of standard performance. A gradual increase in this pressure drop indicated that washing of the turbine was warranted, and this was done on October 15, 1939.

Washing was carried on with the machine in service with about 1000 kw load. The machine was out of service about 10 hr for other necessary work, and the casing reached a temperature of about 700 F. Before the throttle was opened, the steam temperature was reduced by desuperheating to about 680 F. The machine was brought up to speed and synchronized in the normal manner with 1250 lb pressure steam at this reduced steam temperature. Desuperheating water was gradually increased until the steam ahead of the turbine throttle reached a condition of 10 deg superheat. Under this throttle steam condition, the exhaust steam was found to contain about 1 per cent moisture, and a conductivity cell in the exhaust indicated that the deposit was being removed. These steam conditions were then maintained for a 5-hr period, at which time it was indicated that the washing had been completed. The steam temperature was gradually brought up over a 3-hr period to normal throttle temperature. The water washing indicated a decided improvement in performance, and preliminary tests indicate that the machine is about 2 per cent better than the guaranteed performance at 50,000 kw load.

Pressure-Reducing Valves. Considerable trouble has been experienced with the pressure-reducing valves due to excessive vibration. Each valve was designed for 600,000 lb per hr flow, and is now limited to 400,000 lb per hr, and new valves of larger design will be installed.

Tank Pumps. Tank pumps are used to pump the plant water from an atmospheric deaerator to the boiler-feed-pump suction at about 450 lb per sq in. The submergence of these pumps is 30 ft. Three such pumps are installed. Three failures of

tank-pump shafts have been experienced, and these were replaced with shafts of heavier construction.

Drip Pumps. Three shaft failures were experienced on the 2 drip pumps. The failures were due, apparently, to too light a design and also to a highly fluctuating supply of water from the flash tank. The water supply to the pumps was steadied by resetting the drainer on the flash tank to operate within closer limits. The new shafts were of a heavier design.

Boiler Feed Pumps. Three turbine-driven boiler feed pumps are installed. Considerable trouble was experienced with shaft packing. Cooling water fed to the lantern gland apparently corroded the gland and attacked the shaft sleeve. Elimination of water feed to the lantern gland and substitution of a flat metal ring in place of the lantern gland have removed that source of trouble.

Leaking joints on the balance drum and stuffing-box bushing have occurred from time to time. The original copper (asbestos-insert) gaskets have been replaced by solid-metal gaskets.

On two occasions, a check valve on the pump discharge failed to close when the pump was taken out of service, resulting in reversing the pump and slight damage to the thrust bearings.

Automatically operated recirculating valves were provided to limit the minimum flow to 100,000 lb per hr, and these have given satisfactory service.

Deaerators. The atmospheric deaerating heaters have given very good service, and no trouble has been experienced in maintaining feedwater with zero oxygen content.

Evaporators. Double-effect evaporators are used which utilize steam bled from the high-pressure boiler-feed-pump turbines. Either effect can be run separately as a single-effect evaporator. A great deal of trouble has been experienced with the performance of these evaporators. Cracking-down was not sufficient and it was necessary to clean the coils by hand. Since that time, the shell water has been continuously treated with soda ash and city water has been used in place of river water, with a continuous blowdown of about 20 per cent.

Tests are being run by the manufacturer to determine whether or not these evaporators can be kept clean by the cracking-down process, without chemical and evaporating river water. However, we are of the opinion that this cannot be done, and plans are being made to install a zeolite softener ahead of the evaporator.

In conclusion, it is felt desirable to point out the fact that the difficulties encountered with this high-pressure high-temperature installation have been no greater than would normally be expected in placing another plant in operation where the steam conditions were of a more moderate nature.

C. B. CAMPBELL.[3] In this Power Panel discussion frequent reference has been made to the matter of carry-over from the boiler, with the resulting scale deposits in the high-pressure turbines. Deterioration of turbine capacity and efficiency have been mentioned. These are the obvious effects of restricting steam passages through the turbine blading. Of even greater importance, however, is the fact that depositing scale through part or all of the turbine blading changes the pressure distribution and, therefore, the net axial thrust on the rotor. This was the fundamental cause of the two thrust-bearing failures on the Schuylkill Station turbine mentioned by Mr. Baltzly.

It is evident from inspection of several installations that carry-over and blade deposits can be controlled so that washing is seldom, if ever, required. This entails constant vigilance, as once scale is deposited it will not be removed again by normal operation. In isolated cases, deposits have been cleared by shutting down long enough for the turbine to cool. The washing process, one scheme for which was described by Mr. Baltzly, has proved effective and may be safely performed when carefully planned and executed.

First-stage blade failures have occurred in high-pressure superposed turbines of large capacity, some of which were mentioned in the papers and in discussions. Experimental development is now confirming a logical mathematical analysis of the problem. As the next step in this development and its proof, the writer's company, with the valuable cooperation of the Philadelphia Electric Company, is installing a single-stage turbine at the Schuylkill Station, where superposed-turbine operation will be duplicated at full scale. The method of attacking the problem has been such as to investigate it fundamentally and for applications in the future at steam pressures beyond those with which this symposium was concerned.

J. M. DRABELLE.[4] The value of papers dealing with actual operating experiences with high-pressure, high-temperature stations cannot be overestimated. Theoretical considerations involving so-called studies of performance and economics are one thing but the acid test is "how does it work?" For the Society to have the benefit of actual operating experiences is invaluable.

At the Cedar Rapids Station of the Iowa Electric Light and Power Company, a high-pressure high-temperature topping unit was installed. Originally the boiler was fired with a stoker which proved to be unsatisfactory in performance due principally to difficulties with the high-ash, low-fusion-ash western coal, and also a length factor which resulted in a badly disturbed fuel bed as compared to the fuel-bed performance on smaller stokers. The boiler was changed over to pulverized coal and since that change has been operating with entire satisfaction. The back-pressure control on the turbine has performed satisfactorily.

The principal problem in connection with the operation of this unit is on account of the large amount of steam fed to the central heating system which results in high make-up water. Data on this matter will be developed during the winter season and will be made available to the Society at the next Power Panel discussion.

F. P. FAIRCHILD.[5] The superposed unit at the Essex Generating Station of the Public Service Electric and Gas Company has been in operation approximately 17 months. This installation consists of a 50,000-kw General Electric turbine generator, designed for 1250 lb per sq in., 950 F at the throttle, and two Babcock & Wilcox Company boilers, each having a maximum capacity of 605,000 lb per hr, equipped with Foster-Wheeler Corporation Hardinge mills. The turbine exhausts at a constant pressure of about 225 lb per sq in. into the station header. Addition of this unit has increased the capacity of the station from 193,000 kw to the present 243,000 kw.

The turbine is a 6-valve double-casing machine directly connected to a hydrogen-cooled generator operating at 3600 rpm.

The boilers are of the radiant type, with the generating and superheater tubes arranged essentially vertically, designed for direct pulverized-coal or fuel-oil firing.

During the first 2 months of operation the boilers were fired with fuel oil. Then for a period of approximately 7 months pulverized coal was fired regularly. This has been followed by fuel-oil firing, extending from April 1, 1939, to the present time. The type of fuel used depends upon the current fuel prices.

Considering the total elapsed time since the date of initial op-

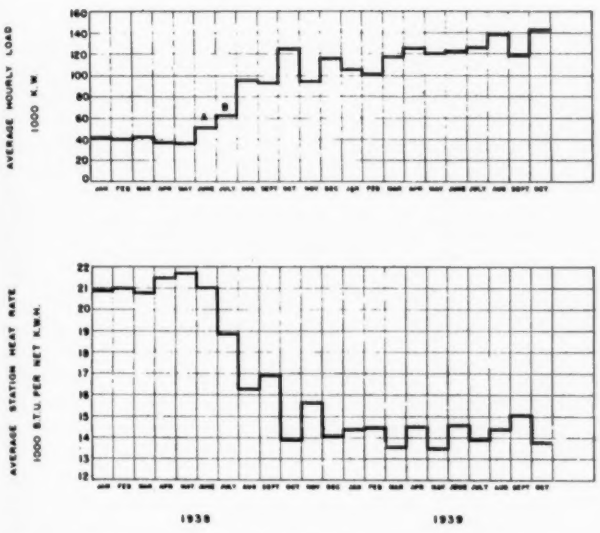

FIG. 1 RELATIVE MONTHLY LOADING OF ESSEX GENERATING STATION AND MONTHLY STATION HEAT RATES
(*A* = High-pressure boilers put into service with reducing value; *B* = high-pressure turbine put into service.)

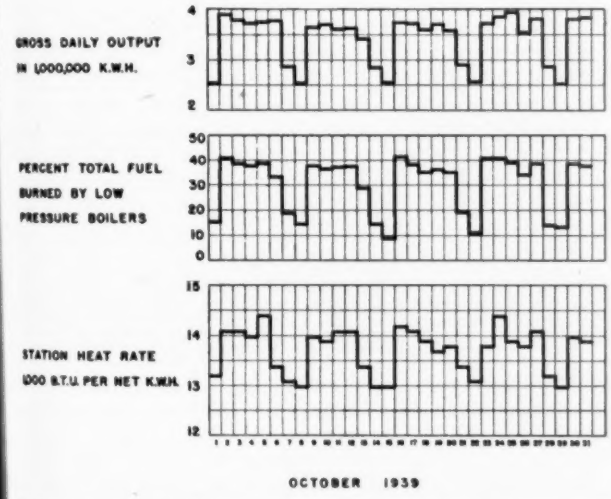

FIG. 2 TYPICAL MONTH'S OPERATION OF ESSEX GENERATING STATION WITH SUPERPOSED UNIT IN SERVICE

eration, the turbine has been in service 92 per cent of the time; the first boiler has been in service 83 per cent of the time; and the second boiler 88 per cent of the time.

Disregarding the first 6 months of operation, which may be considered as a preliminary adjustment period, and considering only operation from January 1, 1939, up to the present time, the turbine has been in operation 97.5 per cent of the time; the first boiler in operation 90 per cent of the time; and the second boiler in operation 91.1 per cent of the time.

Fig. 1 on this page indicates the relative monthly loading of the Essex Generating Station and monthly station heat rates from Jan. 1, 1938, to Oct. 31, 1939. This includes a period before the superposed unit went into service as well as the period since the superposed unit has been operating. It will be noted that the new unit was put into service during July, 1938. The average station heat rate decreased from a monthly average of approximately 21,000 Btu per net kwhr to values of between 13,000 and 14,000 Btu per net kwhr in the most favorable months. As a result of this improvement, the station loading was increased from approximately 40,000 kw to 120,000 kw. The station heat rate depends upon the portion of the total load carried by the low-pressure boilers.

Fig. 2 on this page shows a typical month's operation of the station with the superposed unit in service. The upper curve shows the average daily load throughout the month, the dips in the curve being the week-end periods. The middle curve indicates the portion of the total fuel burned in the low-pressure boilers of the station. The lower curve indicates the average daily station heat rate for the same period.

The unit has operated at the design pressure since the start. However, the steam temperature has been limited to 925 F to build up a background of experience at this temperature before going higher. With superheat control this lower-temperature operation is simply a matter of damper operation. Thus far there have been no indications of trouble from $1^1/_2$ years of operation at 925 F. It is anticipated that the temperature will be raised to 950 F if, at the next inspection of the unit, no evidence of trouble from the present operating temperature exists.

The cover of the turbine has not been lifted for about 13 months, but a complete inspection is scheduled for the spring of 1940.

The boilers, being of a new design, received considerable attention during the preliminary and early operating periods. Extensive testing equipment for measuring circulation, density of steam-and-water mixtures in various parts of the unit, water levels, and temperatures was installed. It is believed that this careful check, carried on principally by the boiler manufacturer, was in a great measure responsible for certain troubles not developing to a point where forced and serious shutdowns might have occurred.

Early operation of the boilers developed several things which were not right. Water-level detectors in the drums showed that levels indicated by the gage glasses were not true levels. Due to the low density and extremely turbulent condition of the mixture in the drums, only a limited rating, about two thirds the steam-water expected maximum, was possible without carry-over. The low-density mixture in the drums also resulted in considerable steam being carried into the downcomer pipes and thus reduced the circulation of solid water. Although there were no tube failures, except a few leaks in shop welds of economizer tubes, the ratings on the boilers were limited to a safe point. Installation of cyclone separators in the two drums of each boiler completely corrected the circulation and carry-over difficulties. Since installation of this equipment, it has been possible to operate the boilers at full load with solids in the steam under 1 ppm at boiler-water concentrations as high as 1400 ppm. Operation with higher concentrations may be possible, but there has been no occasion to carry over 600 ppm regularly.

During early operation, measurements indicated that the temperatures of the top sides of some of the furnace-floor tubes were considerably in excess of the saturated-steam temperature. This was due to steam pockets in the upper part of the tubes caused by insufficient circulation in the relatively flat tubes. Installation of diaphragms in the floor headers to improve water distribution, installation of cores in the floor tubes to increase water velocity, and baffles in the downcomer inlets to reduce the steam-water ratio in the downcomer pipes were inadequate to improve the floor-tube temperature condition appreciably. Solution of this trouble has been the installation of a water-cooled dam at the slag-drip ledge, in order to carry a slightly higher slag level on the furnace floor, with a resulting reduction of the heat input to the floor tubes.

Slagging of the heating surfaces of the unit has not been a serious problem. However, several alterations to the original

soot-blowing equipment have been made to improve the cleaning facilities. The first few rows of close-spaced superheater tubes showed a tendency to bridge across with a spongy form of ash with coal firing. No soot blowers were originally provided for this section of the superheater and, during the early period of operation, steam lancing was necessary to keep these tube spaces open. Later installation of telescopic and retractable blowers at this point eliminated the trouble. Steam at 225 lb pressure is used on most of the soot blowers, but on the superheater by-pass blowers it was found necessary to change to 450-lb pressure steam to provide effective cleaning. Retractable blowers on the furnace walls have proved valuable in maintaining equilibrium conditions in the furnaces.

Recent operation with fuel-oil firing has shown a tendency for the gradual depositing of a hard slag in the first section of the superheater. This slag is made up principally of vanadium oxide and sodium sulphate, and knits very tightly to the tubes. The soot blowers seem ineffective in removing it. It has been necessary to take the boilers from service at about 2-month intervals to hand clean this slag from the superheater tubes.

Thus far no harmful effects of the 925 F operating steam temperature have been found in any of the materials or equipment in the superheated-steam system. As a matter of inspection and to obtain some idea of the effects of $1^1/_2$ years of operation on the superheater-tube material, a section of one of the front legs of a superheater element was recently cut out. Internal inspection of the tube showed no evidence of corrosion, and photomicrographs showed no harmful effects to the metal structure during this period.

As a whole the entire unit, both turbine and boilers, has performed favorably. In the two new plant extensions which this company now has under construction, that is, at the Burlington Generating Station and the Marion Generating Station, equipment of similar design to that at Essex will be installed.

J. C. Hobbs.[6] "Topping" experience over 10 years has convinced the writer that most troubles are chargeable to poor engineering and can be avoided. An analysis of the various reports submitted today on other installations emphasizes a fundamental often overlooked, namely, that the best way to eliminate trouble with a particular feature is to eliminate the feature. It is sometimes possible to eliminate the entire piece of equipment. The writer's experience involving three sets of topping units confirms the great value of this policy. The elimination of those features which have been reported as causing trouble in other installations has made each successive higher-pressure topping unit more reliable than the former, in spite of the greater potential hazards. Briefly, the aim should be extreme simplicity in design, maximum availability for inspection, with a minimum of parts and time required for dissembly.

C. H. Spiehler.[7] The following are the essential particulars of the installation at the Millers Ford Station of the Dayton Power and Light Company, Dayton, O., upon which the writer will discuss the operation experience for the period from September 15, 1937, to September 15, 1939.

The superposed plant incorporates 2 Babcock & Wilcox steam-generating units having an output of 375,000 lb of steam per hr at 1250 lb per sq in. pressure and 900 F total temperature. One 30,000-kw General Electric turbogenerator set is installed operating on 1200 lb per sq in. 900 F steam, exhausting at 230 lb per sq in., and 500 F.

[6] Vice-President, in Charge of Manufacturing, Diamond Alkali Company, Painesville, Ohio. Mem. A.S.M.E.

[7] Results Engineer, Columbia Engineering and Management Corporation, Cincinnati, Ohio. Mem. A.S.M.E.

Originally the low-pressure plant consisted of three 1373-hp boilers delivering steam at 230 lb per sq in. pressure and 550 F (these boilers have been removed); and six 1965-hp boilers having the same steam conditions. Turbine generators include two 12,500-kw, three 20,000-kw, and one 25,000-kw machines, all operating on steam at 230 lb per sq in. pressure and 350 F.

An outline of the difficulties experienced during the first few months' operation of the Millers Ford high-pressure topping plant was given at the Power Panel discussion at the December, 1937, meeting. Those difficulties have been satisfactorily corrected. The reliability of this installation is now considered to be at least as good as that of the low-pressure plant. The turbine was operated for 16 months with only routine maintenance; the internal inspection at the end of that period found the machine in perfect condition. Operating periods of the steam-generating units of 4 or 5 months' duration have been obtained, and the operating department can see no reason why these periods should not be extended to 6 months.

The economy expected has been realized. This plant prior to the installation of the topping unit had a heat rate of 20,000 Btu per kwhr net generated send-out. With the topping unit supplemented by generation from the low-pressure boilers, the heat rate for the first 10 months of 1939 was 15,075 Btu, the best month being 14,000 Btu. The over-all steam-generating-unit efficiency for the 10-month period was 87.5 per cent.

A second high-pressure topping installation is now being made at this station. The new equipment will duplicate the present installation. Changes will be few and of minor nature as follows: The steam-generating units will have more cooling surface in the uptake waterwalls which will be accomplished by installing 2 $^{11}/_{16}$-in-outside-diam tubes between the $3^1/_4$-in-outside-diam tubes which are on 6-in. centers. The only Bailey block to be used in the furnace will be installed on the slope of the downtake waterwalls and below burners. Cyclone separators in the drums will be used in place of the present sprays and baffling.

The forced- and induced-draft fans will have approximately 15 per cent greater capacity. The Cottrell precipitators will have 34 ducts instead of 26 ducts as in the present installation.

Turbine-Generator Operation

The topping turbine was operated until June 1, 1938, with its maximum load limited to 25,000 kw. The present limit of 30,000 kw became effective on that date. During the 2-year period the topping unit has been available 92.37 per cent of the time. It has operated 87.28 per cent of the time and has a capacity factor of 45.09 per cent. Practically all of the inoperative available hours are charged against taking the turbine off to put a high-pressure boiler into service.

When the station load is such that the load on the topping unit is less than 25,000 kw, there normally are no low-pressure boilers in service. The exhaust is regulated manually by the switchboard operator during these periods. As the load on the topping unit approaches 25,000 kw, low-pressure boilers are brought onto the line. Additional station load is picked up by these boilers until they have enough margin to regulate the pressure. Then the topping unit is loaded to its maximum which is normally 29,000 kw. The reverse procedure is followed when the station load is decreasing.

There have been three major turbine outages, as follows:

1 February, 1938; the only indication of trouble was a substantial increase in pressure on the first stage. The turbine was continued in operation under this condition for several days before it was decided to make an internal inspection. Upon inspection it was found that a small section of the first-stage blade shrouding had failed, Fig. 3. The section which had broken away was about $^1/_2$ in. wide and 6 in. long. A 5-blade section

Fig. 4

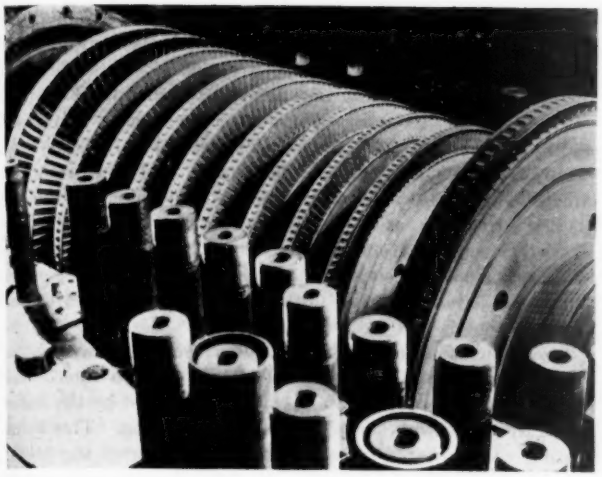

FIG. 3 DAMAGE TO ORIGINAL SHROUDING

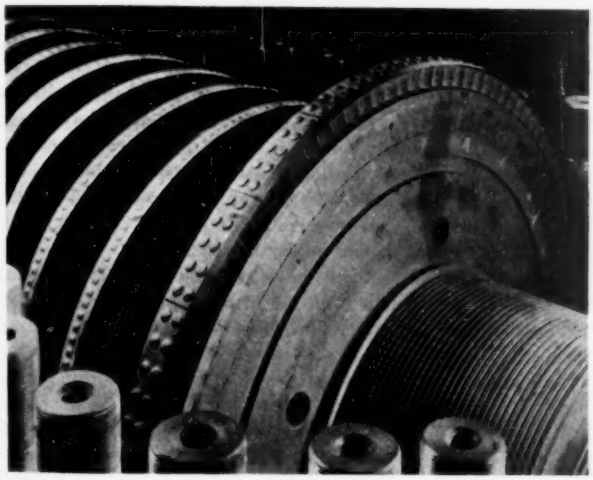

FIG. 4 NEW FIRST-STAGE BLADING AND SHROUDING; SECOND AND THIRD STAGES REBLADED

was attached to the shroud or cover plate by the usual rectangular tenons. New first-stage blading, Fig. 4, was installed with two round tenons and the new shrouding was considerably heavier. The blades on the second- and third-stage wheels had also been damaged and were replaced. Heavy deposits of boiler carry-over were found on the blades in the lower stages. Changes on the economizers and in the drums were completed during this turbine outage, which reduced the solids in the steam to less than 0.5 ppm.

2 This outage occurred in May, 1938, at the request of the manufacturer to inspect the new shrouding which had been installed. Everything was found to be in a satisfactory condition. The blades at this time were free of deposit. No changes were made.

3 An outage occurred in September, 1939, to install a new rotor Fig. 5, having blades with integral shroud caps and shrouding attached to the caps with single rectangular tenons. A change was also made in the high-pressure packing for the purpose of reducing the thrust. The thrust bearing was revamped, as a precautionary measure, to provide greater capacity in both directions.

No trouble had been experienced with the old thrust bearing, although changes were made at the request of the manufacturer.

The turbine was found to be in a satisfactory condition in every particular. The deposit on the blades after 16 months of operation since the last inspection was negligible.

This machine has always operated very smoothly. Vibration has never been a problem.

All other outages have been of a minor nature.

The rotor which was removed, although in perfect condition, is to be changed to duplicate the new rotor and will be used in the turbine now on order.

The only protection provided against overheating with loss of load is the temperature control of the dampers above the economizer passes. This control is designed to maintain 900 F inlet temperature or a maximum of 575 F in the steam leaving the turbine.

The rise in exhaust temperature, when the turbine is taken off the line, does not exceed 100 F.

The back-pressure governor is not used for normal operation.

Hydrogen consumption during this 2-year period has averaged 36.9 cu ft per day. For the month of June, 1939, the consumption went up to 52.8 cu ft per day. With the elimination of leaks, the consumption of hydrogen has been brought down to 25.6 cu ft per day and this rate has been maintained since June.

A reverse-power relay prevents the generator from motoring. The only trouble experienced with the electrical parts of the unit was with the brush holders on the pilot exciter.

OPERATION OF HIGH-PRESSURE BOILERS

From Table 1, it is apparent that boilers No. 7-1 and No. 7-2 would have had an availability of 85.6 per cent and 86.3 per cent, respectively, except for other causes not attributable to the boilers.

Alterations and repairs include changing the economizers from

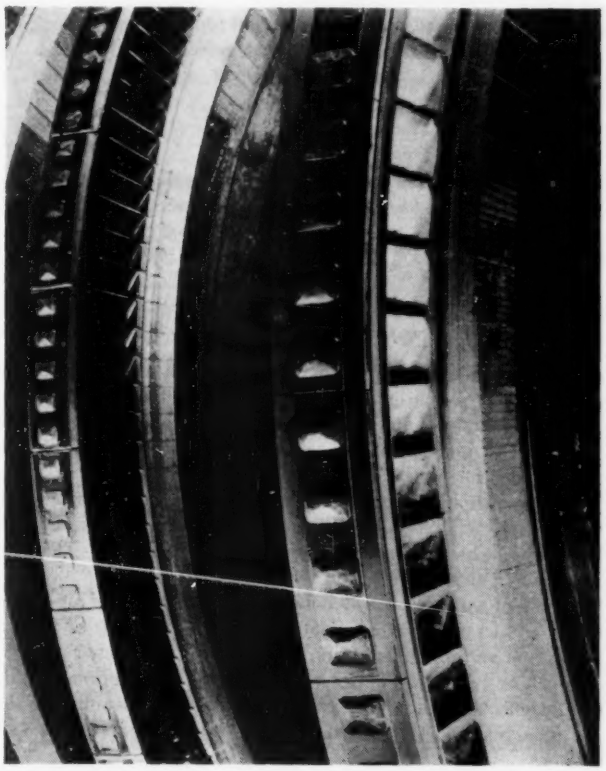

FIG. 5 NEW ROTOR INSTALLED SEPTEMBER 1, 1939, SHOWING NEW-TYPE BLADING AND SHROUDING

TABLE 1 OPERATING RECORD OF HIGH-PRESSURE BOILERS

	Boiler No. 7-1	Boiler No. 7-2
Initial start	May 3, 1937	July 27, 1937
Availability from start to Sept. 15, 1939	Per cent 76.1	Per cent 80.7
Alterations and repairs	14.4	13.7
Tube corrosion	1.7	1.9

Unclassified	1.1	0.8

parallel flow to a combination of parallel-counterflow, changes of the baffles, sprays, etc., inside the drum, seal welding of economizer tubes in the drum and headers, changes in the construction of the furnace corners to obtain a better seal, cap leaks, internal cleaning, etc.

During the first year of operation, heavy sludge and analcite scale formed in the generating tubes and waterwalls. Frequent turbining was necessary. The principal cause of this difficulty was condenser leakage, which could only be corrected by retubing 3 condensers. In the meantime it was decided to use the Akon treatment. The Akon treatment was started July 27, 1938, and was fed at the rate of 2 ppm with a pH of 11 in the boiler water. The next internal inspection disclosed that several of the steam-generating tubes were deeply corroded and had to be replaced. The next inspection about 2 months later showed a similar condition. The Akon was then reduced to 1 ppm and the pH of the boiler water raised to 11.5. Under these conditions the rate of corrosion was materially accelerated. Two forced boiler outages were then caused by tube corrosion. The tubes which blew through were in each instance No. 5 tube in No. 7-1 boiler. The second outage occurred 33 days after the tube had been replaced. The Akon treatment was discontinued March 27, 1939; since that time no further corrosion has been noticed.

At present, the feedwater has a pH of 6.9 and a concentration of 1 ppm of solids. A blowdown of 0.1 per cent maintains a boiler-water concentration of about 150 ppm solids.

A typical analysis of boiler water at present is:

Analysis	Boiler water solids, ppm
SiO_2	10
R_2O_3	2
NaOH	31
Na_2HPO_4	30
Na_2SO_4	35
NaCl	9
Na_2CO_3	3
Organic	16
Total Solids	136
pH	10.6

A United States Bureau of Mines embrittlement tester has not indicated caustic embrittlement to be a problem.

Disodium phosphate is the only chemical added to the feedwater. The addition of a chemical to scavenge oxygen has not, as yet, been necessary.

The operation of soot blower, retractable slag blowers (added to original installation) and hand lancing require one man per 8-hr shift, which operations are generally effective. The coal used has an ash with a fusion temperature of 2850 F.

Traces of corrosion are evident on the upper rows of air-heater tubes on the gas side, air-inlet end. Its extent varies from a fraction of an inch in length on the lower of the affected rows, to as much as 2 ft on the upper row. It is not at all serious and no special effort is made to prevent it. Effective cleaning of the gas passages is accomplished by 6 valve-in-head revolving soot blowers.

The 6 Babcock & Wilcox type-B pulverizer mills have performed satisfactorily. Maintenance has been limited to replacing feeder plates, belts, three pinion shafts and adjustment of ball-spring tension. No balls have been replaced although one mill has pulverized more than 80,000 tons. The original carborundum feeder plates have been replaced with a sectional plate having carborundum imbedded in the metal. This plate wears better and sections can be replaced without a major outage on the mill. Air lines, installed to blow debris from the ledge below the stationary ring, caused trouble and were removed. An inclined plate which guided coal from the spout to the belt on the Richardson scales was moved to a more vertical position to prevent wet coal from arching over and failing to move down to the belt. Mill fineness is generally greater than 80 per cent through a 200-mesh sieve. Mill power varies from 18 to 18.5 kwhr per ton.

Two major failures of the hydraulic couplings have caused forced boiler outages. The first failure was on a forced-draft fan, in which the coupling was demolished, caused by the failure of the thrust bearing, located within the coupling. This thrust bearing was relocated on the outboard bearing of the motor. Trouble with this bearing on an induced-draft-fan coupling caused another outage. This time, however, the damage was limited to the internal thrust bearing.

The gas-burner lighters have been satisfactory in every respect. No trouble has been experienced with the stability of the flame at any load.

Arcing and burning off of electrodes on the electrostatic precipitators was corrected by changes in the design of the electrode shrouds and rapping mechanism. Low efficiency of dust removal was improved by installing baffle plates on inlet- and outlet-gas passages, addition of perforated plates to rod curtains and elimination of gases by-passing the cells by placing vertical baffle plates in each hopper under the cells.

Boiler-feed-pump outages have resulted from trouble with shaft-packing sleeves; erosion at breakdown bushing; leakage at horizontal casing joint, slow leaks from stud hole in casing flange. All outages on the feed pumps were scheduled. The excess-pressure regulators and the 1200-lb 900-F turbine drives have performed satisfactorily.

Carry-over was encountered in the initial operation of the double-effect Foster-Wheeler evaporators. Make-up water, erratic in quality, and in the amount of suspended matter from an overloaded softener, made the internal treatment and blowdown regulation difficult in the evaporators. Lime deposits fouled the steam scrubbers and gill separators.

The installation of a new 5000-gal per hr Cochrane hot-process lime-soda softener, replacing the old smaller softener, now produces a uniform and suspended-matter-free make-up water. A hood placed over the scrubber box eliminates flooding the gill steam-separator chamber. Continuous surface blowdown through a manifold extending across the evaporator shell and weekly cracking with cold water keeps the evaporators clean and free of scale. Internal treatment of Hagan phosphate and tannin is fed intermittently to the suction of the evaporator feed pumps. Carbon dioxide in the second-effect coil severely corroded the copper float of the discharge trap. A stainless-steel float appears to be satisfactory. About 24,000 lb per hr is the usual rate at which the evaporators are operated. With 10 per cent blowdown, the evaporator steam contains less than 1.5 ppm of solids.

The condensate and make-up pass through Worthington deaerating heaters. No trouble has been experienced with the float valves which control the flow of condensate to the heaters. The deaeration is effective. A pressure-reducing valve automatically makes up for any deficiency in the 5-lb exhaust-steam supply to the deaerators.

The high-pressure feedwater heater is a horizontal, lockhead, 4-pass type with $^3/_4$-in-outside-diam, No. 10 B.W.G. arsenical copper tubes. The heater is located on the discharge side of the

high-pressure boiler feed pumps and receives its steam from the boiler-feed-pump turbines exhaust. Most of the maintenance has been caused by gasket leaks and fouling of the water side of the tubes. Slight leaks developed and some of the tubes were rerolled. The pipe flanged joints at the inlet- and outlet-water connections have developed leaks from time to time. Slight grooves have been found in both the male and female flanges at one time or another. These were repaired and the joints seem to hold satisfactorily.

A deposit on the water side of the tubes, about $^1/_{16}$ to $^1/_8$ in. thick, largely composed of calcium ortho phosphate, decreased the heat-transfer efficiency of the cross-over heater. Since the evaporator performance was improved, condenser leakage corrected and boiler-water recirculation eliminated, no appreciable deposits of calcium ortho phosphate have been noted.

The high-pressure reducing valve first installed was unsatisfactory. Excessive vibration caused linkage failures and the fracture of the valve stem. This 6-in. valve was replaced with an 8-in. valve of much heavier construction, the capacity rating remaining the same, namely, 390,000 lb per hr. The new valve has performed in a satisfactory manner but is still noisy. On occasions when the valve is used, it is operated manually by remote control from the boiler control board.

The Bailey 3-element feedwater control maintains a stable water level ever since the changes were completed on the economizer. Before the changes were made the boiler had bad swinging water levels.

The Leeds & Northrup superheat control has performed satisfactorily. The Leeds & Northrup combustion control also performs satisfactorily since the closed manometers using oil were installed in place of the inverted bells. Formerly a deposit formed on the bells, causing the control to become sluggish. With large changes in the turbine load, the change in the pressure drop from the drum to the turbine inlet must be compensated for manually on the master control.

G. B. Warren.[8] To the writer, one of the most significant things developed by the discussion of this subject is that the reliability of the high-pressure high-temperature steam turbine is approaching that of the older low-pressure turbine, at least after the initial difficulties with the high-pressure turbines have been overcome. Availability factors of 96 to 98 per cent have been frequently mentioned.

Surveys of the Edison Electric Institute figures on turbine outage made at intervals have indicated that the outage record of the older high-pressure superposed turbines in service from 7 to 10 years now is better on the average than that of the low-pressure turbines of comparable age, and bear out this recent experience.

Another situation which may be of interest in this connection is that, based upon comparisons which we have made, the present-day materials in these high-pressure high-temperature turbines are being worked more conservatively than were the then available materials in use on lower-pressure and lower-temperature turbines 10 and 15 years ago. This is largely due to our increased knowledge of creep and other properties of materials at high temperature and our definite endeavor to keep within the limitations so imposed. This is quite in contrast to the situation which prevailed in the earlier period, when we had by no means as much information on the behavior of the materials we were then using at the temperatures which were coming into general application.

On the other hand, a word of caution might be in order on the tendency of materials to rupture under low strains when subjected for long periods of time to temperature and stress, a fact which the industry has only recently commenced to appreciate.

A few years ago we thought that the phenomenon of creep gave us an additional safety factor in that it tended to equalize stress, but now we are beginning to learn that, apparently, the excessive localized strains so resulting might be such as to start a rupture which would be hazardous so far as our present knowledge and observation go. Present practice with respect to temperatures and stresses is such we believe, as to preclude any serious consequences from this situation. Extensive studies are under way in the writer's company and in other places to accumulate additional knowledge relative to this situation. In the meantime, all designs are being scrutinized with this factor as well as the creep situation in mind.

The first-stage-bucket situation and, from the standpoint of the writer's company, the first-stage-bucket-cover situation primarily, have been matters of considerable concern. We feel, however, supported now by considerable operating experience on several turbines, that this situation is well in hand.

Louis Elliott.[9] Concerning experience at Deepwater Station of the Houston Lighting & Power Company, at Houston, Texas, during 1932 a topping extension was put into operation in this plant, which previously contained 135,000 kw in 325-lb turbines; this was among the earlier examples of high-pressure superposition plants. As the installation has been described both in technical papers and press, the present discussion is brief.

Equipment includes a 12,000/15,000-kw 1260-lb 710-F turbine, with steam-to-steam reheat in condensing and thoroughfare heaters, raising high-pressure turbine exhaust to temperature of steam in low-pressure header. Steam-generating plant comprises two 375,000-lb per hr 1350-lb 850-F gas-fired boiler units with economizers and air heaters. In 1930, when engineering on Deepwater extension was under way, American experience with utilization of temperatures above 750 F was quite limited, and manufacturers were not offering as standard equipment turbines adapted to a temperature much higher than this.

One or more low-pressure boilers are always in operation, supplying 325-lb steam "in parallel" with exhaust from topping turbine. An automatic by-pass is provided around high-pressure turbine, and this has functioned successfully upon the few occasions when the machine has tripped off.

Both boilers and turbines have shown good availability, and have been run under high average loads; contributing to this possibility has been large capacity upon which high-pressure unit is superposed. Boilers have shown outage hours, largely occasioned by necessary work on these units, totaling less than 6 per cent over recent 4.5-year period; there has been only about 4 per cent boiler outage during the last year. Turbine outage has averaged 1.4 per cent in same 4.5-year period, and less than 0.3 per cent during best year. For entire time since installation was placed in service, outage of high-pressure boilers has averaged about 12 per cent, and of topping turbine approximately 6 per cent of elapsed time, largely due to work on unit in first year.

Total generation by high-pressure unit since 1934 has aggregated 500,000 megawatthours, equivalent to an average generation of 12,800 kw (when operating); this means a unit output factor of 106 per cent based on 0.8 pf rating, or 85 per cent based on 1.0 pf rating. For the entire operating time since early in 1932, the average generation has been 11,900 kw, or nearly the 0.8 pf rating.

Lower availability of boilers and turbine during first year of operation resulted from the usual difficulties incident to starting

[8] Designing Engineer, Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

[9] Consulting Mechanical Engineer, Ebasco Services, Inc., New York, N. Y. Mem. A.S.M.E.

up new equipment, and from a variety of troubles, caused particularly by the high pressure and by the limited experience of manufacturers in designing equipment for high-temperature high-pressure service. Apparatus troubles were experienced with heat exchangers, boiler feed pumps, and feed-line gate valves. High-pressure piping joints, which were of the flange type and of special carefully worked out design, were unusually successful; however, considerable trouble was experienced with high-pressure joints in equipment until proper operating procedures were developed. The record since 1934 shows that the early difficulties have been corrected, and details concerning them would hardly be worth giving at this time.

In view of blading deposits in low-pressure turbines when higher boiler concentrations were permitted, total solids in boiler water are now kept at about 400 ppm, with 100 ppm total alkalinity and 10.8 pH value. Silica is maintained at or below 15 ppm, and it has been found practicable to maintain sulphate carbonate ratio of 3:1.

Mr. Sporn's Closure

The discussions of the papers on "Two Years' Experience With High-Temperature High-Pressure Stations" confirm my informal introductory remarks at the Annual Meeting of the A.S.M.E. in Philadelphia. They show that this group of stations or units which had initially been thought of as ultradaring has become almost commonplace because of their gradual and natural integration with their systems until they are just other stations or units on the line. This is most gratifying. But let us not forget that they now can serve as another starting point for further advances in the art of power generation, advances that must and will proceed inevitably, regardless of the reluctance of any company or group of companies to keep up with progress.

Characteristics of Cloth Filters on Coal Dust–Air Mixtures

By A. R. MUMFORD,[1] A. A. MARKSON,[2] and T. RAVESE,[3] NEW YORK, N. Y.

This paper deals with the installation, operation, and maintenance of cloth filters for handling vented air from pulverized-coal mills. The experiences of the authors in solving problems in connection with the cloth-bag filter system, as used at the Kips Bay Station of the New York Steam Corporation, are the basis on which the subject is developed. Complete performance tests on a 40-ton-mill installation are cited.

TWO INSTALLATIONS of cloth filters have been successfully handling the vented air from two large pulverized-coal mills at the Kips Bay Station of the New York Steam Corporation for nearly three years.

In the application of such equipment to power plants, the magnitude and variation of the draft loss, when related to the frequency of the shaking cycle and to the capacity, assume greater importance than in smaller applications for air cleaning and, therefore, have been very carefully investigated.

Similarly the required maintenance is of greater importance because of the interdependence of the mill and other plant equipment and therefore this item has also been examined.

The presence of a fire hazard in the handling of combustible air mixtures adds to the complexity of the design and operation so the safeguards taken in the design and installation at this plant will be indicated.

Description of Plant

The Kips Bay steam plant was erected in 1926. The station was laid out for the storage system and this design was continued in the 1927 and 1930 extensions.

The millhouse contains seven pulverizing mills with a total capacity of 150 tons per hr. Raw coal entering the millhouse contains about 3½ per cent moisture and of this 2 to 3 per cent is removed in the process of preparation. The coal is dried in external-grid driers, using exhaust steam for four mills while in three mills the coal is dried in the mill by air heated by high-pressure steam in air heaters. Air circulated through each mill system conveys the pulverized coal to the primary cyclone where separation of the coal and air takes place. The conveying air is vented to the atmosphere through a secondary cyclone and dust washer. The air-flow circuit for the 25-ton ball-type mill is given in Fig. 1.

One to two per cent of the coal milled may escape with the air vented from the primary cyclone and 0.25 to 0.5 per cent may escape from the secondary cyclone. For further reduction of the discharge concentration, air washers have been generally used. The use of washers brought secondary problems which required continual attention. These are as follows:

1 Disposal of sludge water and the associated problem of maintaining drain lines free from clogging.

2 Corrosion of air washer and fouling of sprays.

3 Warm-air discharge, high in humidity, creates fog obstructing vision of roof operations.

4 Some spray water is discharged as a very fine mist, deteriorating building walls and creating a bad condition on the millhouse roof.

5 Loss of pulverized fuel as a result of the wet washing.

It is evident that, if the vent coal is to be reclaimed dry, a dry type of filter must be resorted to and further that such dry-filtering equipment must be nearly 100 per cent efficient under all load conditions or a potential nuisance will exist. One of the few types of filters on the market which fulfills the requirements is the cloth or bag filter system.

It was decided in 1936 to purchase two cloth-type filter collectors, each with four filtration compartments for the 25- and 40-ton per hr ball-type mills, eliminating from the vented-air circuit both the secondary cyclone and air washer.

The two filter units were installed under a single housing on the millhouse roof over the raw-coal bunker and adjacent to the south coal tower. The secondary cyclone and air washers on the ball-type mills were left intact after connecting the filter dust collectors so that, in the event of failure of the dry filters, which has not occurred to date, the vent system could be changed over to wet washing in a matter of hours. The dry-filter system air-flow circuit with the change-over provision for wet washing is shown in Fig. 2.

The dust filter compartments are in the same housing to sim-

Contributed by the Fuels Division and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

plify construction, although their operation is entirely separate. The path of flow of the coal-dust and air mixture through the collector is shown in Figs. 3 and 4. Flow of the mixture is up through the bottom of the collector, through a pipe located in the center of the filter then to the four compartments, two of which are located on one side of the inlet and two on the opposite side. At the inlet to each pair of filtering compartments is a gate-type damper which can be used to close off the flow to either compartment but never to both at the same time. Take-up springs are provided on the driving-shaft mechanism to prevent shearing of the damper shaft and also to insure a pressure fit of the damper against a $^1/_2$-in-thick soft-rubber gasket which lines the door frame.

The dusty air enters the filtering compartment and makes a turn of 180 deg to the outside of the filtering surface. The filtering surface consists of a number of bags each shaped as a rectangular envelope open on one end. The bag or envelope is slipped over a galvanized-wire screen, the opposite surfaces of which are held in correct spacing of $1^3/_{16}$ in. by metal struts. The 25-ton mill has 552 such bags and the 40-ton mill 840 bags, six rows high. The path of air flow is through the cloth and out the open end of the envelope. The coal dust builds up a dust layer on the cloth surfaces, which is shaken off periodically, and the cleaned air passes through to an opening provided in the housing. The open end of each bag screen is sealed to the collector casing, dividing it into a dust side and clean side.

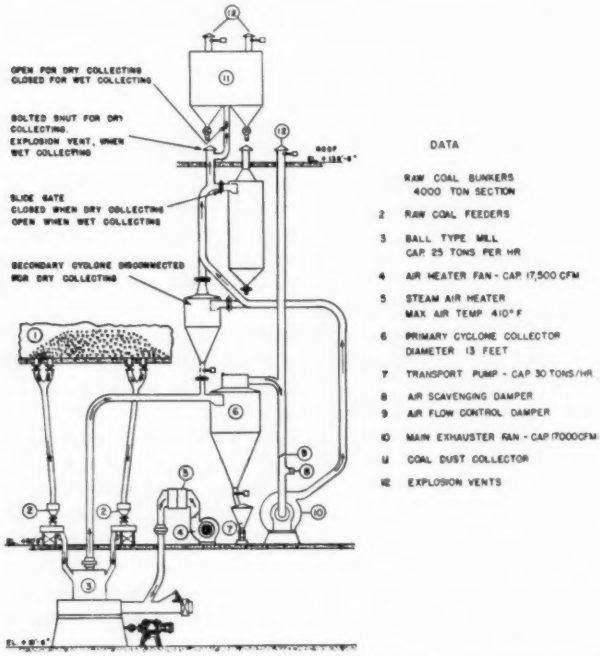

FIG. 2 COAL AND AIR-FLOW CIRCUIT, 25-TON MILL WITH CLOTH FILTERS

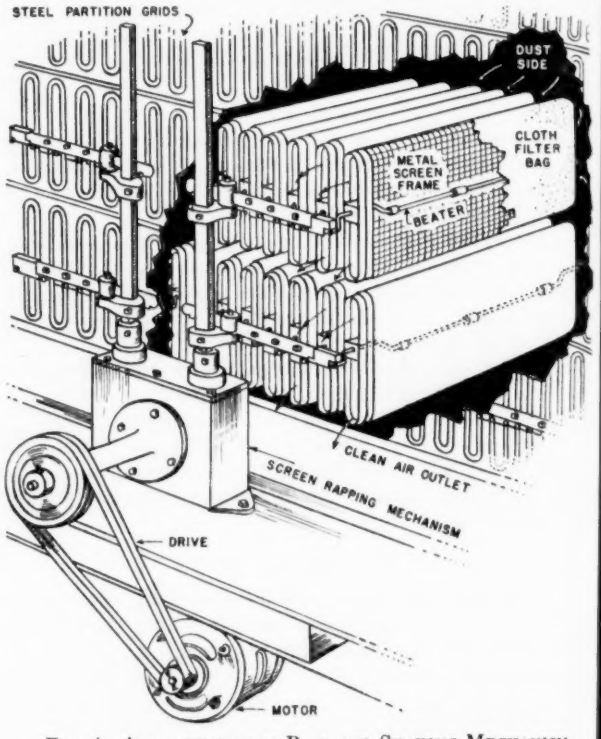

FIG. 4 ARRANGEMENT OF BAGS AND SHAKING MECHANISM

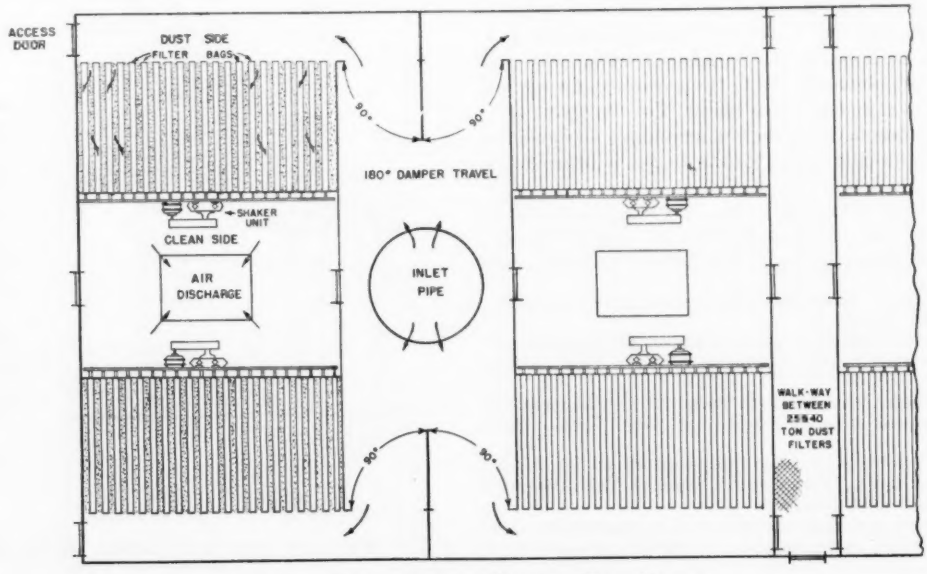

FIG. 3 AIR-FLOW DIAGRAM THROUGH DUST FILTER

The shaker consists essentially of a motor operating a rocker mechanism which transmits oscillating motion to beater rods located along the centers of the bag frames. Coal hoppers are located directly below the cloth surfaces to receive the loosened dust from the bags. A rotary valve, which is air-sealed by means of a rubber flap, rotates at slow speed and discharges the reclaimed coal to a return coal pipe which conveys it to the hopper above the transport pump for delivery with the main body of coal to the boiler fuel bins. Each compartment has its own shaker motor and shaking mechanism. The length of the shaking period and proper sequence is governed by the cam switches on the time-control panel.

Laboratory Tests

The successful installation of the collector depended on several factors, some of which had to be determined in the laboratory because the information was unavailable. The known factors were:

1 Vented-air volume.
2 Vented-air temperature and relative humidity.
3 Vented-coal quantity and screen sizing.
4 Maximum pressure loss allowable in operation.

The factors which had to be investigated because little or no information was available were:

1 Pressure-drop characteristic of the filter cloth.
   (*a*) The effect of flameproofing on the pressure drop.
   (*b*) The effect of coal-dust loading on the pressure drop.
2 Safety considerations.
   (*a*) Precautions necessary to insure safe operation of the cloth filters.

The known quantities as previously established are given in Table 1.

TABLE 1 KNOWN FACTORS OF COLLECTOR OPERATION

	25-Ton mill	40-Ton mill
Vented-air volume, cfm, max	15000	27500
Vented-air temperature, F	130	130
Vented-air, relative humidity, per cent	60	60
Vented coal, lb per hr, max	800	1600
Vented-coal sizing	100 per cent through 325-mesh Tyler screen	
Available pressure for cloth filters, in. water, max	6	6

Tests were made on a number of filter cloths submitted by manufacturers. The cloths were tested for air-flow resistance in the clean condition and also after loading with coal dust. The fabrics tested were made from cleaned cotton having a sateen weave with a count 96 × 64 threads per in. Two weights of fabric tested are reported; one with a weight of 1.05 yd per lb and the other 1.30 yd per lb; both fabrics 54 in. wide. The cloth samples were clamped tight without stretching to one end of a cylindrical chamber approximately 10 in. diam and 3 ft long. Metered clean air was blown in on the other end. Cloth resistance was measured with a U gage connected to the chamber approximately 2 in. from the cloth. The effect of several flameproofing solutions on the pressure drop was also established. The designations of cloth tests reported are given in Table 2.

TABLE 2 DESIGNATIONS OF CLOTHS TESTED

Curve symbol designation	Cloth thread count	Cloth width, in.	Cloth weight, yd per lb	Flameproofing
A	96 × 64	54	1.05	Untreated
A_1	96 × 64	54	1.05	Mixture of ammonium-phosphate and boric-acid solution
B	96 × 64	54	1.30	Untreated
B_1	96 × 64	54	1.30	Sodium-borophosphate solution
B_2	96 × 64	54	1.30	Sodium-ammonium-borophosphate solution

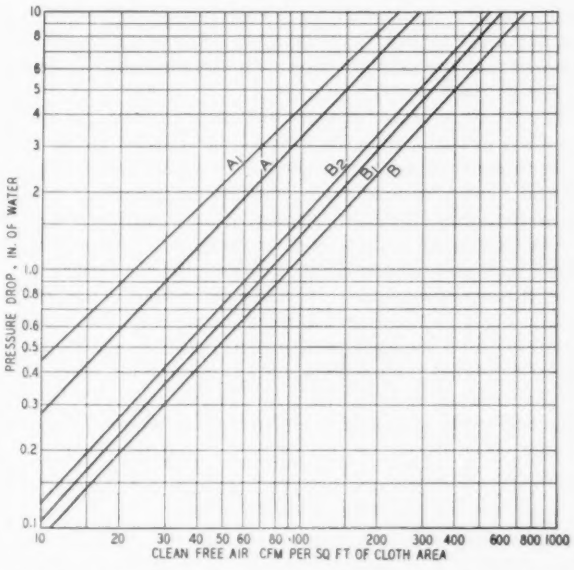

FIG. 5 PRESSURE DROP THROUGH CLOTH WITH CLEAN AIR

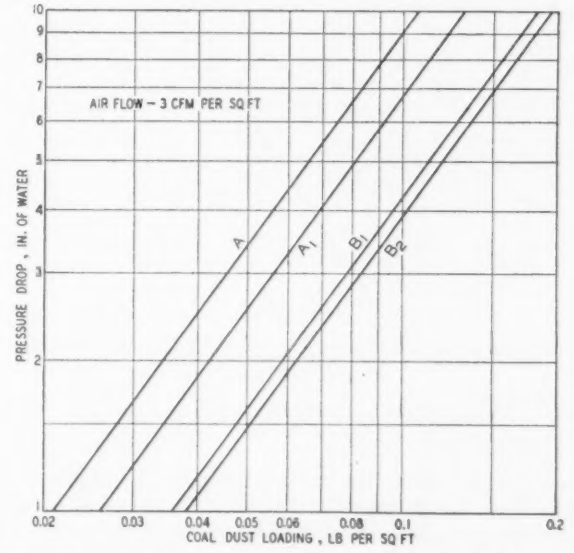

FIG. 6 PRESSURE DROP THROUGH CLOTH LOADED WITH COAL DUST

The results for clean free air are given in the curve in Fig. 5 and indicate that the flow-resistance curves are parallel, with the exception of curve A_1 which may be accounted for by the fact that cloth A_1 may have had an initial stretching.

The difference in the weight of the cloths A and B is reflected in their relative resistance to air flow. Cloth B (the lighter cloth) will pass approximately 2.7 times as much air as cloth A for the same pressure drop. Flameproofing increases the pressure drop of cloth A by about 24 per cent and that of cloth B by about 18 to 25 per cent. The effect of flameproofing on the flow resistance will depend largely on the composition, strength, and also the method of application to the cloth.

Continuing the foregoing test; some fine coal (screened through a 200-mesh Tyler screen) was blown against the cloth and pressure-drop data collected. These data were taken for a number of coal loading points so that it was possible to study the rate at which the pressure drop increased. Powdered coal was intro-

duced into the cylindrical chamber mentioned with an air injector, making it possible to secure a uniform coating of coal on the cloth, the amount of which was determined by weighing the cloth after each run.

The results of these tests are indicated in Fig. 6, which shows the effect of coal loading on the pressure drop for an air flow of 3 cfm free air per sq ft. The curves are plotted for cloths A, A_1, B_1, and B_2 and have the same letter designation given in Fig. 5. If, as an example, for cloth A a point at 0.05 lb per sq ft coal-dust loading is taken the pressure drop is 3.4 in. Comparing with Fig. 5, a pressure loss of 3.4 in. will pass 102 cfm free air per sq ft or 34 times as much air. It will be noted that, in line with the tests of Fig. 5, cloths B_1 and B_2 will allow more coal accumulation on the cloth for the same pressure-drop and flow conditions than cloths A and A_1. Thus for a 3-in. pressure drop, cloth A_1 will allow a coal loading of 0.056 lb per sq ft, whereas cloths B_1 and B_2 will allow 0.078 and 0.083 lb per sq ft, respectively. This, however, does not mean that the normal operating pressure of the cloth filters will be less with cloth B_1 or B_2 than with cloth A_1, but rather that cloths B_1 and B_2 will retain more coal on their surfaces than cloth A_1 and that the residual loading, after the cleaning period of cloths B_1 and B_2, is more than with cloth A_1. The normal operating pressure is approximately the same with either cloth as borne out by actual operating experience with both cloths.

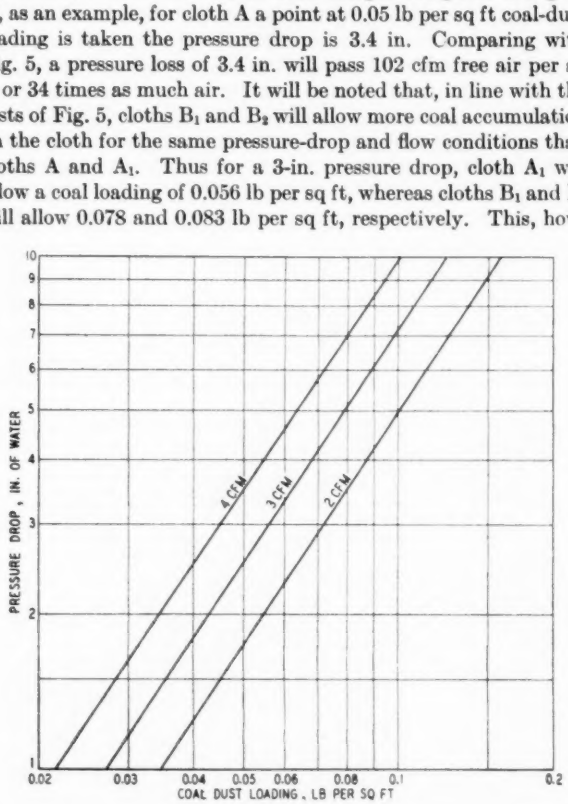

FIG. 7 PRESSURE DROP THROUGH CLOTH A_1 VERSUS COAL-DUST LOADING

Observations made during these tests indicate that coal dust passes through the cloth when it is clean until the pores become filled with dust particles to a point when no more coal dust passes through. The dust retained on the cloth provides a mat filtering medium. This effect is more noticeable with cloths B_1 and B_2 than with cloth A_1. No tests were made with cloth B (untreated cloth) because it had been decided to use flameproofed cloth in the installation.

Cloth A_1 was initially selected for the installation because of its superior mechanical properties. It was believed that the heavier cloth would withstand the effects of temperature and beater rods better than the lighter cloths B_1 or B_2. Flow curves were constructed for cloth A_1, as in Fig. 7.

The design for cloth-filter surface for both mills is contained in Table 3.

TABLE 3 CLOTH-FILTER SURFACE AS DESIGNED

	25-Ton mill	40-Ton mill
Coal milled, lb per hr	50000	100000
Coal to cloth filters, lb per hr	800	1600
Vented air, cfm	15000	27500
Free air cfm per sq ft cloth area (100 per cent area assumed)	2.1	2.6
Free air cfm per sq ft cloth area (75 per cent area)	2.8	3.5
Total cloth area, sq ft	7040	10710
Reduced area, 75 per cent of total, sq ft	5280	8030
Coal-dust loading, lb per M sq ft to give 4 in. normal operating pressure at reduced area	71	62
Total coal on cloth filters, lb	500	665
Shaking interval, min	37	25

From the figures given in Table 3, it is evident that the cleaning-period cycle should be less than 37 min for the 25-ton mill and less than 25 min for the 40-ton mill. It was recognized that the calculated figures are only approximations because it had been assumed that the filter cloths were thoroughly clean at the beginning of each cycle. The limited value of the tests, because of the number of uncontrolled variables, such as temperature, humidity, dust and sizing, did not justify more accurate determination of the cleaning cycle. To simplify the control for these operations, it was decided to operate both mills with the same initial cleaning cycle, a compromise between the two calculated cleaning cycles.

Each filtering unit has four compartments and is so constructed that one compartment at a time is removed from service for cleaning. It is, of course, important that the cleaning operation occur only while the compartment is dampered off. The setting adopted is given in Table 4.

TABLE 4 CYCLE SETTING ADOPTED

	25-Ton mill	40-Ton mill
Number of complete cycles per hr	2	2
Time required for 1 cycle, min	30	30
Total time, unit operating with 100 per cent filtering capacity, min	10	10
Total time per cycle when unit is operating with 75 per cent filtering capacity, min	20	20
Actual shaking time per compartment per cycle, min	3	3
Actual shaking time per compartment per hr, min	6	6
Actual shaking time all compartments per cycle, min	12	12
Actual shaking time all compartments per hr, min	24	24

NOTE: Time control for the cycle was obtained from a synchronous motor through reduction gears driving a shaft onto which were fastened bakelite cams opening and closing contact switches in proper sequence for damper and shaker motor operation. Provision was also made for manual operation of the control limit switches.

The validity of such testing with respect to the resistance of different cloths has a good degree of plausibility, since it is possible to test the cloths under practically identical Reynolds-number conditions as exist in the full-scale apparatus. These tests indicate that the effective filter resistance is principally determined by the filter mat which is formed by the cloth and the so-called residual dust loading. To a considerable degree, independence of filter resistance to the textile specification of the cloth exists, a fact of interest because cloths may be selected principally for their mechanical qualities.

If it should be found that such tests furnish an approximate basis for the design, they would assume considerable importance. The authors' results indicate that this is only roughly true. Since such correlation was not of primary interest at the time of carrying out the work, necessity for further and more extensive data is indicated, especially on different materials.

The laboratory tests indicate two apparent flow-resistance rules. First, at constant loading of the cloth the draft loss varies directly as the flow. This is reasonable enough as the flow through the filter itself must be viscous. Second, at constant air flow, the draft loss varies as the 1.5 power of the loading, a statement by no means so obvious and which must be confined to the limits of the experiments, because it involves several variables

connected with dust sizings, atmospheric conditions, and others not under controlled variation in the experiment.

Field Tests

The installation of the 25-ton-mill filter was completed in the spring of 1937 and placed in service immediately thereafter. For the first several days, operation of the collector was as expected. Initially some coal dust came through the cloth onto the clean side until a dust mat was formed on the cloth after which the air coming through the cloth was perfectly clean. Subsequent operation of the collector showed that the air resistance kept building up and no amount of shaking would bring it back to normal while the mill was in service, although the shaking was effective with the mill shut down. After numerous tests, it was decided to change the timing cycle. New cams were ordered, cut, and installed, which permitted more flexibility in the time-control variation by resetting the cams on the drive shaft and changing the motor reduction gears.

During the shaking cycle, the sequence of the cleaning operation is as follows:

1 Close off compartment to filtering by damper.
2 Time prior to shaking called "rest period."
3 Shaking period.
4 Time after shaking called "settling period."

Changes were made in the number of cleaning cycles per hour and the rest, shaking, and settling periods.

Some of the results of the tests have been plotted in curve form

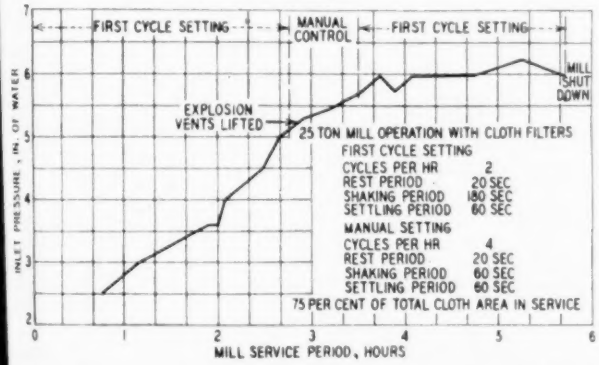

Fig. 8 Variation of Back Pressure With Time; First-Cycle Setting

and indicate the rate of pressure build-up. Fig. 8 is a typical curve of the initial cycle for 75 per cent filtering area. During part of this cycle 100 per cent filtering area was used. However, so that the test results of the original cycle may be compared with subsequent data on cycles which employ 75 per cent filtering area all of the time, the results were plotted for 75 per cent filtering area. In a period of 2 hr 5 min pressure built up to 4 in., the normal design pressure, and increased to $5^1/_4$ in. in an additional 47 min, resulting in a lifting of the explosion vents. After 2 hr 45 min of service the time control was changed to manual with 4 cycles per hr and 60 sec shake, but pressure continued to build up until the vents were continually open. The mill was shut down after 5 hr 45 min of service because of excessive back pressure.

Figs. 9, 10, and 11 are plots of results of the tests in which the cleaning cycles per hour, rest, shaking, and settling periods were changed as indicated on the curve sheets. All tests indicate the filter back pressure rises to 4 in. from 2 to $3^1/_4$ hr and, with the exception of one test (Fig. 10) in which 4 in. is reached in about $1^1/_2$ hr, continued to increase until the vents lifted at $5^1/_4$ in. and the mill was shut down. In each run the milled coal was 21 tons per hr, air flow approximated 14,000 cfm, dry-bulb temperature 125 F, and relative humidity 40 per cent. No effect of the cycle frequency on the filter back pressure is apparent except that the results with the 3-cycle frequency are worse than with

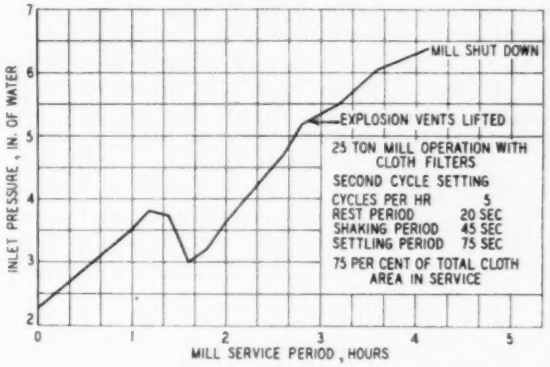

Fig. 9 Variation of Back Pressure With Time; Second-Cycle Setting

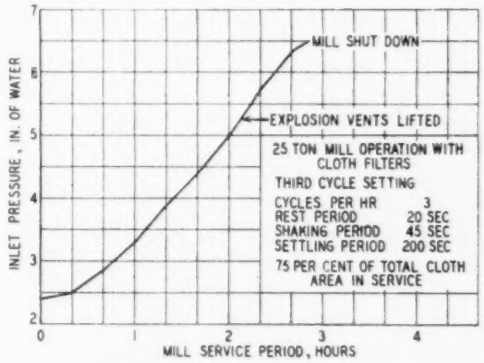

Fig. 10 Variation of Back Pressure With Time; Third-Cycle Setting

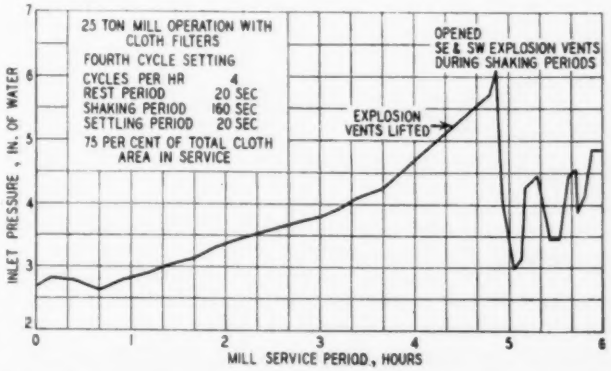

Fig. 11 Variation of Back Pressure With Time; Fourth-Cycle Setting

the 4 or 5 cycle. The duration of the shaking period had no effect on the pressure build-up.

Continued checking of the shaker mechanism and damper-operating mechanism indicated them to be in good working condition. When the damper closed off a compartment to air flow, preparatory to shaking, there was a gradual drop in pressure by virtue of the fact that flow occurs until the pressures on both sides of the filter cloth are in balance. If the time allotted for pressure balance is not sufficient or is offset by air leakage around

the damper seal, then shaking of the cloth no matter what the duration will be ineffective. A checkup of the compartment pressure, when dampered off, indicated a positive pressure of approximately 0.02 to 0.04 in. of water.

During the test run plotted in Fig. 11, two of the vent doors were lifted accidentally while the compartments were dampered off, thus allowing quick equalization of clean- and dirty-side pressures and also providing a sufficiently large area for escape of any inleakage without affecting the pressure balance. The effects were readily apparent. The filter resistance dropped from 6.10 to 4.10 in., after one of the compartment filters had been cleaned, and dropped to 3 in. after the cleaning of the second compartment filters. The pressure increased to 4.4 in. as the first then the second compartment on which the vent doors had been lifted were removed from service. The pressure dropped from 4.4 to 3.45 in. when both filtering compartments were returned to service.

Design of Residual-Pressure Release System

When the pressure filter system, as previously indicated, went into operation the resistance built to very high values. Increase

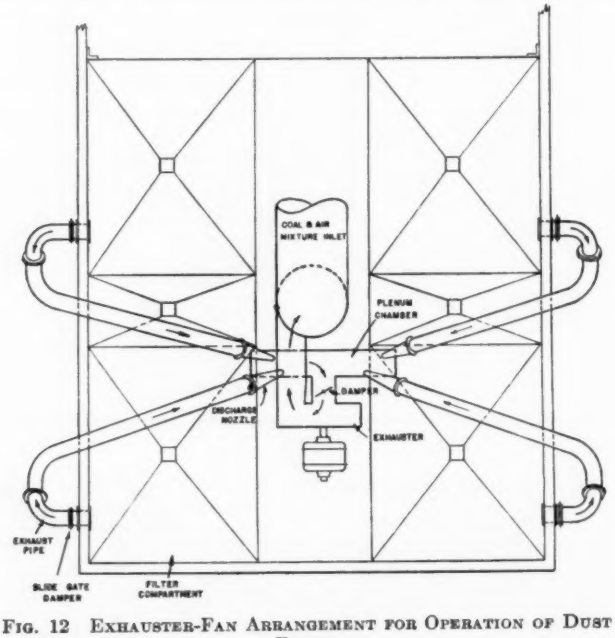

Fig. 12 Exhauster-Fan Arrangement for Operation of Dust Filter

of the number of shaking periods and of the time of shaking was ineffective in eliminating pressure build-up. One theory advanced was that the residual air pressure in the isolated compartment held the coal against the filter in spite of efforts to shake it free. Tests were run to determine the amount of evacuation necessary to allow the free discharge of the dust from the cloth. It was found by measurement of air flow that 275 cfm were required for the filters of 410 cu ft free volume, and 400 cfm for the filters of 590 cu ft free volume. A margin for damper leakage was also allowed.

After consideration this evacuation was carried out in the manner shown in Fig. 12. A single fan was connected to all compartments and continuously operated. Its capacity requirements were based upon the following criteria:

The operating suction at the fan inlet is selected so that variations in flow from operating and nonoperating compartments owing to differences in pressure will be swamped out to a desired degree. This necessitates the introduction of accurate resistances in the individual lines, which may be tapered nozzles, properly designed and discharging in the inlet plenum. The over-all system resistances including the nozzles should be calculated because high line velocities should be used. The total flow into the fan under operating conditions is readily figured and leads to the selection of a fan of proper P-V characteristics. Low velocities and flat spots must be avoided as shown in Fig. 12.

The power requirements of this fan are a charge against operation amounting to 7 hp for the 7040-sq ft filter and 12 hp for the 10,710-sq ft filter.

The necessity for some such installation would exist whether the filter were under pressure or suction. However, for a suction filter, a simple mechanical atmospheric break on the clean side might be provided for each compartment.

The reasoning indicating the necessity for evacuation is expressed mathematically in the following expression which offers a means for evaluating the time which must elapse before the particles may be shaken off in the face of a slight residual pressure.

If Q_t, $\overline{V}$, P_t are, respectively, the weight of air in the filter, the volume of the filter, and the absolute filter pressure at any time t

$$Q_t = k_1 \overline{V} P_t$$

and the time derivative is

$$\frac{dQ_t}{dt} = k_1 \overline{V} \frac{dP_t}{dt}$$

the rate of outflow from the compartment is

$$-\frac{dQ_t}{dt} = k_2 \frac{P_t - P_a}{X} = k_3 (P_t - P_a)$$

in which $\frac{P_t - P_a}{X}$ is the pressure gradient across the filter cloth, P_a being atmospheric pressure.

$$k_3 (P_t - P_a) = -k_1 \overline{V} \frac{dP_t}{dt}$$

from which $-T = K \log (P_t - P_a) + C$

$$\text{or } T_{t_1}^{t_2} = K \log \left(\frac{P_1 - P_a}{P_2 - P_a}\right) = K_4 \log \left(\frac{V_1}{V_2}\right)$$

where V_1 and V_2 are the velocities through the filter mat.

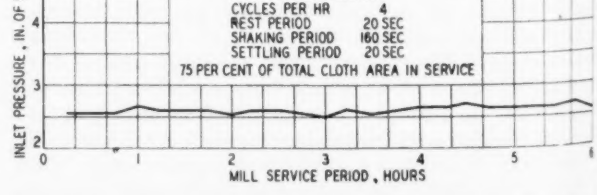

Fig. 13 Variation of Back Pressure With Time; Residual-Pressure Release System

If the time for decrease of the pressure to $^1/_2$ value is observed, the time for the volume rate discharge to change from V_1 to V_2 is given simply enough by the foregoing ratio, assuming that the inlet damper is tight. Theoretically, at least, if the terminal velocity of the particles were known, the time the filter was to be out of service before the pressure decreased to the point at which the particles would fall off the cloth would be determinate.

A consideration of the terminal velocity of fine particles, as discussed by Croft,[4] leads to the general conclusion that the air velocities for the particles encountered here must be less than about 3.5 in. per sec and may have to be as low as 0.001 in. per sec before shaking can be effective. This consideration indicates the necessity for residual-pressure release.

The effect of the residual-pressure release mechanism on the back pressure is clearly shown in Fig. 13 which should be compared with Figs. 8, 9, 10, and 11.

Inspection and Maintenance

Of particular interest in the operation of the dry dust filters is the number of man-hours involved in inspection and maintenance. Inspections while the equipment is in service cover the following:

1 Lubrication of bearing surfaces of coal-conveyer valves, evacuating fans, and motors.
2 Checking housing for leaks from dust side of collector.
3 Observation of clean-air discharge for evidence of torn or defective bags.
4 Checking reclaimed-coal lines for free movement of coal.
5 Checking operation of main exhauster damper control.
6 Checking pressure balance of cloth filter with draft gage.

Items 1 to 4 are covered by the regular millhouse operating crew and are made a routine matter along with other duties at similar locations about every 2 hr. The inspection is primarily a precautionary measure. Items 5 and 6 are looked after by test men in the technical department of the company. A monthly inspection of the damper control is all that is generally necessary and requires about 3 or 4 hr per month. Item 6 is included for the purpose of checking the auxiliary-fan operation and is made about every 3 or 4 months in about $\frac{1}{2}$ hr.

During the shutdown operation it is advisable to check the following and do general internal cleaning:

1 Shaker mechanism.
2 Inspect damper gaskets.
3 Inspect auxiliary-fan piping.

It is good practice to make a general internal inspection of the collector weekly.

Maintenance data on the dust filters are not as complete as they should be at this time because included in the maintenance figures are design changes. These changes in design will undoubtedly lower maintenance charges and decrease outage periods in the future. Figures subsequently cited are for the total operating hours given for each filter.

The largest single item of maintenance in the dust filters is the filter bag. Bag life is approximately 2 yr and the bags, with flameproofing applied, cost approximately $1 each. To remove and replace bags requires about 180 man-hr for the 25-ton mill and 275 man-hr for the 40-ton mill, assuming all bags are replaced. Defective bags are located from the clean side of the collector and are replaced from the dust side of the collector. Since there are 552 bags in the 25-ton-mill installation and 840 bags in the 40-ton-mill installation, this replacement is therefore an appreciable item and worthy of investigation.

At the present time, tests are under way to confirm a proposed decrease in shaking frequency and time. One other change has been made which should improve the life of the bags. Formerly the flow of clean air was downward but now the flow is upward through the top, in order to prevent clean air with high vapor content passing from one collector to the other when one of the collectors is out of service.

The next largest item of maintenance is general cleaning and gasket repair. Approximately 400 man-hr have been spent in this work but it is reasonably certain that this item will virtually disappear, because 90 per cent of the time devoted to cleaning would not have been necessary if the collector were dust-tight initially. For example, the access doors and coal-hopper casing leaked dust continually while the collectors were in service and required constant cleaning and patching, which otherwise would not have been necessary. Dust-tight access doors were made to replace the initial doors and the hopper casing was welded to make it dust-tight. Gasket maintenance is a relatively small item and has approximated 50 man-hr, which time is spent about once a year renewing gaskets on explosion vents, access doors, and damper frames.

Reclaimed coal drive systems have had approximately 330 man-hr maintenance, a considerable portion of which can be considered as due to the dusty atmosphere, resulting from leakage which in turn caused bearing maintenance and maintenance of the chain drive. Rotary valves which feed the coal into the screw conveyer and return coal pipe have had no maintenance. Some trouble had been experienced in the early days with flooding of the conveyer screw, causing plugging of the return coal pipe at the point where it connects to the screw, but this has been rectified by increasing the angle of inclination of the outlet coal pipe. At the present time the coal drive system runs continuously, but it is planned to try out intermittent operation of the drive system which, if successful, will decrease maintenance.

The shaker mechanism has needed 205 man-hr of maintenance which has been due largely to wear of the roll which fits in the cam groove of the rocker mechanism. The roll was worn egg-shaped because it did not rotate with the cam but slid in the cam groove. Some of the rolls were worn down to the pin in a period of 6 to 8 months but, when a grease-seal ball bearing was substituted as a cam follower in place of the hardened steel roll, very slight uniform wear resulted in a period of 18 months. There has been some loosening up and falling out of setscrews fastened to the rocker shafts which have been replaced with a self-locking type of setscrew.

Approximately 75 man-hr have been charged to resetting limit switches. This is not excessive, since it is good practice to check the limit switches on the gate-damper motors about once every 6 months. The purpose of the check is to insure a good seal of the damper against the door frame at all times so that the pressure balance of the cloth will be proper for effective shaking.

The 25-ton mill has been in service 6197 hr and the 40-ton mill 5759 hr since the installation of the dry filters. During this time it is estimated that 4400 tons of coal have been reclaimed by the dust filters. The operation of the filters has been normal and no major incidents in their operation have occurred.

Safety Measures

It is recognized that coal milling is a process which must be carefully handled to prevent fires during the operation. Protective equipment and safe procedures had been employed in the millhouse in line with best practice and this policy was extended to the dry filters. Numerous tests on filter cloth, both treated and untreated with flameproofing, indicated the desirability of treating the cloth, although it was recognized that such treatment would increase the flow resistance of the cloth slightly and perhaps affect its life. The effect of the flameproofing was found to be that of retarding the burning of the cloth and localizing it, although the time required for ignition of the treated and untreated cloth seemed the same.

Long horizontal runs of pipe are objectionable as are low pipe

[4] "The Calculation of the Dispersion of Flue Dust and Cinders From Chimneys," by H. O. Croft, Trans. A.S.M.E., vol. 57, 1935, paper FSP-57-1, pp. 5–10.

velocities. Accordingly in the layout of the pipe lines leading to the collector, the velocities are maintained at above 3000 fpm and the pipe runs are all practically vertical with the exception of the tie-in connection to the collector on the 40-ton mill, which is approximately 25 ft long. Exposed pipe above the roof is well insulated and provided with waterproof covering. In addition the horizontal run is provided with an inspection and access door. Dry-coal return lines are vertical with minor exceptions, where 45-deg bends were necessary. These were provided with cleanout plugs.

It has been mentioned that the dust filters were installed on the millhouse roof. The collector, therefore, had to be well insulated to prevent condensation. A 4-in. layer of rock wool backed up with $^1/_4$-in. transite sheet was provided, the collector itself being lined with No. 14 gage sheet metal. The temperature drop through the collector is therefore small, in the order of 10 F, and the exit-air temperature is above the dewpoint.

Each compartment is provided with an explosion vent in addition to those already existing on the mill proper. Each filtering compartment has an access door.

Published data on the subject of inflammability of coal dust–air mixtures are meager with reference to the problem at hand. Two general statements may be made:

1 The dust must be present in a cloud of inflammable density and composition.

2 There must be a source of ignition, such as freely burning coal or an electric spark.

These two basic conditions may be discussed in terms of the factors which determine them. With regard to any distinction between inflammability and explosiveness, investigators of the Bureau of Mines[5] find, as a practical matter, that it is impossible to distinguish between them and that it is inadvisable to attempt such distinction.

When the coal–air mixture at Kips Bay Station leaves the primary cyclone, the velocities and composition are as given in Table 5.

TABLE 5 VELOCITIES AND COMPOSITION OF COAL–AIR MIXTURE, LEAVING PRIMARY CYCLONE

	25-Ton mill	40-Ton mill
Grains of dust per cu ft of air at 130 F	6.2	6.8
Velocity in pipe, ft per min	3300	3400
Dust fineness	(100 per cent through 325-mesh Tyler screen)	

The question of mill drying by flue gases was studied at length and abandoned as economically impractical in this instance.

The regulation of air flow from the mill to the filters is accomplished by a high-quality automatic control which throttles the mill fan discharge to maintain a constant suction at the mill cyclone outlet. This function, the maintenance of constant mill air flow, has performed admirably with concurrent advantages in mill operation. Variations in filter pressure are not felt in the mill system.

On the receiving hoppers of the filter, mechanical rappers were installed and have worked very well. The rotary valves for discharging the hoppers are mechanically driven and isolate the hoppers at all times from the receiving screw conveyers.

The receiving screw conveyers were the scene of several fires in the early operation due to spontaneous combustion of packed coal in the barrels. This condition was eliminated by minor changes. Such precautions are also directed against fire due to spontaneous combustion.

[5] "Coal-Dust Explosibility Factors Indicated by Experimental Mine Investigations, 1911–1929," by G. S. Rice and H. P. Greenwald, U. S. Bureau of Mines, Washington, D. C., Technical Paper No. 464, 1929.

It is also necessary to insure against the hazards of static electric discharges. This insurance is largely inherent in the fact that this filter is a mass of metal mesh supporting the cloth, giving almost continuous grounding with a minimum free volume for the occurrence of intercloud discharges.

There is some evidence that high humidities reduce the inflammable character of the mixture, although publications of the Bureau of Mines declaim the futility of relying on this. For instance, Rice and Greenwald[6] unequivocally reject the influence of humidity in practical work. However, high humidities may reduce static-electricity hazard considerably.

Appendix

Three rather complete performance tests on the 40-ton-mill cloth-filter installation are given in Table 6. Of particular interest is the power consumption of the cloth filters and the fineness of the reclaimed coal. Power consumption of the cloth-filter installation is less than 0.2 kw per ton of milled coal, which is approximately 1.5 per cent of the total. Fineness of the reclaimed coal indicates that practically 100 per cent passes through a 325-mesh Tyler screen and also that the density of the reclaimed coal is approximately one half that of the milled coal. It is of interest to note that the efficiency of the primary cyclones is better than 99 per cent.

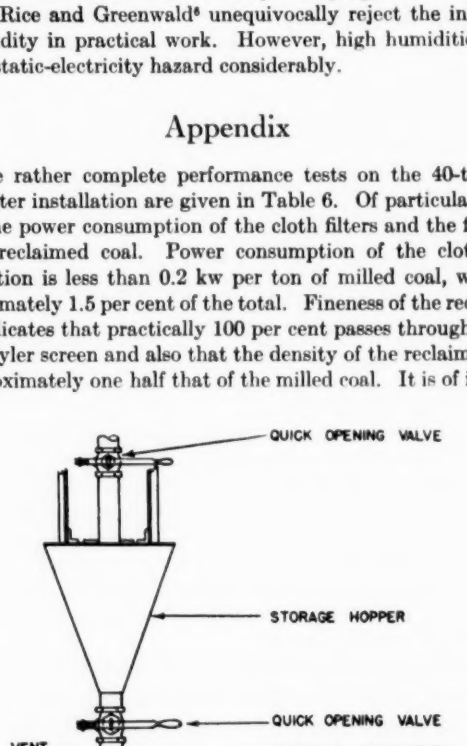

FIG. 14 RECLAIMED-COAL WEIGHING DEVICE

The tests were made with 4 cleaning cycles per hr on the cloth filters. The duration of each shaking period was approximately 20 sec per compartment for each cleaning cycle.

The reclaimed-coal weighing device used in these tests is indicated in Fig. 14. The particular advantage of the installation

[6] See reference (5), p. 8.

TABLE 6 PERFORMANCE TESTS OF 40-TON MILL WITH CLOTH FILTERS

Date	June 17, 1938	June 20, 1938	June 21, 1938
Test no.	2	3	4
Duration, hr	4.53	4.02	5.0
Total coal milled, tons	192.2	150.3	188.1
Coal milled per hr, weighed, tons	42.35	37.35	37.62
Power Consumption:			
Mill including heater fan, kwhr	377.0	371.8	381.8

shown is that it permits continuous movement of the coal dust in the pipe line, because it incorporates a storage hopper in addition to the weighing hopper and also that it is dust-tight which, in this particular application, is rather important. It is, of course, important if the dust-conveying pipe is under pressure other than atmospheric that the weighing hopper be vented during the weighing period. For this purpose, a vent valve is provided in the weighing-hopper cover plate. This particular type of installation has also been used successfully in weighing flue dust from pulverized-fuel installations. The hoppers are fabricated from 3/32-in. plate and all seams are welded.

Discussion

J. E. FULWEILER.[7] It would be interesting to know if any serious objections to the installation discussed in this paper were offered by the engineers of the insurance company covering the risk; also whether the demonstrated safe operation of this completely dry equipment was satisfactory proof that sprays are not necessary when the other precautions described are taken.

In view of the tendency to insist upon sprays in connection with explosive industrial dusts, this example may prove of considerable value in the art, because some of the dusts involved are of value if kept dry and utterly ruined if wet.

The wetting of the dusts also seems to increase rather than minimize the disposal problem as well as to entail considerable trouble, due to the freezing of the water in cold weather. An installation of this size and importance, operating dry, is therefore of considerable interest to the writer.

RALPH A. SHERMAN.[8] The writer would like to suggest that supplementary information covering the proximate analysis and calorific value of the dust, which is collected in the bag filters, would aid in a comparison of the remainder of the coal collected in the cyclones.

R. F. THRONE.[9] There are upward of 100 installations of cloth filters in service, handling vents from pulverized-coal equipment. The general experience has been quite satisfactory. Some provisions have been necessary to drain off the static electrical charge, and some installations have required special attention to the slope of the inclined surfaces. Only a few of the installations use flue gas as an inert gas, the circulating gas in most cases being air.

Cloth-type filters have the highest reclaim capacity, especially in their ability to remove the microscopic sizes under 10μ. These sizes represent as high as 80 per cent of the total dust and constitute a major visual nuisance.

Precaution must be exercised to maintain the gas humidity below 100 per cent, as the resistance through the cloth greatly increases as it absorbs free moisture, as well as permits the coal dust to cake onto the filter surface, thus increasing the difficulty of restoring the filtering medium. The tubular free-hanging type of cloth filter, can be adequately cleaned in service merely by closing the outlet-gas damper without in turn closing the inlet-gas damper. The agitating mechanism is sufficient to shake the coal dust from the filter cloth without allowing a time period for equalization of gas pressure on either side. The most effective procedure is to have a reverse flow of the gas through the filter cloth during the shaking operation, but such reversal, either with the cleaned gas from other sections or with room air, cools the gas in the compartment being cleaned, to and below its dew point, causing condensation. Cloth filters have proved equally successful under negative pressures as high as 26 in., as well as under positive pressure. The major disadvantage of negative-pressure operation is the detection of air-inleakage areas.

Fire hazard is increased in the employment of cloth filters. This becomes an important factor, especially with the "younger" coals, for which the affinity for oxygen is high. The combustion of filtering cloth with the resulting flame adds a menacing factor to what would otherwise be an easily controllable condition. Flue gas as the circulating medium has not proved satisfactory in avoiding ignition of coal dust and the resulting loss of filter bags on the "western" coals. Even though a noninflammable filtering cloth material should be developed, considerable question remains whether with these "younger" coals, the large area available is not a definite hazard.

J. C. WITT.[10] The writer would like to know whether any installations of the type described have been involved in fires? He has had some experience with one all-steel dust-collector installation in which a fire occurred. Much of the equipment was rendered worthless by the heat, although nothing was burned. The question therefore arises: What benefit would come from fireproofing the cloth, in this instance, if a fire should start?

AUTHORS' CLOSURE

The authors believe that the successful operation of the cloth-filter installation described is in a large measure made possible by the safety features incorporated in the design and also because of the systematic inspection program carried out by the operating personnel. The insurance carrier, in the case of this installation, interposed no requirements with those on pulverized-coal installations in general.

The powdered-coal proximate analyses omitted in the performance tests and requested by Mr. Sherman have been obtained. Average laboratory results of the powdered-coal analyses are tabulated as follows:

POWDERED-COAL PROXIMATE ANALYSES

	Milled coal	Reclaimed coal (collected by cloth filter)
Moisture, per cent	1.4	0.8
Volatile matter, dry, per cent	34.4	33.8
Ash, dry, per cent	7.7	7.4
Fixed carbon, dry, per cent	57.9	58.8
Sulphur, dry, per cent	1.45	1.10
Calorific value, dry basis, Btu per lb	14110	14150

No appreciable difference in laboratory analyses of the two powdered-coal samples is evident. Although the primary cyclone efficiency is better than 99 per cent, it is not sufficient to detect differences in proximate analysis between milled coal and the vented coal, if such a difference exists. For this installation at least, the conclusion must be that the proximate analyses of the powdered coals are the same.

Mr. Throne points out that it is necessary to insure against the hazards of static electric discharges. This insurance is largely inherent in the collector described. The importance of maintaining the temperature of the coal dust conveying air in the collector above the dew point cannot be overemphasized. Careful selection of heat-insulating materials has eliminated difficulties of this kind.

Pressure balance of the cloth may be secured by closing either the inlet- or outlet-gas damper. It is not necessary to close both. In this installation, the inlet dampers were used because it simplified construction and outlet dampers were not provided because they were unnecessary. It has been found by experience that shaking in a screen-type collector is ineffective if the cloth pressure is unbalanced as little as 0.02 in. of water. Reverse gas flow is unnecessary and is of doubtful value.

Mr. Throne states that cloth pressure balance is unnecessary with the tubular free-hanging-type collector. It is quite unnecessary with all types if draft loss is no object. It would be of interest to know the magnitude of the pressure unbalance for the installation mentioned. It is certain that, if a pressure unbalance exists at the time of shaking, it is also true that more effective shaking is possible if the pressure unbalance is eliminated. Cloth maintenance will be reduced as a result. Needlessly high

pressure drops should be avoided on large installations because fan-power requirements will be high and cloth maintenance will be a very costly item. Although the collector described operated at a pressure above atmospheric, the system will operate equally satisfactorily at a pressure below atmospheric. The pressure-release system in the latter case will be rather simple.

The authors agree with Mr. Witt that fireproofing the cloth does not protect the dust-filter equipment after a fire has started in the collector. As pointed out in the paper, the primary purpose of the cloth flameproofing is that of localizing a fire after it has started. At this stage, the chief concern of the operator would be to prevent spreading to other parts of the mill system and to adjacent equipment. From this point of view as well as the moral value, the slight additional cost of the flameproofing is justified. The authors do not know of any coal-dust cloth-filter installations of the type of design described in which fires have occurred. There have been fires in the type of collector described with bakelite-dust installations and other similar dusts. None of the fires were directly attributed to the collector but they were carried into it from other parts of the system.

Mean Temperature Difference in Design

By R. A. BOWMAN,[1] A. C. MUELLER,[2] AND W. M. NAGLE[3]

In heat-transfer apparatus the rate of heat flow from the hot to the cold fluid is proportional to the temperature difference between the two. For design purposes, it is necessary to be able to determine the mean difference in temperature from the inlet and exit temperatures. Numerous investigators have contributed analyses of the temperature difference for exchangers with neither countercurrent nor cocurrent flow. This paper coordinates the results of previous studies on the same basis to give as complete a picture as possible of all the various arrangements of surface and flow. Shell-and-tube exchangers with any number of passes on shell side and tube side are covered as are the crossflow exchangers with different pass arrangements and with mixed and unmixed flow. The special cases of trombone coolers, pot coolers, and batch processes, not previously published, are also treated in detail.

Nomenclature

THE following nomenclature is used in the paper:

A = area of heating surface
C = specific heat of shell-side (or hot) fluid
c = specific heat of tube-side (or cold) fluid
e = base of natural logarithms
F = correction factor, dimensionless
M = weight of fluid batch
N = number of shell-side passes
$P = (t_2 - t_1)/(T_1 - t_1)$, dimensionless
$p = (T_1 - T_2)/(T_1 - t_1)$, dimensionless
Q = quantity of heat transferred
$q = (t_2 - t_1)/(T_1 - t_1)$, dimensionless
$R = wc/WC$, or $(T_1 - T_2)/(t_2 - t_1)$, dimensionless
$r = \Delta t_m/(T_1 - t_1)$, dimensionless
r_0 = value of r for countercurrent flow
T_1 = inlet temperature shell-side (or hot) fluid
T_2 = outlet temperature shell-side (or hot) fluid
t_1 = inlet temperature tube-side (or cold) fluid
t_2 = outlet temperature tube-side (or cold) fluid
Δt_m = mean temperature difference
U = over-all heat-transfer coefficient
W = weight rate of flow of shell-side (or hot) fluid
w = weight rate of flow of tube-side (or cold) fluid
Θ = time

Introduction

Heat-exchanger design is based primarily on the equation

$$Q/A\Theta = U\Delta t_m \quad \ldots\ldots [1]$$

In this basic equation, the amount of heat transferred per unit of time and surface is shown to equal the product of the over-all heat-transfer coefficient U, and the mean temperature difference, Δt_m. The value of U may be estimated from correlated over-all coefficients determined in similar exchangers under similar conditions, or it may be obtained by combination of individual coefficients. The mean temperature difference Δt_m is calculated from terminal temperatures, the method of calculation varying with the type of exchanger and method of operation.

For simple heat exchangers in which there is steady-state operation and countercurrent flow of the hot and cold fluids, integration of the differential equation, relating the temperatures of the two fluids, leads to the well-known log-mean temperature difference

$$\Delta t_m \text{ (countercurrent flow)} = \frac{(T_1 - t_2) - (T_2 - t_1)}{2.3 \log_{10} \dfrac{T_1 - t_2}{T_2 - t_1}} \quad \ldots [2]$$

The integration involves the following assumptions:

1 The over-all heat-transfer coefficient U is constant throughout the heat exchanger.

2 The rate of flow of each fluid is constant.

3 The specific heat of each fluid is constant.

4 There is no condensation of vapor or boiling of liquid in part of the exchanger. Condensation of pure saturated vapor or boiling of pure saturated liquid throughout the entire length of the heat exchanger, resulting in $T_1 = T_2$ or $t_1 = t_2$, does not affect the integration if the first assumption remains true.

5 Heat losses are negligible.

For heat exchangers in which there is steady-state operation and cocurrent flow, the corresponding integrated average temperature difference is

$$\Delta t_m \text{ (cocurrent flow)} = \frac{(T_1 - t_1) - (T_2 - t_2)}{2.3 \log_{10} \dfrac{T_1 - t_1}{T_2 - t_2}} \quad \ldots\ldots [3]$$

For any set of terminal temperatures, the average temperature difference for cocurrent flow is always less than that for countercurrent flow, unless the temperature of one fluid stream is constant throughout the exchanger.

In the majority of industrial installations true countercurrent heat exchangers are not as economical as multipass and crossflow units. In multipass exchangers the flow is cocurrent in part and countercurrent in part and, as a result, the mean temperature difference lies somewhere between Δt_m for cocurrent flow and Δt_m for countercurrent flow. The mean temperature difference for the various types of crossflow exchangers is also less than that for countercurrent flow and greater than that for cocurrent flow. The relationships between terminal temperatures and mean temperature difference limit the performance of each type of exchanger. For a given set of temperature and rate conditions, the mean temperature difference for some types of multipass or crossflow exchangers may be zero, and the exchanger therefore inoperable, while a countercurrent or another type of multipass exchanger may operate satisfactorily. Formulas or curves are available for calculating the mean temperature difference from terminal temperatures in various types of heat exchangers. These are assembled in this

Contributed by the Heat Transfer Professional Group and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

paper and, where possible, are expressed in the form of a correction factor, F, by which the log mean Δt for countercurrent flow is multiplied to give the true mean temperature difference.

$$\Delta t_m = (F)\ (\Delta t_m \text{ for countercurrent flow})$$

$$= (F)\ \frac{(T_1 - t_2) - (T_2 - t_1)}{2.3 \log_{10} \dfrac{T_1 - t_2}{T_2 - t_1}} \quad \ldots\ldots\ldots\ldots\ldots [4]$$

This method of presentation is believed to show most clearly the degree to which the mean temperature difference of any exchanger is inferior to the log-mean Δt for countercurrent flow.

Multipass Heat Exchangers

The widely used shell-and-tube heat exchangers are often provided with baffled heads to route the fluid inside the tubes back and forth from one end of the exchanger to the other. In some cases the shell-side fluid is also caused to travel the length of the heat exchanger more than once by means of longitudinal baffles. Differential equations for a number of such arrangements have been derived and integrated. In the integration the following assumptions are made:

1 The over-all heat-transfer coefficient U is constant throughout the heat exchanger.
2 The rate of flow of each fluid is constant.
3 The specific heat of each fluid is constant.
4 There is no condensation of vapor or boiling of liquid in part of the exchanger.
5 Heat losses are negligible.
6 There is equal heat-transfer surface in each pass.
7 The temperature of the shell-side fluid in any shell-side pass is uniform over any cross section.

The first five assumptions are those employed in the derivation of the ordinary log-mean temperature-difference formula. The sixth is in accord with usual heat-exchanger design practice and the seventh is essentially true where many transverse baffles are incorporated in the exchanger.

Multipass exchangers with an even number of tube-side passes per shell-side pass were studied by Nagle (1),[4] Underwood (2), Bowman (3), and Yendall(15). Their results are summarized as follows:

One Pass Shell Side; Two Passes Tube Side. The correction factor F for multipass heat exchangers, having one shell-side and two tube-side passes, is plotted in Fig. 1 against P and R. The latter are dimensionless ratios, defined as follows:

$$P = (t_2 - t_1)/(T_1 - t_1)$$

$$R = (T_1 - T_2)/(t_2 - t_1)$$

The curves of Fig. 1 are based on the integrated equations obtained by Underwood (2) and by Yendall, rather than on the graphical integrations of Nagle (1), from which they differ by as much as 2 per cent. The integrated equation for Δt_m is

$$\Delta t_m \text{ (one-two exchanger)} = \frac{\sqrt{(T_1 - T_2)^2 + (t_2 - t_1)^2}}{\log_e \left\{ \dfrac{T_1 + T_2 - t_1 - t_2 + \sqrt{(T_1 - T_2)^2 + (t_2 - t_1)^2}}{T_1 + T_2 - t_1 - t_2 - \sqrt{(T_1 - T_2)^2 + (t_2 - t_1)^2}} \right\}} \quad \ldots\ldots [5]$$

This equation may be transposed into the following form, in which the F factor for one-two exchangers is expressed in terms of P and R.

$$F_{1,2} = \frac{\sqrt{R^2 + 1}}{R - 1} \log_{10} \frac{1 - P}{1 - PR} \Bigg/ \log_{10} \frac{(2/P) - 1 - R + \sqrt{R^2 + 1}}{(2/P) - 1 - R - \sqrt{R^2 + 1}} \quad \ldots\ldots [6]$$

In Equation [6], and in subsequent Equations [7] and [8], the expression

$$\frac{1}{R - 1} \log_{10} \frac{1 - P}{1 - PR}$$

becomes indeterminate when $R = 1$, but the usual treatment for such indeterminates reduces this expression to

$$\frac{P}{2.3\ (1 - P)}$$

The correction factor is exactly the same whether the shell-side fluid enters at the fixed or the floating head.

One Pass Shell Side; Four Passes Tube Side. The correction factor for one-four heat exchangers is slightly less than that for one-two exchangers, but the difference is so small that separate curves are unnecessary. Underwood's integration is expressed in hyperbolic functions, and Yendall's in logarithms; but the numerical results appear to be the same. Based on Yendall's work, the correction factor may be expressed as

$$F_{1,4} = \frac{\sqrt{4R^2 + 1}}{2(R - 1)} \log \frac{1 - P}{1 - PR} \Bigg/ \log \frac{1 + V\left(\sqrt{4R^2 + 1} - 2R\right)}{1 - V\left(\sqrt{4R^2 + 1} + 2R\right)} \quad \ldots [7]$$

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

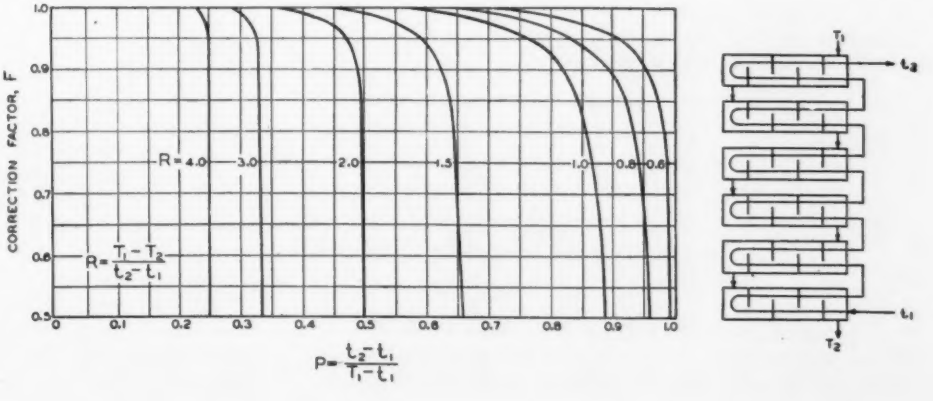

FIG. 5 CORRECTION-FACTOR PLOT FOR EXCHANGER WITH SIX SHELL PASSES, AND TWELVE, TWENTY-FOUR, OR ANY MULTIPLE OF TUBE PASSES

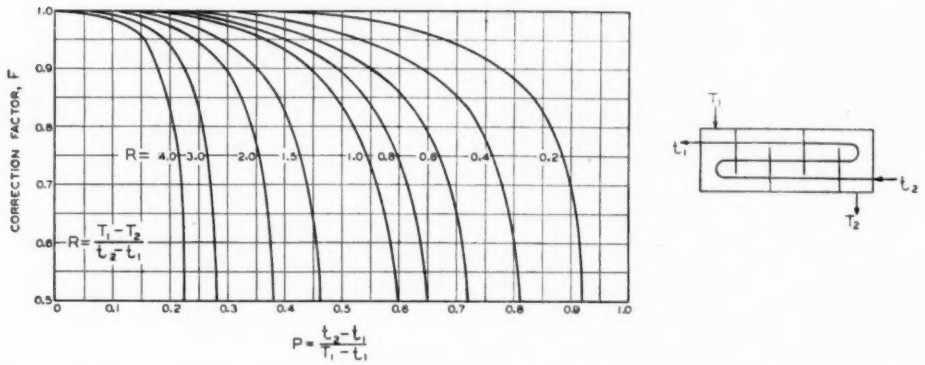

FIG. 6 CORRECTION-FACTOR PLOT FOR EXCHANGER WITH ONE SHELL PASS, AND THREE, SIX, OR ANY MULTIPLE OF TUBE PASSES; MAJORITY OF TUBE PASSES IN COUNTERCURRENT FLOW

where

$$V = \frac{t_2 - t_1}{4T_1 - (t_1 + 2t_i + t_2)}$$

and t_i is the intermediate temperature of the tube-side fluid where it leaves the second and enters the third tube-side pass. The value of t_i may be obtained by trial-and-error solution of

$$\left(\frac{t_i - t_1}{t_2 - t_i}\right)^{\sqrt{4R^2+1}} = \frac{1 + V\left(\sqrt{4R^2+1} - 2R\right)}{1 - V\left(\sqrt{4R^2+1} + 2R\right)}$$

One Pass Shell Side; Six Passes Tube Side. Nagle (1) found that the correction factors for one-six exchangers agreed so closely with those of one-two exchangers operating with the same terminal temperatures that the curves of Fig. 1 may be used for this case.

One Pass Shell Side; Infinite Passes Tube Side. It has been pointed out by Bowman (3) that the correction factor F for a multipass heat exchanger, having one shell-side pass and a very large number of tube-side passes, approaches as a limit the case of crossflow with both fluids completely mixed. Even in the limit, however, the value of F is generally only 1 to 2 per cent less than that of the one-two exchangers.

Two Passes Shell Side; Four Passes Tube Side. The foregoing discussion indicates that the correction factors for heat exchangers with one shell-side pass and two, four, six, and infinite tube-side passes are essentially the same. In many jobs that reach the designer, however, these types of exchangers are inefficient or entirely inoperative, and an arrangement giving higher values of F is required. This may be obtained by the use of two exchangers in series or of a single exchanger having two shell-side passes and four tube-side passes. The correction factor F for two-four exchangers piped in the usual manner to approach countercurrent flow is given graphically in Fig. 2 and algebraically by the following rearrangement of Underwood's equation for two-four heat exchangers

$$F_{2,4} = \frac{\sqrt{R^2+1}}{2(R-1)} \log_{10} \frac{1-P}{1-PR} \Bigg/ \log_{10} \frac{(2/P) - 1 - R + \frac{2}{P}\sqrt{(1-P)(1-PR)} + \sqrt{R^2+1}}{(2/P) - 1 - R + \frac{2}{P}\sqrt{(1-P)(1-PR)} - \sqrt{R^2+1}} \quad \ldots [8]$$

The derivations leading to Fig. 2 and Equation [8] involve the additional assumptions that there is no leakage of fluid or heat across the transverse baffle separating the two shell-side passes.

Three and More Shell-Side Passes. Bowman (3) developed a general method for calculating the F factors of three-six, four-eight, six-twelve, etc., heat exchangers from the correction factors of one-two exchangers. At any given values of F and R, the value of P for an exchanger having N shell-side and $2N$ tube-side passes is related to P for a one-two exchanger by the equation

$$P_{N,2N} = \frac{1 - \left(\frac{1 - P_{1,2}R}{1 - P_{1,2}}\right)^N}{R - \left(\frac{1 - P_{1,2}R}{1 - P_{1,2}}\right)^N} \quad \ldots [9]$$

For the special case of $R = 1$, Equation [9] becomes an indeterminate which reduces to

$$P_{N,2N} = \frac{P_{1,2}N}{P_{1,2}N - P_{1,2} + 1}$$

The results are given in Figs. 3, 4, and 5, which may also be used with little error for exchangers that are multiples of the one-four or the one-six, rather than the one-two exchanger.

From an inspection of Figs. 1 through 5, it may be seen that, for any value of P and R, the correction factor approaches unity as the number of shell-side passes is increased. This is to be expected, since a multipass exchanger with several shell-side passes approaches the ideal countercurrent heat exchanger more closely than does one with one shell-side and two or more tube-side passes.

In all the cases mentioned, the ratio of tube-side to shell-side passes is an even number, such as 2, 4, or 6. However, Fischer (4) has pointed out that there is some improvement in the mean temperature difference if the ratio of tube-side to shell-side passes is an odd number and the exchanger is so connected that the tube-side fluid is flowing counter to the shell-side fluid in over half the passes.

One Pass Shell Side; Three Passes Tube Side. The correction factors F, for one-three heat exchangers and for two-six, three-nine, and four-twelve exchangers have been derived by Fischer (4) and presented in the form of tables and charts. In each case, the value of F is greater than is found in exchangers having the same number of shell-side passes but an even numbered ratio of tube to shell passes. The improvement in mean temperature difference resulting from the use of three tube-side passes per shell-side pass instead of two or four is, however, by no means as great as that resulting from an increase of one in the number of shell-side passes. Correction factors for the one-three exchanger are given in Fig. 6.

Effect of Variation in Heat-Transfer Coefficient. The preced-

ing derivations are based on the assumption that the over-all heat-transfer coefficient U is constant throughout the heat exchanger. For the case of countercurrent flow in which U varies linearly with temperature, Colburn (13) has derived the general heat-transfer equation

$$\frac{Q}{A\Theta} = \frac{U_2 (T_1 - t_2) - U_1 (T_2 - t_1)}{2.3 \log_{10} \dfrac{U_2 (T_1 - t_2)}{U_1 (T_2 - t_1)}}$$

where U_1 is the value of U at the T_1 end of the exchanger and U_2 at the T_2 end. This equation has been combined by Sieder and Tate (*Industrial and Engineering Chemistry*, vol. 28, 1936, p. 1434) with the correction factor F for use with multipass heat exchangers

$$\frac{Q}{A\Theta} = (F) \frac{U_2 (T_1 - t_2) - U_1 (T_2 - t_1)}{2.3 \log_{10} \dfrac{U_2 (T_1 - t_2)}{U_1 (T_2 - t_1)}}$$

Until this equation has been tested more extensively its use should be limited to multipass exchangers having only one shell-side pass.

Examples Applying to Multipass Exchangers

The examples illustrating the variation of the mean temperature difference with type of heat exchanger are shown in Table 1.

TABLE 1 EXAMPLES ILLUSTRATING VARIATION OF MEAN TEMPERATURE DIFFERENCE WITH TYPE OF HEAT EXCHANGER

Example No. 1:
Where T_1 = 300 F, T_2 = 200 F, t_1 = 100 F, t_2 = 200 F
(R = 1, P = 0.5)

Exchanger	F	Δt_m, deg F
Countercurrent flow	1.000	100.0
Six-twelve multipass	1.000	100.0
Two-pass countercurrent crossflow, one fluid mixed	0.970	97.0
Horizontal film-type, helical connection	0.960	96.0
Two-four multipass	0.958	95.8
Horizontal film-type, return-bend connection	0.915	91.5
Single-pass crossflow, both fluids unmixed	0.910	91.0
One-three multipass	0.840	84.0
Single-pass crossflow, one fluid mixed	0.835	83.5
One-two multipass	0.804	80.4
One-four multipass	0.798	79.8
Single-pass crossflow, both fluids mixed	0.790	79.0
Two-pass cocurrent crossflow, one fluid mixed	0.405	40.5
Cocurrent flow	0	0

Example No. 2:
Where T_1 = 300 F, T_2 = 200 F, t_1 = 160 F, t_2 = 260 F
(R = 1, P = 0.714)

Exchanger	F	Δt_m, deg F
Countercurrent flow	1.000	40.0
Six-twelve multipass	0.970	38.8
Horizontal film-type, helical connection	0.795	31.8
Two-pass countercurrent crossflow, one fluid mixed	0.745	29.8
Single-pass crossflow, both fluids unmixed	0.682	27.3
Two-four multipass	0.645	25.8
Horizontal film-type, return-bend connection	0.395	15.8
One-three multipass	Impossible	
Single-pass crossflow, one fluid mixed	Impossible	
One-two multipass	Impossible	
Single-pass crossflow, both fluids mixed	Impossible	
One-four multipass	Impossible	
Two-pass cocurrent crossflow, one fluid mixed	Impossible	
Cocurrent flow	Impossible	

In the first example, all arrangements except that of cocurrent flow can be used. In the second example only countercurrent-flow heat exchangers, or multipass exchangers, which have two or more shell-side passes, can possibly give the desired results.

In the design of multipass heat exchangers, the general rules of Fischer (4) applying to mean temperature difference should be kept in mind. These are quoted as follows:

1 When the number of tube passes per shell pass is even, the mean temperature difference is independent of the direction of flow of the shell fluid in each shell pass.

2 When the number of tube passes per shell pass is odd, the mean temperature difference depends on the direction of flow of the shell fluid in each shell pass and is greatest when the counterflow tube passes exceed the parallel-flow tube passes in each shell pass.

3 In multi-shell-pass exchangers the over-all mean temperature difference depends on whether the flow of the fluids between the shell passes is counter or parallel flow.

4 The equations available for solving the true mean temperature difference applying to multipass heat exchangers can be made general by letting the T values represent the hot-fluid and t values represent the cold-fluid terminal temperature.

Use of Correction Factors in Design. From the standpoint of mean temperature difference alone, it is desirable to use the same number of shell passes as of tube passes since by so doing true countercurrent flow can be obtained. However, structural and servicing considerations limit the number of shell passes, two passes in general being the maximum number for one shell. On the other hand the minimum number of tube passes is set by the quantity of fluid, the allowable pressure drop, the available space, and the costs of construction. Any reduction in the number of tube passes below this figure will result in a lowered heat-transfer rate which may overbalance any gain in mean temperature difference.

The usual procedure in designing a heat exchanger is, then, to choose the number of tube passes on the basis of the foregoing considerations and then to select the number of shell passes which will give a satisfactory mean temperature difference. If the use of two passes gives too low a correction factor, the usual practice is to divide the required surface among two or more shells in series.

Probably the most noticeable feature of the correction curves is the fact that they all have a very steep gradient for the lower values of the correction factor. In other words, a relatively small change in temperature conditions will cause a large change of F and consequently of the mean temperature difference. It also follows that a small deviation from the assumed conditions on which the curves are based will cause an appreciable error in mean temperature differences derived from this part of the curves. For instance, an exchanger might be expected to work with a mean temperature difference of 50 per cent that of a countercurrent exchanger on the basis of the correction-factor curves, whereas, it may actually be an impossible condition, due to the fact that there is leakage of fluid or heat through the longitudinal shell baffle contrary to the assumption of zero leakage.

Consequently, the use of correction factors below 0.8 seems to be questionable from a design standpoint. In those cases where such low correction factors are indicated, one or more additional shell passes should be used. Also test data, obtained under conditions which give low correction factors, should not be accepted too readily for general application.

The use of exchangers with three tube passes per shell pass gives some improvement in mean temperature difference and there are applications where this is of value. Unfortunately, the greatest improvement comes at the lower values of correction factor where the use of the calculated data for any type of exchanger is none too safe. Furthermore, mechanical and thermal difficulties may prevent the use of this arrangement in the majority of cases.

When only the inlet temperatures, rates of flow, heat-transfer area, and coefficient are known, the method of Ten Broeck (5) is especially useful. The exit temperatures are easily obtained from his type of plot, eliminating the necessity of trial-and-error solution.

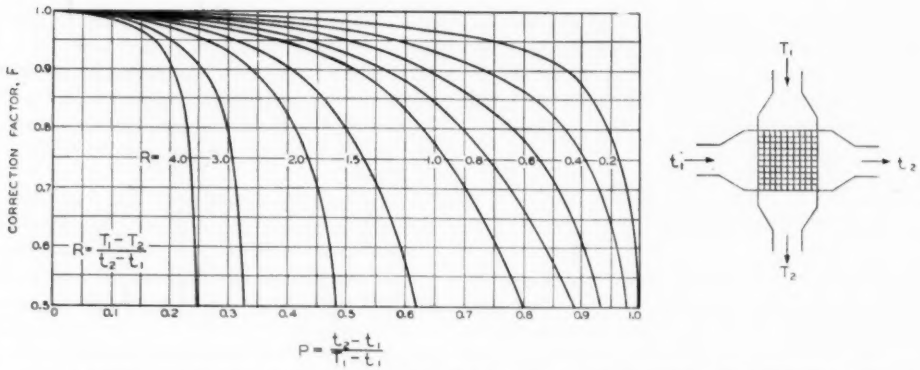

FIG. 7 CORRECTION-FACTOR PLOT FOR SINGLE-PASS CROSSFLOW EXCHANGER, BOTH FLUIDS UNMIXED

CROSSFLOW EXCHANGERS

Crossflow exchangers have the fluids flowing at right angles, therefore, neither the cocurrent nor countercurrent equations for mean temperature differences can be applied. The temperature of the fluid may vary in a direction normal to its flow as well as with the direction of flow. At the outlet, all infinitesimal sections of the stream may be at different temperatures as each was subjected to a different range of temperatures of the other fluid. The final outlet temperature is obtained by complete mixing of all infinitesimal sections. Mixing may take place within the exchanger and, if completely mixed, the fluid will have a temperature gradient only in the direction of flow. Therefore, the mean temperature difference is dependent upon whether either or both fluids are unmixed or mixed. In any practical crossflow exchanger, the case of unmixed fluids is more nearly approached than that of completely mixed fluids. Shell-and-tube exchangers with many transverse baffles are not crossflow exchangers because, even though the flow is normal to the tubes, the temperature change of the shell fluid is negligible for any baffle pass, the temperature gradient being parallel to the tubes. Conversely, as the number of shell-side passes in crossflow exchange is increased, the more closely will the case of cocurrent or countercurrent flow be approached.

Mathematical analysis of the mean temperature difference in a single-pass crossflow exchanger was initiated by Nusselt (6, 7). Smith (8) finished the analysis of the remaining cases of single-pass crossflow and extended it to two cases of two-pass crossflow exchangers. While others have presented equations or methods to determine the mean temperature difference, only Nusselt (7) and Smith (8) have carried out their calculations and presented tables or graphs from which the mean temperature difference may easily be computed from the known terminal temperatures.

There are several methods of presenting the results of the analyses of crossflow; each has certain advantages. Smith and Nusselt use a method in which the temperature-difference relationships depend upon three parameters which are defined as

$$p = \frac{T_1 - T_2}{T_1 - t_1}$$

$$q = \frac{t_2 - t_1}{T_1 - t_1}$$

$$r = \frac{\Delta t_m}{T_1 - t_1}$$

Substituting these parameters in the log-mean temperature-difference equation for countercurrent flow yields

$$r_0 \text{ (countercurrent flow)} = \frac{p - q}{\log_e \dfrac{1 - q}{1 - p}}$$

The method adopted for this paper is that of comparison to the log-mean temperature difference for countercurrent flow, which represents the maximum obtainable difference. This involves the use of F, P, and R which can be expressed in terms of the three parameters by the following relationships

$$F = \frac{r(\text{crossflow})}{r_0 \text{ (countercurrent flow)}}$$

$$R = \frac{p}{q} = \frac{T_1 - T_2}{t_2 - t_1}$$

$$P = q = \frac{t_2 - t_1}{T_1 - t_1}$$

By means of these relationships Smith's data (8) have been transposed into the curves Figs. 7 to 11. In the present form, the efficiency of the type of exchanger being considered is given by F. It is also easily apparent whether the exchanger will operate under the given conditions and what penalty is paid in the form of a poor correction factor F. For performance calculations on a known exchanger, the method of Ten Broeck (5) is especially useful.

The single-pass crossflow exchanger is the only case which has been completely investigated for all types of flow. Only several of the more important types of flow have been presented for the double-pass exchanger and the double-pass trombone exchanger. Mean temperature differences for more than two passes have not been determined except for the trombone exchangers. As the number of passes increases, the log-mean temperature difference for cocurrent or countercurrent flow will be approached, but no rule can now be given for the number of passes required before serious errors are introduced by use of these limits.

The integrations for mean temperature difference were made under the following assumptions:

1 The over-all heat-transfer coefficient U is constant throughout the heat exchanger.

2 The rate of flow of each fluid is constant.

3 The specific heat of each fluid is constant throughout the heat exchanger.

4 There is no condensation of vapor or boiling of liquid in part of the exchanger.

5 Heat losses are negligible.

6 There is equal heat-transfer surface in each pass.

7 The fluid is either unmixed or completely mixed normal to the flow, depending upon the type of flow assumed.

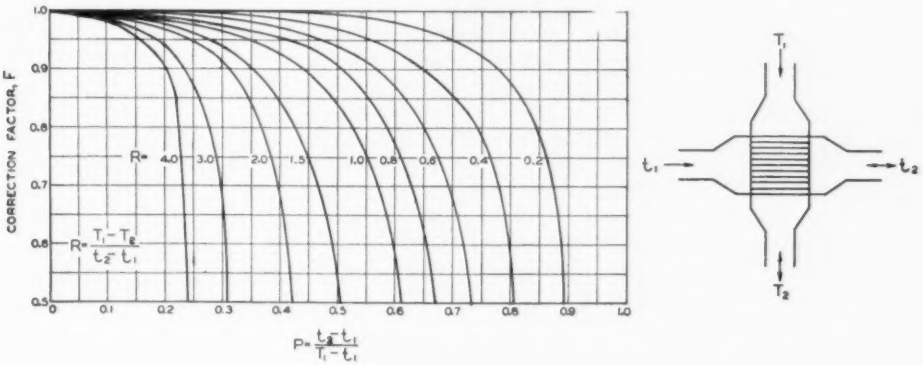

FIG. 8 CORRECTION-FACTOR PLOT FOR SINGLE-PASS CROSSFLOW EXCHANGER, ONE FLUID MIXED, OTHER UNMIXED

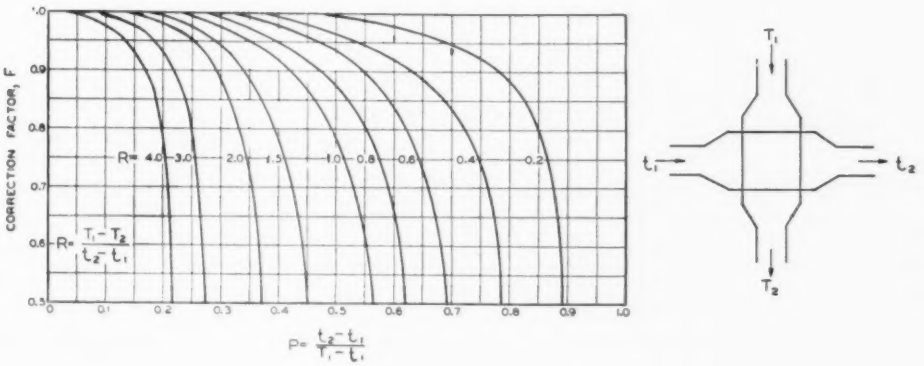

FIG. 9 CORRECTION-FACTOR PLOT FOR SINGLE-PASS CROSSFLOW EXCHANGER, BOTH FLUIDS MIXED

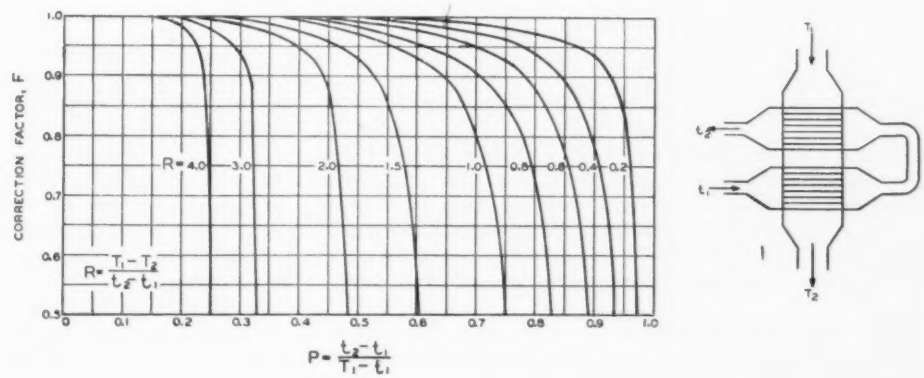

FIG. 10 CORRECTION-FACTOR PLOT FOR TWO-PASS CROSSFLOW EXCHANGER, SHELL FLUID MIXED, TUBE FLUID UNMIXED
(Shell fluid flowing across second and first passes in series.)

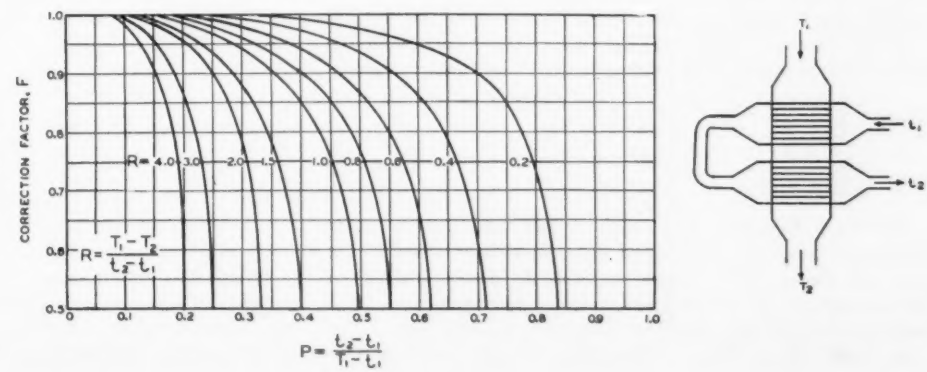

FIG. 11 CORRECTION-FACTOR PLOT FOR TWO-PASS CROSSFLOW EXCHANGER, SHELL FLUID MIXED, TUBE FLUID UNMIXED
(Shell fluid flowing across first and second pass in series.)

Single Pass; Both Fluids Unmixed. Each fluid crosses in a series of independent infinitesimal streams between which there is no mixing or heat transfer until the outlet is reached. Since each stream is subjected to a different range of temperatures of the other fluid, the streams will have different outlet temperatures, the final outlet temperature being the result of mixing of all streams. This assumption represents only the limit for any actual heat exchanger. However, it is nearly approached when one fluid flows through many tubes and the second fluid, crossing outside the tubes, is divided into many streams by baffles. In plate exchangers, mixing is prevented by baffles on each side.

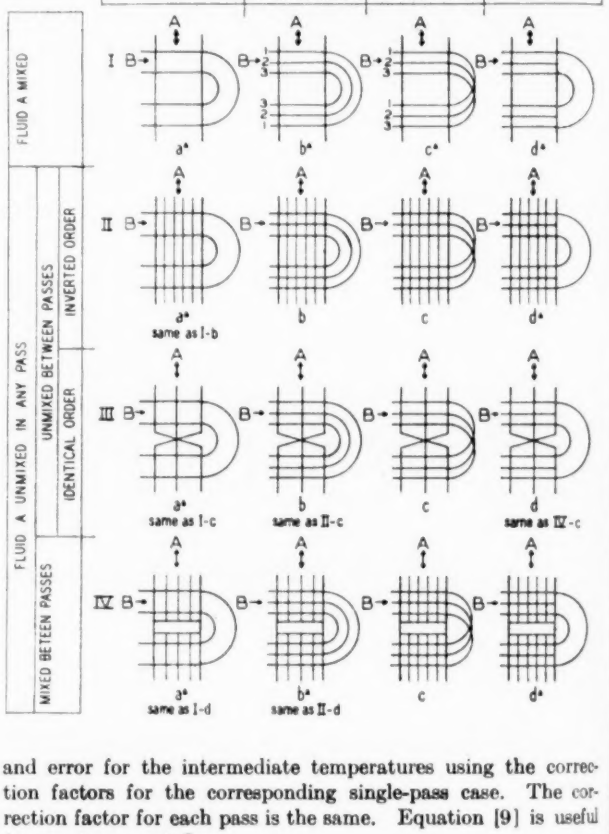
This type of crossflow has been frequently investigated. Nusselt's first solution (6) contained slowly converging series and in a later paper (7) a more rapidly converging series was obtained. Roszak, Véron, and Tripier (9), Binnie and Poole (10), and Liebaut (11) have all presented solutions of varying complexity. Fig. 7 was obtained from values calculated by Nusselt and based on the equation

$$r = \sum_{u=0}^{u=\infty} \sum_{v=0}^{v=\infty} \left\{ (-1)^{u+v} \frac{(u+v)!}{u!(u+1)!v!(v+1)!} \left(\frac{p}{r}\right)^u \left(\frac{q}{r}\right)^v \right\} \quad \ldots\ldots [10]$$

Single Pass; One Fluid Mixed, Other Unmixed. In this case, one fluid is so completely mixed normal to its flow that there is no temperature gradient. The second fluid is assumed to consist of independent streams between which there is no mixing. This is approached by the first fluid flowing across tubes with no baffles to prevent mixing and the second fluid flowing through tubes. This type of flow is obtained in a single-pass trombone exchanger. Here, as in subsequent cases where one fluid is mixed, p refers to the mixed fluid, q to the unmixed. Fig. 8 is based on the graphs of Smith (8) which were calculated from the equation

$$r = \frac{q}{\log_e \dfrac{1}{1 - \dfrac{q}{p} \log_e \dfrac{1}{1-p}}} \quad \ldots\ldots [11]$$

Comparison of the graphs shows the correction factors F are lower than in the preceding case. If an exchanger is to be designed with predetermined terminal temperatures, but the choice of fluid which is to be mixed is open, a larger correction factor F is obtained if the fluid with the greater temperature change is chosen for the mixed fluid. However, the increase in most cases is small.



Single Pass; Both Fluids Mixed. The remaining limiting case for single-pass crossflow is where each fluid is completely mixed so there is no temperature gradient normal to its flow. In Fig. 9 the correction factor F, is lower than in either of the two other cases. Here it is possible to get into a region where reversed heat flow may take place, that is, near the outlet the original cold fluid may be hotter than the other fluid. Fig. 9 is based on the graphs of Smith (8) which were calculated from the equation

$$r \left\{ \frac{\frac{p}{r}}{1 - e^{-\frac{p}{r}}} + \frac{\frac{q}{r}}{1 - e^{-\frac{q}{r}}} - 1 \right\} = 1 \quad \ldots\ldots [12]$$

Two-Pass Crossflow Exchangers. Two identical crossflow exchangers may be connected in series in at least ten different ways, as shown schematically in Table 2. Each of these arrangements can be operated either co- or countercurrent. The cases which have been partly or completely solved follow:

Ia Both Fluids Mixed. This case can be solved by trial and error for the intermediate temperatures using the correction factors for the corresponding single-pass case. The correction factor for each pass is the same. Equation [9] is useful for countercurrent flow.

TABLE 2—SCHEMATIC ARRANGEMENTS OF VARIOUS CASES OF TWO-PASS CROSS-FLOW
(CASES MARKED WITH TRIANGLE ARE EITHER PARTIALLY OR WHOLLY SOLVED)

Ib Fluid A Mixed, Fluid B Unmixed, Passes Connected in Inverted Order. This is exemplified by the trombone cooler with return-bend connections.

Ic Fluid A Mixed, Fluid B Unmixed, Passes Connected in Identical Order. This is exemplified by the trombone cooler with helical connections.

Id Fluid A Mixed, Fluid B Unmixed, Except Between Passes. Here it is assumed that the unmixed fluid makes two passes through the tubes but is mixed to a uniform temperature between the passes. The second fluid is completely mixed at all times and flows across the tubes of the second and first tube passes in series. Fig. 10 was obtained from the graphs by Smith (8) which were determined from the equation for the countercurrent case

$$r = \frac{q}{2 \log_e \dfrac{1}{1 - \dfrac{q}{p} \log_e \dfrac{\sqrt{\dfrac{1-q}{1-p}} - \dfrac{q}{p}}{1 - \dfrac{q}{p}}}} \quad \ldots\ldots [13]$$

When the present case is changed to cocurrent flow it is possible to obtain reversed heat flow due to the temperatures of the fluids crossing. The correction factors F in Fig. 11 apply to the log-mean temperature difference for countercurrent flow

as this is the basis for all other graphs. Fig. 11 is based on the graphs of Smith (8) which were calculated from the equation

$$r = \frac{q}{2 \log_e \dfrac{1}{1 - \dfrac{q}{p} \log_e \dfrac{p + q}{q + p\sqrt{1 - (p + q)}}}} \quad \ldots\ldots [14]$$

IId Both Fluids Unmixed, One Mixed Between Passes. This case is treated by Schumann (14) for co- and countercurrent flow. The method of analysis developed depends upon calculating each pass separately. At the present time, no simple relationship has been developed to determine the mean temperature difference for both passes from the terminal temperatures. One pass is the same case developed by Nusselt, the other, however, is complicated by an initial temperature distribution entering the pass.

IVd Fluids A and B Unmixed But Mixed Between Passes. This is treated in the same manner as *Ia*.

Horizontal Film-Type Exchangers

Horizontal film-type exchangers (also called trombone or trickle coolers) are simply banks of horizontal pipes, one above the other, over which a film of fluid is distributed. These exchangers are frequently used because of their simple and cheap construction and the ease of cleaning the outside of the pipe.

The equations for any number of passes of horizontal film-type exchangers have been derived. The cases solved are for countercurrent flow and for the return-bend and helical systems of connecting the passes. The usual assumptions given at the beginning of this section are made. In addition, it is assumed that the temperature of the fluid, inside the pipe, T, is uniform throughout its cross section at any point. It is also assumed that the liquor flowing over the banks of pipes is not mixed laterally. The final temperature of the liquor, t_2, is the result of complete mixing of each independent stream, which was at a different temperature when leaving the bottom pipe.

Return Bends. Here the fluid in the tube in one pass flows in an opposite direction to the fluid in the pass immediately above or below. There is only one bank of pipes formed with this system of connections. Fig. 12 is based on curves obtained for two passes from the equation

$$\frac{1}{1 - p} = e^{Kp/q}\left[\cosh \frac{Kp}{q} + (1 - K) \sinh \frac{Kp}{q}\right] \ldots [15]$$

where $K = 1 - e^{-q/2r}$.

Helical Connection. In this case the pipe may be considered as an elongated coil forming two banks of pipes. The direction of flow through all pipes in a given bank is the same. Fig. 13 is based on curves obtained for two passes from the equation

$$\frac{1}{1 - p} = e^{Kp/q}\left(e^{Kp/q} - K^2 \frac{p}{q}\right) \ldots\ldots [16]$$

where $K = 1 - e^{-q/2r}$.

Mean Temperature Difference for Tanks in Series, Heated or Cooled by Coils

There are occasional processes where a fluid is heated or cooled in a series of tanks by coils. One fluid overflows from one tank to another, each tank being at a different temperature. Fluid in the coils may be in series countercurrent to the tank fluid or each coil in a tank may be fed separately. The problem in design or analysis of data arises when only the number of tanks and the terminal temperatures are known. A method has been derived for such cases. For this case, assumptions are made as follows:

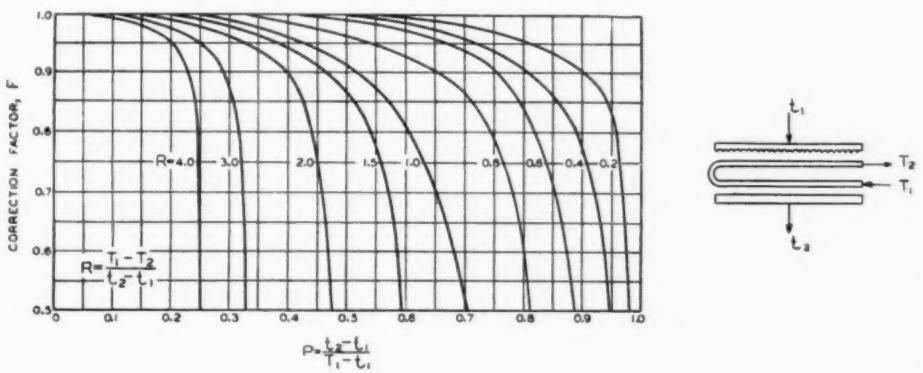


Fig. 12 Correction-Factor Plot for Two-Pass Horizontal Film-Type Exchanger, Return-Bend Connections

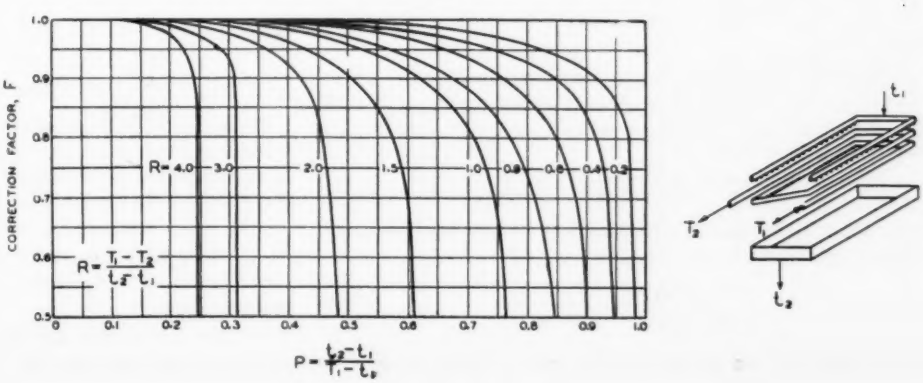

Fig. 13 Correction-Factor Plot for Two-Pass Horizontal Film-Type Exchanger, Helical Connections

1 Heat-transfer area and coefficient in each tank are the same.
2 Each tank is at a constant and uniform temperature.
3 Heat transferred is sensible heat.
4 Specific heats are constant.
5 Temperature and flow of fluids are constant.

Tanks in Series; Coils in Series Counterflow

Let $T_1, T_2, \ldots, T_n$ = temperature of feed to first, second, ... n tank
= temperature of coil liquid leaving the first, second, ... n tank
= temperature of liquid entering n tank

By a heat balance

$$\frac{wc}{WC} = R = \frac{T_n - T_{n+1}}{t_n - t_{n+1}} = \frac{T_1 - T_{n+1}}{t_1 - t_{n+1}} \quad \ldots\ldots [17]$$

for any tank, say tank No. 2

$$wc\,(t_2 - t_3) = UA\,\frac{(T_2 - t_3) - (T_3 - t_2)}{\log_e \dfrac{T_2 - t_3}{T_3 - t_2}} \quad \ldots\ldots [18]$$

and with UA constant for all tanks

$$\frac{UA}{wc} = \log_e \frac{T_{n+1} - t_{n+1}}{T_{n+1} - t_n} \quad \ldots\ldots [19]$$

From Equations [17] and [19] it may be shown that

$$R - \frac{R-1}{\phi} = \frac{T_1 - t_1}{T_2 - t_2} = \frac{T_i - t_i}{T_{i+1} - t_{i+1}}$$

where $$\phi = \frac{T_{n+1} - t_{n+1}}{T_{n+1} - t_n}$$

Therefore, the ratio of the terminal temperature differences for n tanks is

$$\frac{T_1 - t_1}{T_{n+1} - t_{n+1}} = \left(R - \frac{R-1}{\phi}\right)^n = Z^n \quad \ldots\ldots [20]$$

By adding Equation [18] for every tank and noting the relationship given in Equation [19]

$$wc(t_1 - t_{n+1}) = UA\,\frac{t_1 - t_{n+1}}{\log_e \phi}$$

but $wc(t_1 - t_{n+1}) = UAn\Delta t_m$ by definition, therefore

$$\Delta t_m = \frac{t_1 - t_{n+1}}{n \log_e \phi} \quad \ldots\ldots [21]$$

which may be expressed in terms of the terminal temperatures.

If R, ϕ, and the inlet temperatures are known, Equations [20] and [17] may be used in calculating the intermediate temperatures.

From Equation [20]

$$T_1 - t_1 = Z^n T_{n+1} - Z^n t_{n+1} \quad \ldots\ldots [22]$$

and from Equation [17]

$$T_1 - T_{n+1} = Rt_1 - Rt_{n+1} \quad \ldots\ldots [23]$$

solve for t_1 in Equation [22], substitute in Equation [23], and simplify to obtain

$$\frac{t_1 - t_{n+1}}{T_1 - t_{n+1}} = \frac{Z^n - 1}{RZ^n - 1} \quad \ldots\ldots [24]$$

These relations can be constructed into a simple graph. In Fig. 14, the line OG is drawn through point T_1, t_1 with a slope of R. The line OH is drawn to divide any horizontal segment GI between OG and the diagonal OI in such proportion that $GI/HI = \phi$. By similar triangles $GI/HI = GE/HJ$, which latter expression is ϕ by definition. The temperature in any tank is found by proceeding stepwise from T_1 and t_1 for n steps.

Tanks in Series; Coils in Parallel. In this case, let t_1 = inlet temperature of all coils and $t_2, t_3, \ldots t_{n+1}$ = outlet temperature for first, ... n tanks.

For any tank, say tank No. 1

$$wc(t_2 - t_1) = UA\,\frac{(T_2 - t_1) - (T_2 - t_2)}{\log_e \dfrac{T_2 - t_1}{T_2 - t_2}} \quad \ldots\ldots [25]$$

If UA is the same for each tank

$$\frac{UA}{wc} = \log_e \frac{T_{n+1} - t_1}{T_{n+1} - t_{n+1}} \quad \ldots\ldots [26]$$

From Equations [25] and [26], it is readily found that

$$R\left(1 - \frac{1}{\psi}\right) + 1 = Y = \frac{T_1 - t_1}{T_2 - t_1} = \frac{T_2 - t_1}{T_3 - t_1}, \text{ etc.} \quad \ldots [27]$$

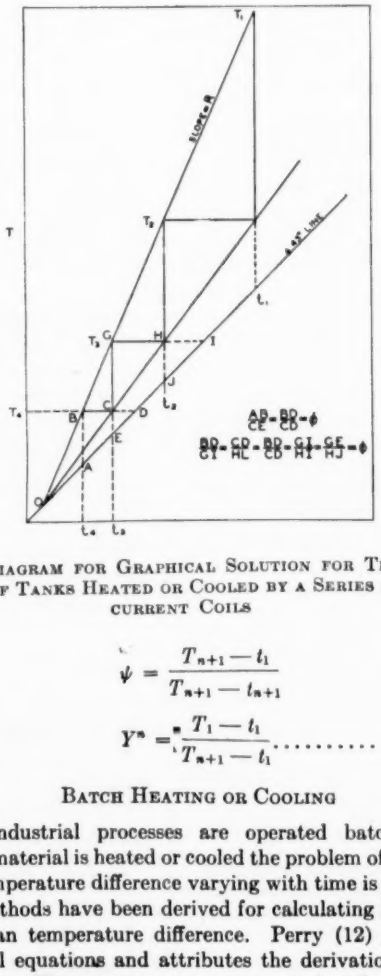

FIG. 14 DIAGRAM FOR GRAPHICAL SOLUTION FOR TEMPERATURES IN SERIES OF TANKS HEATED OR COOLED BY A SERIES OF COUNTERCURRENT COILS

where $$\psi = \frac{T_{n+1} - t_1}{T_{n+1} - t_{n+1}}$$

whence $$Y^n = \frac{T_1 - t_1}{T_{n+1} - t_1} \quad \ldots\ldots [28]$$

BATCH HEATING OR COOLING

Many industrial processes are operated batchwise; and where the material is heated or cooled the problem of determining a mean temperature difference varying with time is encountered. Several methods have been derived for calculating heat transfer or the mean temperature difference. Perry (12) presents one of the final equations and attributes the derivation to Boelter and Cherry. The equations were integrated with the following assumptions:

1 The rate of flow and inlet temperature of the heating or cooling medium are constant

2 The specific heat of each fluid is constant.

3 Only sensible heat is involved, there being no change of phase or heats of reaction.

4 The batch fluid is well agitated and of uniform temperature T.

5 Heat losses are negligible.

6 The over-all heat-transfer coefficient U is constant.

The general design equation is

$$Q = UA\Delta t_m\Theta = MC(T_1 - T_2) \quad [29]$$

and expressed differentially as

$$\frac{dT}{(T-t)_m} = \frac{-UAd\Theta}{MC} \quad [30]$$

where $(T - t)_m$ is the log mean of $(T - t_a)$ and $(T - t_b)$, t_a and t_b being the inlet and outlet temperature of the flowing fluid at time Θ. A heat balance on the batch and cooling media at time θ is

$$wc(t_b - t_a)d\Theta = -MCdT \quad [31]$$

Solve Equation [31] for t_b and substitute in the log-mean temperature difference $(T - t)_m$ in Equation [30]. This gives

$$\log_e \frac{T - t_a}{T - t_a + \dfrac{MCdT}{wcd\Theta}} = \log_e \frac{\Delta t_a}{\Delta t_b} = \frac{AU}{wc} \quad [32]$$

which may be rewritten and integrated over time period Θ, to give

$$Q = wc\Theta(T - t_a)_m \left(1 - e^{-\frac{AU}{wc}}\right) \quad [33]$$

or

$$-UA = 2.3\, wc \log_{10}\left(1 - \frac{Q}{wc\Theta\,(T - t_a)_m}\right)$$

where $(T - t_a)_m$ is the log-mean difference of the terminal batch temperatures and the inlet temperature t_a of the medium.

Either Equation [32] or [33] may be used depending upon the information available. Equation [32] is useful when the temperature rise of the heating or cooling medium is known at any time Θ and batch temperature T. With this equation experimental data may easily be investigated to determine the variation of the over-all coefficient U. If the over-all coefficient varies as a straight-line function of temperature T, then Colburn (13) has shown that the value of $U\Delta t_m$ should be the log mean of $U_1\Delta t_2$ and $U_2\Delta t_1$. Equation [33] is useful in design because it is not necessary to know the exit temperature of the flowing fluid. The foregoing equations were derived on the assumption of complete mixing of the batch at any time; this, however, is seldom realized in actual operation. In the other extreme of no mixing the problem is that of unsteady-state conduction. Methods of determining mean temperature for various degrees of mixing have not been developed.

Acknowledgment

The authors are grateful for permission to include the previously unpublished results of A. P. Colburn for the batch heating process, of T. B. Drew for horizontal film-type exchangers and tanks in series, and of E. F. Yendall on the one-two and one-four heat exchangers.

Discussion

E. A. Schumann, Jr.[5] The writer is well aware of the enormous labor expended in the preparation of the various correction-factor plots given in this paper and feels that the authors are to be thanked for their contribution to heat-transfer-design data.

A comment seems appropriate on the significance of the dimensionless correction factor F in studies of the relative merits of counterflow and unmixed crossflow heat exchangers. It is readily seen that the correction factor represents a ratio of mean temperature differences.

$$F = \frac{\Delta t_m \text{ (crossflow)}}{\Delta t_m' \text{ (counterflow)}}$$

and further, that

$$F = \frac{U'}{U} \times \frac{A'\text{(counterflow)}}{A\text{(crossflow)}}$$

Since F is less than unity

$$UA > U'A'$$

and for identical rates of heat absorption in both types of exchanger, it is apparent that the extent of crossflow heating surface need not be greater than that in the counterflow exchanger, as is sometimes supposed.

On the contrary, designs which can be adapted to high mass-flow rates of the shell-side fluid (tubular-type unmixed crossflow exchanger) commensurate with economical pressure drop may be made to operate with higher shell-side fluid conductances than could be obtained in a counterflow installation.

Finally, any correction factor based on the authors' argu-

[5] Engineer, Construction Department, The Detroit Edison Company, Detroit, Mich. Jun. A.S.M.E.

ment P, and fluid ratio R, is only as reliable as the assumption made regarding the strictness with which the expected or actual flow directions adhere to the ideal crossflow.

Authors' Closure

The intent of this paper is to present a simplified method for determining the true mean temperature difference for various types of flows encountered in heat exchangers from the log-mean temperature difference by applying a correction factor. The correction factor F should not be interpreted as indicating the relative merits of countercurrent exchangers with other flow-type exchangers as this would hold only under the special conditions of identical flow rates, temperatures, and heat-transfer coefficients. While it may be possible by using an exchanger other than a countercurrent type to increase the over-all heat-transfer coefficient more than the lowering of the true mean temperature difference, there are, however, some types of exchangers for which certain temperature conditions cannot be met irrespective of the value of the heat-transfer coefficient; this is shown in example 2 of Table 1. No method of calculating the true mean temperature difference for the crossflow case has been developed for cases where the flow is not either completely mixed or unmixed; this was specified in the assumptions on which the equations are based.

Automatic Control in the Presence of Process Lags

By C. E. MASON,[1] FOXBORO, MASS., and G. A. PHILBRICK,[2] FOXBORO, MASS.

In this paper, the methods of "Quantitative Analysis of Process Lags" developed in a previous paper[3] are extended to include automatic control. Carrying on the idea of representation by liquid-level systems, a specific system is postulated as a model for a typical industrial process which may or may not be thermal. Continuing the quantitative approach, the mathematical machinery is demonstrated by which the operation of control on processes may be investigated. A selected succession of controllers, characterized by the laws of control which govern them, are considered in connection with their performance on the model system. Although no attempt has been made to formulate rules governing the proper application of the various types of controllers considered or governing the adjustment of any of these individual types, the authors consider that analyses of this sort may well serve as a guide to practical theorems in a technology of automatic control.

THE quantitative behavior of certain resistance-capacity systems was discussed in a former paper[3] presented before this Society. These systems exhibited characteristics similar to those of industrial processes in which control-resisting lags are found, and were thus proposed as convenient models for such processes. To bear out the implied analogy, the models themselves, considered as liquid-level systems, were developed side by side with equivalent thermal systems. In this way it was found possible to give definite analytic form to the all-important dynamic properties of equipment to which the application of automatic control is contemplated, and to justify a professed effort to fill the gap in a literature otherwise primarily concerned with the properties of the controls themselves.

Having already dealt with the inherent attributes of a few such model systems, the authors will show in the present paper, how the treatment may be extended to cover their behavior under automatic control. The procedure will be to choose a specific model process to which to apply a succession of types of controls (assumed to be pneumatically operated), the model being one which is representative of a typically difficult prototype system, involving a combination of capacity and transfer lags. For concreteness, this prototype system may be considered as a thermal process, although it could equally well involve hydraulic, pneumatic, or electrical phenomena, either singly or in combination.

Although the alleged purpose of an automatic-control installation is that of holding constant a certain process variable, this is in reality only accomplished by a series of recoveries from threatening unbalances, the continuity of which constitutes the record of control. In practice, the disturbances are normally gradual to some degree. It is this fact which makes possible the apparent elimination of the effects of upsetting influences.

Since it is obviously impractical to draw conclusions as to the over-all (transient) characteristics of the combined system through the application of any series of influences, it is desirable to select an isolated, suddenly applied, disturbing influence. The results of such a disturbance must involve the complete transient characteristics of the process and controller in combination.

The model system selected as representative is shown in Fig. 1. The capacity and resistance elements of which it is constructed are the same sort as previously described.[3] T_a, T_b, and T_c are

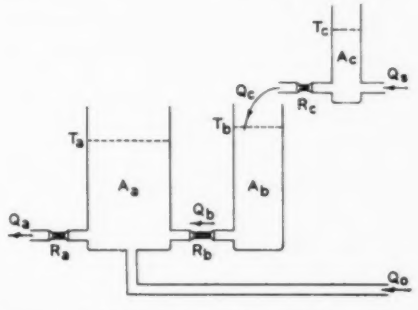

FIG. 1 HYDRAULIC MODEL OF A TYPICAL CONTINUOUS PROCESS

levels (potentials) in the three tanks, the equivalent areas[4] (capacities) of which are A_a, A_b, and A_c. These areas are interconnected through the restrictions (resistances) R_a, R_b, and R_c. The flows Q_a, Q_b, Q_c, Q_s, and Q_o are disposed as shown.

The level T_a in A_a is intended to be the controlled variable, while the supply flow Q_s is to be given the role of manipulated variable by means of which the control of T_a is accomplished. The auxiliary-supply flow Q_o provides a means for altering the load condition, for on the value of this flow depends the value of Q_s necessary to produce any given eventual (or potential) value of the controlled variable T_a. The output flow Q_a is directly dependent at any time on the value of T_a and in equilibrium is equal to the sum of Q_s and Q_o.

TABLE 1 SUMMARY OF PHYSICAL UNITS FOR HYDRAULIC MODEL AND THERMAL PROCESS

	Dimensional symbol	Units: Hydraulic counterpart	Units: Thermal counterpart
Quantity	[W]	Pound (weight)	Btu (heat)
Potential (T)	[P]	Inch (level or head)	Deg F (temp)
Time (t)	[T]	Minute	Minute
Flow (Q)	[WT^{-1}]	Lb/min	Btu/min
Capacity (A)	[WP^{-1}]	Lb/in.	Btu/deg
Resistance (R)	[$W^{-1}PT$]	In./(lb/min)	Deg/(Btu/min)

The physical units for the various constant and variable factors or quantities will be taken as those employed in the former paper,[3] although of course any consistent system of units could

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] A factor proportional to the area, and numerically dependent upon the units used.

be chosen. Table 1 summarizes these units both for the hydraulic model and for the corresponding thermal process.

Since the model shown in Fig. 1 is similar in form to that given as case VI (Fig. 11) in the former paper,[3] differing therefrom only in the inclusion of the cascaded capacity A_c, it will be appropriate to assign the same numerical values to the constants of the system, in so far as this is possible (Table 2). The units to be assumed for these system constants are as given in Table 1, whether for the hydraulic model or for the thermal prototype.

TABLE 2 NUMERICAL VALUES OF SYSTEM CONSTANTS

$A_a = 32.00$	$R_a = 0.1250$
$A_b = 16.00$	$R_b = 0.2500$
$A_c = 4.00$	$R_c = 0.0625$

As pointed out, the original process, of which the hydraulic system of Fig. 1 is to be considered a model, might have any one of a variety of forms. Its nature has been taken arbitrarily as thermal. It might, for example, be thought of as a process identical with the two-capacity thermal system shown in Fig. 4 of the previous paper,[3] but with the modification that the electric heating agency is indirectly manipulated by means of an operation involving simple capacity lag, such as exists with a large air motor setting a current regulator.[5] In any event, for present purposes it may be assumed that the model has been faithfully constructed, and thus the hydraulic system as such may be dealt with directly. Incidentally, the possibility should not be overlooked that the original, or prototype, system might be of the same nature as the model, as for instance a large-scale industrial liquid-level process having transfer lag.

Before proceeding to the application of automatic controls, let us briefly discuss the properties of the specific hydraulic system (or analog) from the point of view of the former paper.[3] Since this is a three-capacity system, the differential equation describing the dynamic relation between the significant variables (T_a, Q_s, and Q_o) will be of the third order. The derivation of this equation will not be given in its entirety since it follows straightforwardly from the methods of the previous paper. The fundamental hydraulic equations are

$$\left.\begin{array}{ll} T_a' = (Q_b + Q_o - Q_a)/A_a & T_a = R_a Q_a \\ T_b' = (Q_c - Q_b)/A_b & T_b - T_a = R_b Q_b \\ T_c' = (Q_s - Q_c)/A_c & T_c = R_c Q_c \end{array}\right\} \quad \ldots . [1]$$

Eliminating all variables except the significant ones

$$(A_3)T_a''' + (A_2)T_a'' + (A_1)T_a' + T_a = R_a Q_s + R_a Q_o + R_a(B_1)Q_o' + R_a(B_2)Q_o''$$

$$\left.\begin{array}{ll} \text{where } (A_1) = A_a R_a + A_b R_a + A_b R_b + A_c R_c \\ (A_2) = A_a R_a A_b R_b + A_c R_c (A_a R_a + A_b R_a + A_b R_b) \\ (A_3) = A_a R_a A_b R_b A_c R_c \\ (B_1) = A_b R_b + A_c R_c \\ (B_2) = A_b R_b A_c R_c \end{array}\right\} \quad \ldots [2]$$

which is the complete process equation for the system of Fig. 1. In the present investigation, the auxiliary flow Q_o will be kept always at steady values except when suddenly changed from one steady value to another in simulation of an instantaneous upset; thus for the time intervals considered

$$Q_o' = Q_o'' \equiv 0$$

and the process equation becomes

$$(A_3)T_a''' + (A_2)T_a'' + (A_1)T_a' + T_a = R_a(Q_s + Q_o) \quad \ldots . [3]$$

[5] In this manner, the so-called "valving" lags may be included as parts of the process rather than as parts of the controls.

Upon insertion of the numerical values given in Table 2

$$4\,T_a''' + 18.5\,T_a'' + 10.25\,T_a' + T_a = 0.125\,(Q_s + Q_o) \quad \ldots . [4]$$

in which, by way of recapitulation,

T_a = controlled variable
Q_s = manipulated variable
Q_o = auxiliary supply flow

The supply flow Q_s is to be operated on by the controlling apparatus in its effort to maintain T_a at a constant value. The auxiliary flow Q_o will suddenly be changed from one value to another under otherwise steady conditions to provide a disturbance to the controlled system at an arbitrarily initial instant ($t = 0$).

As in the former paper, let the desired or normal value $(T_a)_{norm}$ of T_a be

$$(T_a)_{norm} = 80 \text{ (in. or deg)}$$

In the thermal counterpart of Fig. 4,[3] the auxiliary flow Q_o was the flow of heat energy—above 0 F—contained in the mechanical flow of 8 lb per min of water. Assuming again that initially the inlet-water temperature is 60 F, then the disturbance can consist of a sudden decrease in this temperature from 60 F to 40 F. Thus, for the thermal system, the flow Q_o had been initially $8 \times 60 = 480$ Btu/min, while the altered value of Q_o is $8 \times 40 = 320$ Btu/min. Hence for either system

$(t < 0)$ $Q_o = 480$ (lb per min or Btu per min)
$(t > 0)$ $Q_o = 320$ (lb per min or Btu per min)

Allow the range in which the variable Q_s may be changed by the controls to be given by

$$(Q_s)_{min} \leqq Q_s \leqq (Q_s)_{max}$$

where $(Q_s)_{min} = 0$ (lb per min or Btu per min)
$(Q_s)_{max} = 640$ (lb per min or Btu per min)

If the controlled variable T_a is to be at its desired value $(T_a)_{norm}$ in the balanced or undisturbed preinitial state, then, since the value of the auxiliary flow Q_o is already determined for that epoch, it will be seen from the steady-state version (all derivatives equal zero) of Equation [3] (or Equation [4]) that the initial balanced value of Q_s must be

$$(Q_s)_{init} = [(T_a)_{norm}/R_a] - (Q_o)_{init} = (80/0.125) - 480 = 160$$

Our system is thus prepared for the application of the controlling apparatus which will now be considered.

Application of Control Apparatus

The complete or interconnected control circuit, comprising both controlled process and controller, is symbolically shown in Fig. 2, in which the process is characterized by the group of its inherent system constants, and where the other various components of the controlled system are shown in their functional relationship to one another.

Fig. 3 gives a somewhat more realistic picture of the combined system. In Fig. 1 the elements of the process under control are shown in greater detail.

The manipulated supply flow Q_s is assumed to be under successful control by means of a flow controller, in which instrument the balanced value of flow, or the flow control point, may be set by the operating means (the pneumatic operating pressure) of the level controller, which is the direct analog of a temperature controller in the thermal counterpart. This instrument contains the measuring means and the control mechanism, while the flow controller acts as a positive controlling means. These assumptions will be followed for all types of control mechanism considered.

Suppose for simplicity that, as the operating air pressure P, Fig. 3, of the control mechanism varies from zero to its maximum value, namely, the supply pressure P_s, the resulting supply flow Q_s maintained by the flow controller varies proportionately from zero to its maximum value $(Q_s)_{max}$. Thus

$$\frac{P}{P_s} \equiv \frac{Q_s}{(Q_s)_{max}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

With the operating means of the control mechanism thus directly linked to the manipulated flow, the equation of the control mechanism may be expressed as a functional relationship between the controlled variable T_a and the manipulated variable Q_s, or as

$$Q_s = F_c(T_a) = \text{"controller function" of } T_a \ldots\ldots [6]$$

This corresponds to the form of the process equation which may be written

$$T_a = F_p(Q_s) = \text{"process function" of } Q_s \ldots\ldots [7]$$

Equations [6] and [7] are of course symbolic since the functions are in general differential expressions and involve time. They

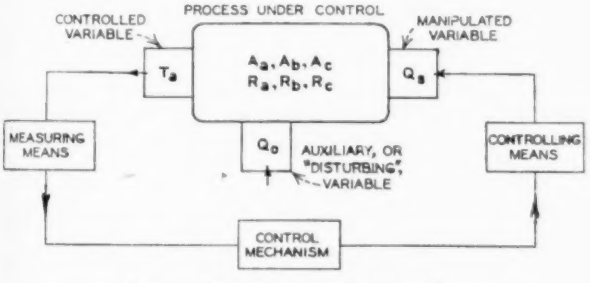

FIG. 2 DIAGRAMMATIC CONTROL CIRCUIT

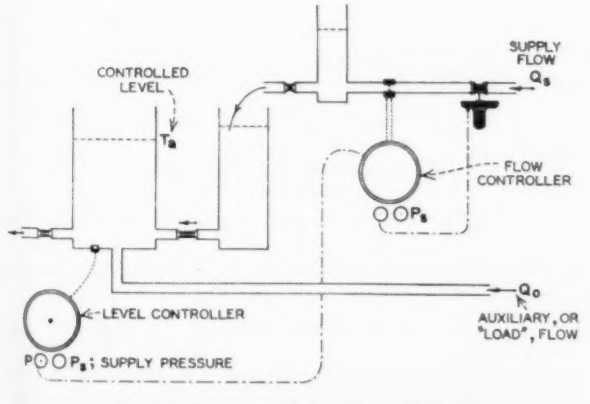

FIG. 3 COMPLETE CONTROLLED SYSTEM

serve, however, to illustrate the reversal of cause and effect in passing from process to controller or from controller to process. In tabular form:

	Cause	Effect
Process	Manipulated variable	Controlled variable
Controller	Controlled variable	Manipulated variable

In the "philosophy" of control, this concept may be considered basic.

The exact nature of the functional relation Equation [6] will depend upon the particular type of controller under consideration. The functional relation Equation [7] for the process is provided in the present case by Equation [3] (and/or [4]). For purposes of comparison, not only among the general controller types but between different conditions of adjustment for any one type of controller, the same initial conditions and also the same manner and magnitude of upset will be assumed throughout. Before taking up the controllers in order, it will be informative to determine the effect on the controlled variable T_a of the disturbance to be employed when this disturbance acts on the system in equilibrium and with the controls assumed inoperative. The resulting deviation of T_a will be a standard by which to ascertain the actual amount of correction brought about by the action of the controllers when operative on the process. Thus, it will be assumed that the foregoing initial conditions are in effect on the process and that, at $t = 0$, the chosen disturbance is inflicted. Since no controller is acting, the supply flow Q_s will remain constant at its initial value, while the auxiliary flow Q_o will have its new balanced value. Thus from the initial conditions and from the process Equation [4]

$$4\,T_a''' + 18.5\,T_a'' + 10.25\,T_a' + T_a = 0.125\,(160 + 320)$$

or

$$(T_a - 60)''' + 4.625\,(T_a - 60)'' + 2.5625\,(T_a - 60)' + 0.25\,(T_a - 60) = 0 \ldots\ldots [8]$$

The solution of Equation [8] to find the variation of T_a as a function of time is a procedure similar to those described in the previous paper.[5] It involves the roots of the auxiliary algebraic equation.

$$k^3 + 4.625\,k^2 + 2.5625\,k + 0.25 = 0 \ldots\ldots [9]$$

and the initial values of the first and second derivatives of T_a (rate of change and acceleration immediately following the disturbance).

The roots of Equation [9] are all real and negative and may be found by any desired method, although in general for speed and precision Graeffe's method[6] is recommended for any linear algebraic equation of higher degree than the second. As a matter of fact Equation [9] is directly factorable in this case (due to the cascaded nature of the analog process) and may be written

$$(k^2 + 0.625\,k + 0.0625)\,(k + 4) = 0 \ldots\ldots [9a]$$

The roots are thus

$$k_a = -0.125 \qquad k_b = -0.5 \qquad k_c = -4 \ldots\ldots [10]$$

The initial values of the first two derivatives of T_a may be determined, through the use of Equations [1], from the change in Q_o constituting the disturbance. Since the initial value of the third derivative of T_a will also be necessary in later examples and may conveniently be found in conjunction with the other two derivatives, all three have been found for the assumed upset and are listed as follows:

$$\left.\begin{array}{lll} (T_a')_o = -5 & \text{(in. per min or deg per min)} \\ (T_a'')_o = +1.875 & \text{(in. per min}^2\text{ or deg per min}^2\text{)} \\ (T_a''')_o = -0.859375 & \text{(in. per min}^3\text{ or deg per min}^3\text{)} \end{array}\right\} \ldots [11]$$

Reference to Appendix 1[7] shows the solution in this case to be of the form

$$T_a - T_p = T_a - 60 = C_a e^{k_a t} + C_b e^{k_b t} + C_c e^{k_c t} \ldots\ldots [12]$$

[5] "Mathematics of Modern Engineering," by R. E. Doherty and E. G. Keller, John Wiley & Sons, Inc., New York, vol. 1, 1936, pp. 98–130.

[7] The Appendixes referred to throughout the paper form a mathematical supplement which does not appear in this publication. A limited number of copies of this supplement are available, however, and may be obtained from the authors on request.

where the k's are the roots given and the C's are integration constants involving both the roots and the initial values of the derivatives in a manner shown in Appendix 1.[7] Inserting the numerical values there results

$$T_a = 60 + 13.33\,e^{-0.125t} + 6.67\,e^{-0.5t} + 0.00\,e^{-4t}$$

The integration constant C_c is reduced automatically to zero for the case chosen, since the system is essentially two-capacity with respect to changes in Q_o alone, Q_c Fig. 1 remaining constant along with Q_s for the period considered. Thus for the effect of the disturbance on T_a in the absence of control

$$T_a = 60 + 13.33\,e^{-0.125t} + 6.67\,e^{-0.5t} \quad \ldots\ldots [13]$$

$$\left.\begin{array}{ll} \text{Thus when } t = 0 & T_a = (T_a)_o = 80 \text{ (in. or deg)} \\ \text{and when } t \to \infty & T_a \to (T_a)_\infty = 60 \text{ (in. or deg)} \end{array}\right\} \quad \ldots\ldots [14]$$

The behavior of T_a following $t = 0$ is shown in Fig. 4. An even-

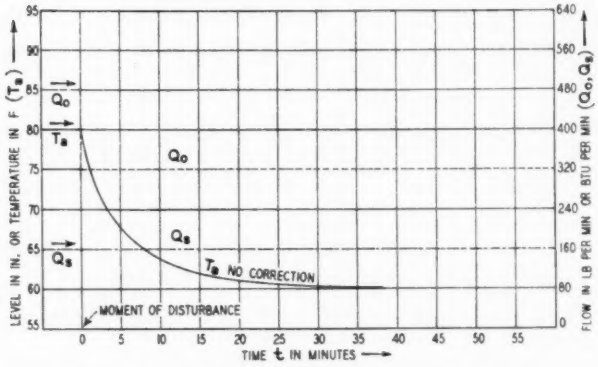

FIG. 4 EFFECT OF DISTURBANCE WITHOUT CONTROL

tual departure of 20 units from the desired value is evident. Plotting may be carried out directly from Equation [13] by means of exponential tables, or through the rather more convenient indirect graphical method used in the previous paper (Appendix 4[7]).

In either manually or automatically controlling this process (Fig. 1), the flow Q_s is changed in an attempt to counteract the effect of the disturbance on T_a, and eventually to restore this variable to its original value. The equation for T_a' (see Equations [1]) and the curve of Fig. 4 show that a change in Q_o has an immediate effect on T_a. On the other hand a change in Q_s, however great, can be shown to have no immediate effect on the value of T_a, due to the intervening parts of the process between the point of application of the manipulated flow Q_s and the location of the controlled variable T_a. Thus no matter what operations are performed on Q_s, a certain inevitable departure of T_a will be experienced, the magnitude of which will depend, not only upon the character (including transfer lags) of the intervening parts of the process, but also on the amount of the available corrective change in Q_s. This leads naturally to the subject of automatic control. First, that type of control will be considered which can produce the greatest initial change in the manipulated variable namely

"TWO-POSITION" CONTROL

Other terms commonly applied to this category are: "on-and-off," "open-and-shut," "fixed-position" control, and the various "....stats." The French "*tout ou rien*" seems particularly picturesque. Certainly there is no need to linger over this characteristic. The law of control may be summarized briefly, in connection with the system under consideration, as

$$\left.\begin{array}{ll} Q_s = (Q_s)_{max} = 640 & \text{for } T_a < (T_a)_{norm} = 80 \\ Q_s = (Q_s)_{min} = 0 & \text{for } T_a > (T_a)_{norm} = 80 \end{array}\right\} \quad \ldots [15]$$

Since in operation, the value of Q_s is constant except for discontinuous changes involving (theoretically) zero time intervals, the resulting behavior of T_a may be discovered by a series of solutions of the process equation itself using methods similar to those in the foregoing part of this paper and in the previous paper.[1] This procedure involves dividing the time following the disturbance into intervals between successive crossings of the desired value by the controlled variable. Fortunately the linearity of the equations permits superposing additively the individual results of the members of any combination of causes in determining their combined effect. Thus, in the beginning, it is merely necessary to add, to the disturbance deviation given by Equation [13] or Fig. 4, the deviation caused by suddenly increasing Q_s alone from its preinitial balanced value (160) to its maximum value (640). This deviation is similar to curve (*a*) of Fig. 12 in the former paper and is readily obtained, requiring merely a different set of boundary conditions to be imposed on Equation [4], namely,

$$\begin{array}{ll} Q_s = 640 & (T_a')_o = 0 \\ Q_o = 480 & (T_a'')_o = 0 \\ & T_p = 140 \end{array}$$

Reference to Equation [1] will show why the first two derivatives are initially unaffected by a sudden change in Q_s. The numerical

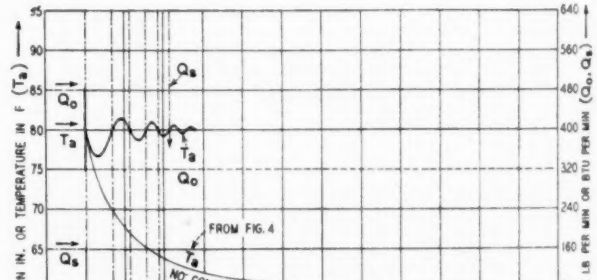

FIG. 5 RECOVERY TRANSIENT WITH IDEAL TWO-POSITION CONTROL

solution, which is found in a similar manner to that for the curve of Fig. 4, is

$$T_a = 140 - 82.59\,e^{-0.125t} + 22.87\,e^{-0.5t} - 0.28\,e^{-4t} \quad \ldots [16]$$

When this deviation is added to that occasioned by the disturbance alone, the first loop of the control transient is obtained, in which T_a passes through its first (inevitable) minimum and returns sharply toward a new potential value. This stage continues only until the desired value is attained, at which time another deviation must be added to the sum of the other two. This is the deviation caused by an independent sudden variation in Q_s from its maximum to its minimum value. This algebraic addition of a new deviation, at each crossing of the desired value (or control-point setting), to the sum of all previous deviations, may be continued as far as is practical or desired. Thus, at approximately 15 min in this case, we are substantially adding together 10 distinct curves. The accuracy of the result becomes increasingly questionable due to the difficulty involved in exact determination of the time intervals. The resulting control transient (or "recovery" transient) is shown in Fig. 5. The

intervals become increasingly shorter as time progresses while the amplitude tends toward zero. Limiting conditions of this sort are only true in an ideal sense, of course, since even slight imperfections, such as dead zones, friction, discontinuity, etc., will make them invalid. It may be noted that, even though the flow Q_s theoretically never becomes steady, its fluctuations are becoming increasingly fast and its average value in this ideal case must approach that required to give T_a the desired value. Thus

$$(Q_s)_{avg} \rightarrow 320 \text{ (lb per min or Btu per min)}$$

To avoid the irrational assumption that, preceding the disturbance, the flow hypothetically had been in a state of constant motion throughout its entire range, it will be assumed that the process was in equilibrium with the controls inoperative prior to $t = 0$, at which time the controller is made operative simultaneously with the imposition of the upset.

As already noted, the foregoing results apply only to an assumedly ideal two-position control mechanism. This condition may be approached only with a highly sensitive and responsive measuring means. It will be interesting to consider, as an example of what may come under this heading in general, the case of a two-position controller in which a certain degree of dead space is involved, for example in the detection of the controlled variable. Here the control mechanism might not sense the actual value of T_a itself but instead that of another variable in imperfect correspondence therewith. The imperfection meant here is one

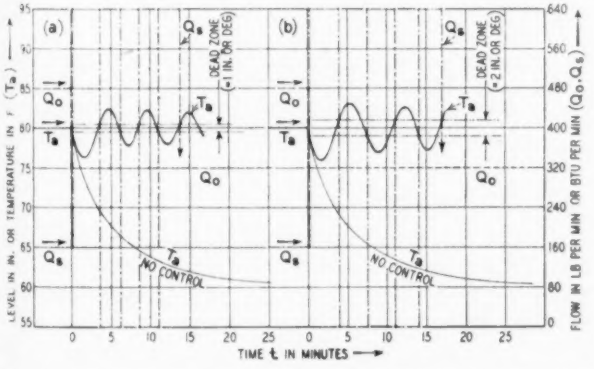

FIG. 6 RECOVERY TRANSIENTS WITH TWO-POSITION CONTROLLER HAVING "DEAD SPACE"

which allows the variable corresponding to T_a to follow T_a at a constant separation when the latter variable moves persistently in one direction and to remain unaffected when T_a reverses its direction until T_a has proceeded in the opposite direction by an amount equal to twice the constant separation. This behavior is similar to the action of two imperfectly meshed gears when the rotation of the driver is reversible. Let us determine the effect on the recovery transient.

The recovery transient for the two-position controller with dead space may be found in much the same way as for the ideal instrument, except that the correcting changes undergone by Q_s occur, not when the desired value of T_a is crossed, but when T_a has passed beyond that value by an amount equal to $^1/_2$ the dead zone. This merely requires, in plotting, that the individual effects of the changes involved are added together at different initial instants. Fig. 6 shows the results for 1 and for 2 units (in. or deg) of dead zone, assuming the same initial conditions, etc., as before. The oscillations of T_a can never die out in this case but will eventually settle down to a steady state of oscillation with an amplitude which is always greater than the dead zone and which may even be several times the width of this zone when complicated process lags are involved. The manipulated variable Q_s will continue to fluctuate regularly between its maximum and minimum values at definite intervals, which may be of objectionable duration.

TWO-POSITION-WITH-RATE CONTROL

This descriptive, though not particularly euphonious, name has been tentatively assigned to a class of control which is widely represented in relatively simple applications. Closely allied to the simple two-position class, it differs therefrom in that it gives to the action of the controlling means a definite constant rate when the controlled variable is on one side of the control-point setting, and gives (usually) the same rate in the opposite

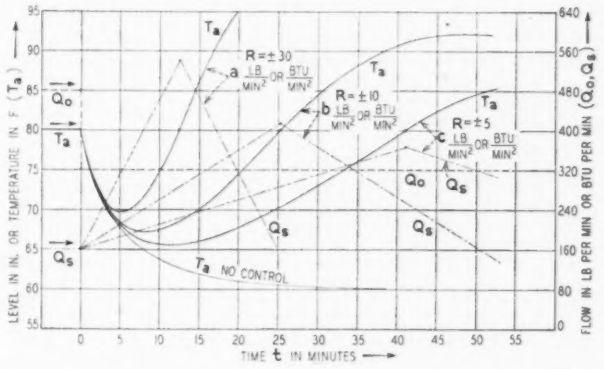

FIG. 7 RECOVERY TRANSIENTS UNDER "TWO-POSITION-WITH-RATE" CONTROL

sense when the controlled variable is on the other side of the control-point setting. This "law of control" may be expressed for the case under consideration, as

$$Q_s' = +R \quad \text{when} \quad T_a < T_{cp}$$
$$Q_s' = -R \quad \text{when} \quad T_a > T_{cp}$$

The quantity R is the constant rate at which the manipulated variable (the flow Q_s) changes. It should be added that this expression of the law requires that Q_s remain between the limits zero and $(Q_s)_{max}$. This type, it is evident, approaches two-position control as the rate R becomes progressively larger.

This characteristic is included primarily for the sake of completeness; its behavior in the face of process lags is markedly inferior. Thus we shall not give the mathematical procedure by which determination of its behavior on the chosen system may be found, but merely note that this involves solution—by stages—of the nonhomogeneous differential equation

$$(A_3)T_a''' + (A_2)T_a'' + (A_1)T_a' + T_a - R_a(Q_0 \pm Rt) = 0$$

Results of such determinations are shown in Fig. 7, in which the following rates are assumed:

$$\text{Case } (a) \quad R = 30 \left(\frac{\text{lb}}{\text{min}^2} \text{ or } \frac{\text{Btu}}{\text{min}^2}\right)$$

$$\text{Case } (b) \quad R = 10 \left(\frac{\text{lb}}{\text{min}^2} \text{ or } \frac{\text{Btu}}{\text{min}^2}\right)$$

$$\text{Case } (c) \quad R = 5 \left(\frac{\text{lb}}{\text{min}^2} \text{ or } \frac{\text{Btu}}{\text{min}^2}\right)$$

The relatively fast rate used in case (*a*) is seen to produce an excessive overshoot on return, while a considerably slower rate, as in case (*c*), delays recovery from the upset and permits a greater

deviation. It is evident that a compromise, as in case (*b*), is ineffective in avoiding these two evils.

The inadequacy of this type of control in the present instance is due to the inclusion of transfer lags in the process. This method of control has been used successfully in certain commercial applications, however, but its success has resulted from an abundance of capacity in that part of the process in which the controlled variable is measured. When such conditions prevail, two-position control would be even more successful in the degree of control obtainable, but the two-position-with-rate method allows much smaller fluctuations in the manipulated flow.

Illusion of an Immediate, "Exact" Correction

It may be interesting to note the effect, on the behavior of T_a following an upset, of an enforced immediate change in Q_s to a

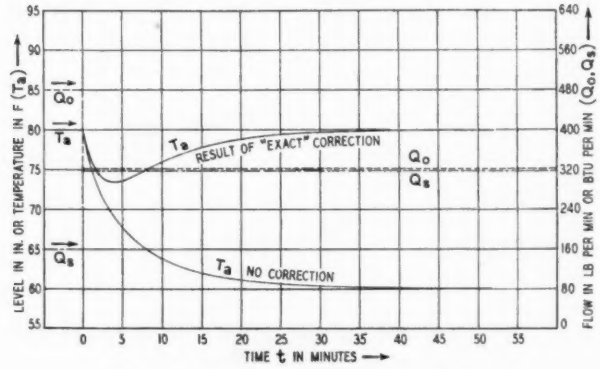

Fig. 8 Effect of an "Exact" Correction

new steady value of such magnitude as to produce eventual return by T_a to its desired value. Such a change in Q_s would necessitate a precise knowledge of the disturbance suffered, and might be thought to be an ideal correction. It is ideal, however, only in the steady-state sense. By the foregoing superposition method employed we may plot the resulting deviation by adding to that of Fig. 4 the result of suddenly changing Q_s from 160 to 320 units (an "exact" correction). Fig. 8 shows the consequent behavior of the controlled variable as a relatively slow aperiodic return to the desired value, involving a considerable maximum deviation. This type of correction would be satisfactory, in the transient sense, only if negligible lags existed between the manipulated and controlled variables. Furthermore, it does not lend itself to automatic execution since the measuring means can respond only to the result of a disturbance and cannot measure the cause which provoked it.

Proportional Control

This type is also called "throttling" control, due to the definitely allocated band of values (termed the "throttling band") in which the mechanism acts. The operating means of the control mechanism, here the value of the pneumatic operating pressure, is made to correspond linearly with the values of the controlled variable within the throttling band in such a way that the operating pressure has its maximum value when the controlled variable is at the lower limit of the throttling band and has its minimum value when the controlled variable is at the upper limit of that band. Whenever the controlled variable is below (or above) the throttling band, the operating pressure stands at its maximum (or minimum) value. When the controlled variable is precisely in the center of the throttling band, at a value arbitrarily called the "control-point setting," the operating pressure stands halfway between its extreme values. Since the manipulated variable Q_s is made coextensive with the operating pressure of the control mechanism, the foregoing remarks on the behavior of the operating pressure apply directly to that variable as well. Thus, assuming that the minimum value of the manipulated variable Q_s is zero, the law of control may be expressed as

$$\frac{Q_s - \frac{(Q_s)_{max}}{2}}{(Q_s)_{max}} = -\frac{(T_a - T_{cp})}{b}$$

where T_{cp} = control-point setting, or value of T_a at center of throttling band

b = absolute extent of throttling band in same units as T_a

For completeness the following boundary conditions should also apply

$$Q_s = (Q_s)_{max} \quad \text{for } T_a < T_{cp} - (b/2)$$
$$Q_s = 0 \quad \text{for } T_a > T_{cp} + (b/2)$$

It will be seen that the equations given merely embody the description of the mechanism's operation. Written in a more usable form

$$Q_s = \frac{(Q_s)_{max}}{2} - \frac{(Q_s)_{max}}{b}(T_a - T_{cp}) \quad \ldots\ldots [17]$$

or, with the assumed numerical datum as to $(Q_s)_{max}$

$$Q_s = 640\,[1/2 - (1/b)(T_a - T_{cp})] \quad \ldots\ldots [18]$$

The control-point setting T_{cp} and the throttling band b are of course "adjustables" of the mechanism. It may be said that the characteristic of this controller is a static one, in that the value of the manipulated variable at any time depends only upon the coincident value of the controlled variable and is independent of all previous or subsequent behavior of the latter variable.

The first step in the investigation of the performance of this type of control in connection with the specific process will be to combine the controller Equation [17] with the process Equation [3], obtaining

$$(A_3)T_a''' + (A_2)T_a'' + (A_1)T_a' + T_a = R_a Q_o + R_a\left[\frac{(Q_s)_{max}}{2} - \frac{(Q_s)_{max}}{b}(T_a - T_{cp})\right]$$

or

$$(A_3)T_a''' + (A_2)T_a'' + (A_1)T_a' + (1 + s)(T_a - T_p) = 0$$

where

$$s = \frac{R_a(Q_s)_{max}}{b} \quad \ldots\ldots [19]$$

$$T_p = \frac{R_a Q_o + s\,[T_{cp} + (b/2)]}{1 + s} \quad \ldots\ldots [20]$$

Now since s and T_{cp} will be constant during the time interval considered, the combined equation may be written as

$$(A_3)(T_a - T_p)''' + (A_2)(T_a - T_p)'' + (A_1)(T_a - T_p)' + (1 + s)(T_a - T_p) = 0 \quad \ldots [21]$$

The solution of Equation [21] under the usual initial conditions will give the behavior of T_a following the disturbance under proportional control. The meaning of T_p is shown (by Equation

[21]) to be the value at which T_a will eventually balance after the oscillations following the disturbance have faded. The controlled variable will not, except for one particular value of Q_o, balance out at the control-point setting. This general phenomenon is often referred to as "loss of control point." With this type of control the values of $(T_a)_{norm}$, T_p, and T_{cp} are distinct and different except for special cases.

Since the initial value of Q_o is known, Equation [20] will yield the value of T_{cp} necessary to give an initially balanced value of T_a, namely $(T_p)_o$, equal to the desired value $(T_a)_{norm}$. Thus

$$T_{cp} = \frac{(1+s)(T_a)_{norm} - R_a Q_o}{s} - \frac{b}{2} \quad \ldots\ldots [22]$$

Two separate cases will be considered in which the throttling bands are

$$(a) \ldots b = 10 \text{ (in. or deg)}$$
$$(b) \ldots b = 40 \text{ (in. or deg)}$$

Corresponding to these we have, from Equation [19]

$$(a) \ldots s = 8 \text{ (dimensionless sensitivity constant)}$$
$$(b) \ldots s = 2 \text{ (dimensionless sensitivity constant)}$$

Assigning to $(T_a)_{norm}$ the usual value of 80, Equation [22] gives, for the two cases, respectively

$$(a) \ldots T_{cp} = 77.5 \text{ (in. or deg)}$$
$$(b) \ldots T_{cp} = 70.0 \text{ (in. or deg)}$$

Thus, from Equation [20], the final balanced values are

$$\left.\begin{aligned}(a) \ldots T_p &= 77.78 \text{ (in. or deg)} \\ (b) \ldots T_p &= 73.33 \text{ (in. or deg)}\end{aligned}\right\} \quad \ldots\ldots [23]$$

The combined differential Equation [21] for controller and process becomes, respectively, in each of the two cases

$$4(T_a - T_p)''' + 18.5\,(T_a - T_p)'' + 10.25\,(T_a - T_p)' + 9\,(T_a - T_p) = 0 \ldots [24]$$

and $$4(T_a - T_p)''' + 18.5\,(T_a - T_p)'' + 10.25\,(T_a - T_p)' + 3\,(T_a - T_p) = 0 \ldots [25]$$

where the values of T_p are given by Equation [23].

The solutions of Equations [24] and [25] involve cyclically varying functions of time. The process of solution differs from

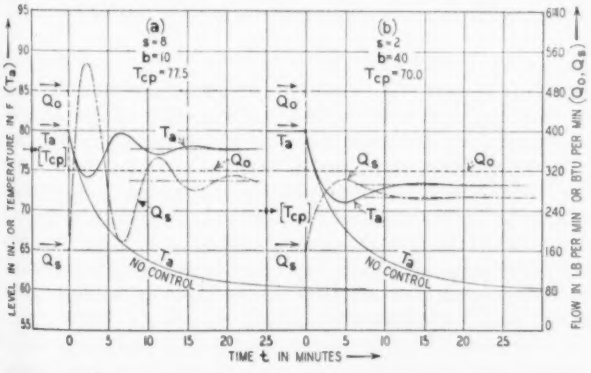

FIG. 9 RECOVERY TRANSIENTS WITH PROPORTIONAL CONTROL

those cases encountered heretofore in that the roots of the auxiliary algebraic equation are not all real. Appendix 2[7] shows a formal method of integration which may be used here, and which gives, for the two examples

$$T_a = 77.78 + 0.0472\,e^{-4.127t} + 6.549\,e^{-0.2440t}\cos(0.6959t + 1.231) \ldots [26]$$

and $$T_a = 73.33 + 0.0120\,e^{-4.036t} + 11.602\,e^{-0.2944t}\cos(0.3149t + 0.9599) \ldots [27]$$

These equations describe the behavior of T_a following the instant of upset and are plotted (Appendix 4[7]) in Fig. 9. It is essentially the exponential-cosine (or damped-sinusoid) term of the solution which governs the nature of the oscillations which the control transient comprises. The frequency (or period) and the damping factor are implicitly contained in this term.

For any given process, the roots of the auxiliary algebraic equation, and hence also the nature of the resulting damped sinusoid, are dependent exclusively upon the dimensionless constant s, which is the only variable of the controller entering the coefficients of Equation [21]. The factor s, which has been called the sensitivity constant of the combined system, depends directly upon both the output resistance R_a of the process and the maximum value $(Q_s)_{max}$ of the manipulated supply flow, and is inversely proportional to the extent of the throttling band b, Equation [19]. As the numerical value of the constant s is increased toward a value which would produce discontinuity for the particular upset, the period of cycling becomes shorter, the eventual departure from the desired value $[T_p - (T_a)_{norm}]$ becomes less, while the variation of the manipulated variable Q_s increases. The throttling band b is ordinarily an adjustable of this type of control mechanism, and is used to influence the sensitivity constant s. In practice, an optimum value for s (or for $1/b$) depends upon the permissible variation of Q_s for normal disturbances, and upon the mechanical perfection of the attendant apparatus.

Determination of the fluctuations suffered by the manipulated variable Q_s is fairly direct in this case since this may be accomplished from the already discovered behavior of T_a (Equations [26] and [27]) through the use of the controller Equation [17] or [18]. These fluctuations are also plotted in Fig. 9.

The effect of inertness or dead space in this type of control mechanism would be worthy of very intensive study, due to its inclusion in varying degrees in most commercial instruments. In the case of wide throttling bands, or when the magnitude of dead space is small compared to the throttling band, the effect is principally a proportionate increase in the amplitude and period of oscillation. When the dead space is commensurate with the throttling band, however, the effects may become far-reaching. This condition is especially threatening for small throttling bands; it will be seen that the detrimental effect of dead space as shown in the case of open-and-shut control becomes more influential as the throttling band approaches zero.

Once a substantial balance is attained with proportional control having dead space, the insensitivity of the controlling means to changes of the controlled variable within the dead space may result in complete inactivity of the controls during intervals of minor disturbances. Following larger disturbances, however, intervals of violent cycling can occur which may persist even after the cessation of the upsets. Many inexpensive regulators of this nature are in commercial use which apparently function ideally under small or slow disturbances, but which, when changes occur, calling for significant action by the control mechanism, seem to "lose their heads" and require manual assistance to regain their requisite inactivity.

"FLOATING" CONTROL

The name "integrating control" is sometimes given to this classification for reasons which will be evident. Except for the fact that some of the less complex regulating devices have approximately this characteristic, it is not in common use today. It is important, however, as a component of the more complex types, and has some unique features.

The functioning of this class of mechanism may be described by the statement that the action of the operating means of the control mechanism is a linear function of the integral of the deviation of the controlled variable from a desired value. Taking this value as the control-point setting T_{cp}, we may write, in terms of the operating pressure and using a proportionality factor c

$$\frac{P}{P_s} = -\frac{1}{c}\int (T_s - T_{cp})dt$$

or, with a definite integral

$$\frac{P}{P_s} - \left(\frac{P}{P_s}\right)_0 = -\frac{1}{c}\int_0^t (T_s - T_{cp})dt \quad \ldots\ldots [28]$$

A more universally pleasing form is obtained merely by differentiating either of these equations with respect to time; thus

$$\frac{P'}{P_s} = -\frac{1}{c}(T_s - T_{cp}) \quad \ldots\ldots [29]$$

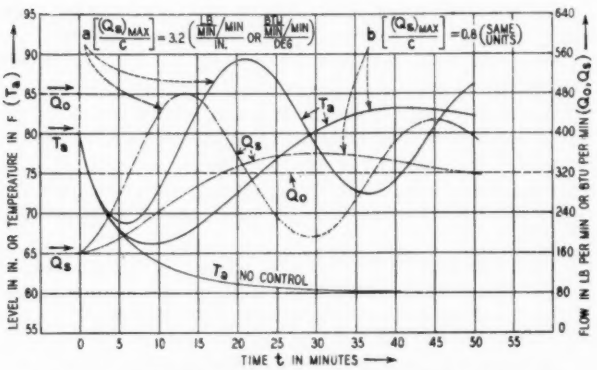

FIG. 10 RECOVERY TRANSIENTS UNDER FLOATING CONTROL

By the continued assumption that the manipulated variable is made coextensive with the operating pressure, we have from identity [5] and Equation [29]

$$Q_s' = -\frac{(Q_s)_{max}}{c}(T_s - T_{cp}) \quad \ldots\ldots [30]$$

Thus the floating characteristic may be described as one in which the rate of change of the manipulated variable is made proportional to the deviation of the controlled variable from a desired value. The constant factor $(Q_s)_{max}/c$ may be thought of as the rate per unit deviation, or as

$$\left[\frac{\text{lb}}{\text{min}} \Big/ \frac{\text{min}}{\text{in.}}\right] \quad \text{or} \quad \left[\frac{\text{Btu}}{\text{min}} \Big/ \frac{\text{min}}{\text{deg}}\right] \quad \ldots\ldots [30a]$$

The negative sign in Equations [28] to [30] assures the occurrence of the corrective action in the appropriate direction, and allows the proportionality factor to be an inherently positive constant.

The combination of the controller Equation [30] with the time derivative of the process Equation [3] gives the following fourth order differential equation (Q_c being constant disappears in differentiating):

$$(A_3)T_s'''' + (A_2)T_s''' + (A_1)T_s'' + T_s' + q(T_s - T_{cp}) = 0$$

where

$$q = \frac{R_a(Q_s)_{max}}{c} \quad \ldots\ldots [31]$$

or, since T_{cp} is constant

$$(A_3)(T_s - T_{cp})'''' + (A_2)(T_s - T_{cp})''' + (A_1)(T_s - T_{cp})'' + (T_s - T_{cp})' + q(T_s - T_{cp}) = 0 \quad \ldots\ldots [32]$$

A solution of Equation [32] is possible by methods similar to those used previously and specifically indicated in Appendix 3.[7] Two cases will be considered, in which different values are assigned to c. Before giving the results we may note a fact of great importance from Equation [32]. When the effects of all disturbances are balanced out, all derivatives become zero, and the equation shows that under such conditions $T_s = T_{cp}$. Hence this control characteristic eliminates any permanent or residual effects of changes in load; thus there is no "loss of control point." Although shown here in a specific case, this recognized fact is applicable in general. The shortcomings of this controller type lie in its inability to cope with the immediate effects of a disturbance.

Shown in Fig. 10 are the recovery transients, following the same disturbance as used throughout, for the following adjustments

(a) .... $(Q_s)_{max}/c = 3.2$ (units given by Equation [30a])

(b) .... $(Q_s)_{max}/c = 0.8$ (units given by Equation [30a])

It is evident, from Fig. 10 that, for a larger value than in (a) the extent of the first return loop, or first maximum, would become excessive. Instability, or oscillation of increasing amplitude, lies not far in that direction. For smaller values than in (b), on the other hand, the recovery would involve both an excessive deviation and an excessively slow return. At a certain smaller value of this adjustment, the recovery would become critically aperiodic; that is, the return curve would approach the desired value at the most rapid rate possible without crossing.

Only in the relative absence of transfer lags between the manipulated and controlled variables could the value of $(Q_s)_{max}/c$ be made sufficiently large to give satisfactory sensitivity to the controlling means.

The behavior of the manipulated variable Q_s, as shown in Fig. 10, may be obtained by solution of the original equations for Q_s instead of T_s, or more conveniently (although less accurately) by graphical integration from the recovery curves of T_s (see Equation [28]). The figure plainly shows the lagging phase relationship borne by Q_s to T_s, and that the rate of change of the manipulated variable is zero whenever the deviation is zero.

PROPORTIONAL-PLUS-FLOATING CONTROL

This is a type of control having a characteristic which combines properties of the proportional type and the floating (or integrating) type. Other names are, "throttling-plus-floating," "throttling-plus-reset," "proportional reset," etc. The use of this characteristic is fairly well known today. The success which practical controllers of this type have met with, and which they shall continue to enjoy, may be attributed to the fact that they inherit the particular advantages of their component devices, while the separate or distinct disadvantages of each are fortunately canceled in the combination.

To bear out this conception of its origin, we may show how the equation describing the law of control of this mechanism is synthesized from those of the proportional and of the floating controllers, namely, from Equations [17] and [30]. Differentiating Equation [17]

$$Q_s' = -\frac{(Q_s)_{max}}{b}(T_s - T_{cp})' \quad \ldots\ldots [33]$$

Equation [33] states that the rate of change of the manipulated variable is proportional to the rate of deviation of the controlled

TABLE 3 NUMERICAL VALUES OF ROOTS AND INTEGRATION CONSTANTS

Case	r	s	(b)	$+k_a$	$-k_b$	$-k_c$	$-k_d$	$+C_a$	$+C_b$	$-C_c$	$+C_d$
(a)	0.1335	13/12	73.85	0.07791	0.2210	0.1639	4.019	0.5822	54.95	45.91	0.00647
(b)	0.1335	2	40	0.2661	0.2255	0.1390	4.035	1.158	18.09	7.268	0.01165
(c)	0.1335	4	20	0.4448	0.2014	0.1356	4.069	1.317	10.93	2.763	0.02212
(d)	0.1335	8	10	0.6700	0.1788	0.1344	4.133	1.422	8.089	1.239	0.04013
(e)	0.4452	4	20	0.4831	0.04836	0.4648	4.063	−1.253	− 8.362	−2.594	0.02056
(f)	0.4452	1/8	160	0.1559	0.6362	0.4896	4.008	−1.225	−17.15	−5.805	0.00285

variable; this is merely a paraphrasation of the characteristic of the proportional controller. Now if Equations [30] and [33] were in effect additively, we should have, for the new value of Q_s'

$$Q_s' = -\frac{(Q_s)_{max}}{b}(T_a - T_{cp})' - \frac{(Q_s)_{max}}{c}(T_a - T_{cp}) \quad \ldots [34]$$

Equation [34] is the law of control for the proportional-plus-floating mechanism.[8] It shows the rate of change of the manipulated variable depending additively upon the deviation of the controlled variable from the control-point setting (desired value) and on the rate of change of that deviation. This equation may also be written

$$Q_s' = -\frac{(Q_s)_{max}}{b}[(T_a - T_{cp})' + r(T_a - T_{cp})] \quad \ldots [35]$$

in which

$$r = b/c \quad \ldots [36]$$

The constant r may be called the "reset constant." From Equation [35] it is apparent that this term governs the ratio between the influence of the deviation and that of the rate of deviation, or the ratio of the proportional to the integrating effect. The integrating (or "floating") influence brings about eventual equilibrium of the controlled variable at the desired value, and this action has been called "reset." The dimensions of r are (1/time), and its units are "inverse minutes." The constant b is the familiar throttling band of the proportional controller and has, when referred to immediate changes, the same meaning in the present mechanism. Both b and r (and of course T_{cp}) will be considered as "adjustables" of the mechanism.

To obtain the differential equation of the interconnected system, we combine Equation [3] for the process with Equation [35] for the controller, in a similar manner to that followed in obtaining Equation [32] for the integrating case, and obtain thus

$$(A_1)(T_a - T_{cp})'''' + (A_2)(T_a - T_{cp})''' + (A_1)(T_a - T_{cp})'' + (1+s)(T_a - T_{cp})' + (rs)(T_a - T_{cp}) = 0 \quad \ldots [37]$$

where s is given by Equation [19] and depends inversely on the throttling band, while the role of r has been just described. This equation describes the behavior of the controlled variable T_a under any circumstances (within limits of continuity) and may be solved under the usual specific conditions to show recovery transients obtained with this type of control. Several solutions of this sort will be carried out for various values of the adjustable constants r and s (or of $1/b$). It may be shown that there are rather definite values for r and s to give critically aperiodic return. Strictly definite values giving this critical state would be conveniently obtainable if the combined Equation [37] had been of the third order. This equation would have been of the third order but for the inclusion of the valving lag described earlier and represented in the hydraulic analog, Fig. 1, by the cascade capacity. Hence, by neglecting this lag, values may be computed for the constants r and s which are approximately critical for the complete system. Adjustments of r and s (or of $1/b$), below those values which would give critically aperiodic return, produce a control characteristic which has been called "averaging control." The effect obtained is to reduce the fluctuation of the manipulated flow at the expense of variations in the controlled variable. It has found wide practical application in level-control problems. Except in such applications, however, the adjustments giving aperiodic behavior following a disturbance are not the most favorable.

In the periodic, or usual, cases Appendix 3[7] shows the solution of Equation [37] to be

$$T_a = T_{cp} + C_d e^{k_d t} + C_c e^{k_c t} + C_b e^{k_b t}\cos(k_a t + C_a) \quad \ldots [38]$$

where the C's and the k's depend upon the coefficients of Equation [37] and hence are affected by the reset constant r and by the sensitivity constant s (or the reciprocal of the throttling band). Table 3 shows the numerical values of the roots and integration constants, for substitution in Equation [38], which result when certain chosen values are assigned to the constants r and s. Case (a) involves the values of r and s which give the substantially critical case, in which neither the magnitude of the throttling band nor the reset constant are such as to cause cyclic behavior. The recovery transient for case (a) is plotted as curve (a) in Fig. 11. Except for a greater deviation, curve (a) exhibits a similar recovery to that resulting from an exact instantaneous correction as described previously and plotted in Fig. 8. This similarity is due to the fact that the flow attains its final value essentially without overshoot in the comparatively brief interval of 11 min. Curve (a) of Fig. 12 shows the recovery transient

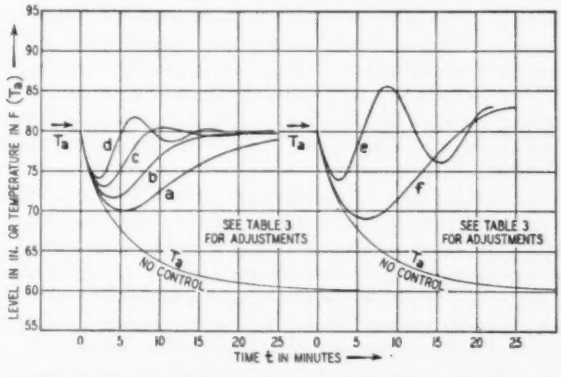

FIG. 11 RECOVERY TRANSIENTS UNDER PROPORTIONAL-PLUS-FLOATING CONTROL; CONTROLLED VARIABLE

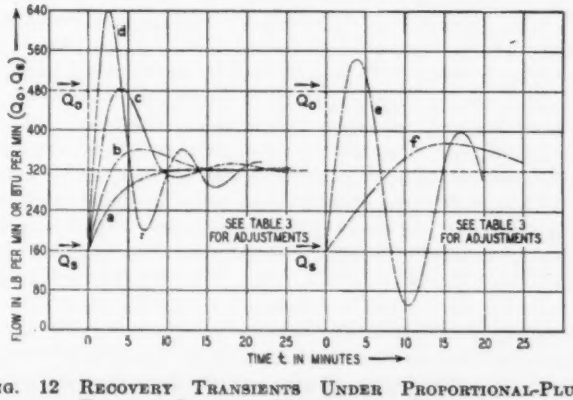

FIG. 12 RECOVERY TRANSIENTS UNDER PROPORTIONAL-PLUS-FLOATING CONTROL; MANIPULATED VARIABLE

[8] This equation could also have been developed from the mechanics of a particular control device faithfully embodying proportional-plus-floating characteristics.

for the manipulated flow in this case. The flow transients for this type of control may be found from the transients of the controlled variable by methods indicated previously.

The remaining cases selected for illustration were not chosen at random, for the results of such a procedure might well be confusing. The adjustments, giving the recovery curves shown, form an orderly sequence which, it is felt, will serve to demonstrate their separate influence on the control behavior.

Assuming for the moment that the adjustments giving the critical case (curves (*a*), Figs. 11 and 12) are in effect, let us consider, in a qualitative sense, the result of allowing b to remain at its critical value and of changing the adjustment r. Without resorting directly to actual solution, we may observe that when under such conditions, r is made smaller (slower reset rate), a longer time will be required for the manipulated flow to attain a substantially balanced state close to its final, or potential, value (320 lb/min or Btu/min). It is apparent, from the discussion previously given of the critical values of b and r, that a periodic recovery transient will result if the constant b is decreased, or the constant r increased, from its critical value. Considering separately an increase in the reset constant r, it is evident that such an increase will bring about an earlier crossing, by the manipulated flow Q_s, of its final or potential value. These relationships are best discernible in the light of the individual characteristics of the component devices, namely, of the floating and the proportional mechanisms, as exhibited in Figs. 10 and 9, respectively. The control influence of the floating part of the characteristic tends to make the rate of change of the manipulated flow proportional to the deviation of the controlled variable from its desired value; this influence tends to prevent reversal of that rate until the controlled variable has crossed its desired (and potential) value (Fig. 10). On the other hand, the control influence of the proportional part of the characteristic tends to reverse the rate of change of the manipulated flow in coincidence with the reversal of the controlled variable (Fig. 9). The desirability of this latter effect suggests that it might be informative to show the effect, on the recovery transients, of progressive reduction in the magnitude of the throttling band b (or of progressive increments in the sensitivity constant s) with the reset constant r remaining at its critical value.

The results of these adjustments are plotted in Fig. 11. Given in Fig. 12 are the curves showing the behavior of the manipulated variable in the corresponding cases. Starting with the practically aperiodic case (*a*), the reset constant r is left at its critical value and the sensitivity constant s is increased in geometrical steps above its original value. This initial series of adjustments may of course be considered to be obtained by successive reductions in the throttling band b. As s is increased, or as the throttling band is decreased, the cyclic period and the damping per cycle both become smaller, for the oscillations of Q_s as well as of T_a. The initial deviation of T_a is reduced by the successive adjustments, but the corresponding fluctuations of Q_s are seen to increase in magnitude. In each of the first four cases the promptness of return to the region of the desired value is creditable.

With this type of control, discontinuity should be avoided; thus, the choice of an optimum value, for throttling band (*b*) for any given process, will also be influenced by the available range of the manipulated variable Q_s as well as by the desired stability of that variable and the mechanical perfection of the apparatus.

Smaller values of r, or reset rates slower than the critical, would merely delay the return in each case. The effect of larger values of r (faster reset rates) is indicated by case (*e*), in which the magnitude of the throttling band is left the same (20 units) as in case (*c*), but in which the reset constant is increased approximately threefold. Although this adjustment slightly decreases the period of oscillation, as well as the magnitude of the initial deviation, the amplitude and damping of the subsequent oscillation is seriously impaired. Herein lies the only real danger arising from haphazard manipulation of this adjustment in the commercial use of this type of control mechanism.

From field experience derived from the application of control mechanisms which involve a proportional control effect (or which have a throttling band, in the usual sense), a general rule has evolved to the effect that cycling can be reduced or eliminated by the expedient of an increase in the magnitude of the throttling band. In the case of the proportional-plus-reset control mechanism, this rule is only of practical value provided that the reset rate (or the reset constant r) is reasonably near the critical value demanded by the lag characteristics of the process under control. Case (*f*) shows the futility of increasing the extent of the throttling band in an attempt to attain satisfactory control when the reset rate is excessively fast for the process under consideration.

The authors' experiences in the mathematical investigation of other types of processes, as well as actual field experience, indicate that there exists—for every process—a critical reset rate (or reset constant r) which is independent of the disturbances to which the process may be subjected and of the throttling band which may be employed in the mechanism.

In spite of the necessarily limited generality of the mathematical approach in the present paper, in that a single specific process has been dealt with, the authors suggest that it may at least serve to introduce a method by which the development of rational theorems may be made possible on an analytic basis. It is evident that the formulation of rules sufficiently practical for industrial use must be the result of sincere cooperative effort on the part of the technical groups both of the users and of the manufacturers of industrial control equipment.

For the present, experience alone can supply the necessary criteria in the application and adjustment of the more complex control mechanisms. Even this brief introductory treatment, however, would seem to establish certain of the properties characteristic of the reset adjustment. It is evident that, although an optimum reset rate may exist for any process, the determination of this optimum is not a simple routine deduction; furthermore, the usefulness of the reset feature in eliminating "loss of control point" is seen to be limited by the critical nature of its adjustment at values below the optimum.

This paper was prepared, as a continuation of the previous paper,[3] to give, together with that paper, a more complete exposition of a suggested method for a quantitative approach to the development of a science of automatic control. The authors wish to submit, for consideration by the A.S.M.E. Committee on Industrial Instruments and Regulators, the suggestions embodied in both papers, and also to offer their sincere cooperation in the accomplishment of the purposes of the committee. In this connection, they will equally welcome comment or critical discussion from any individuals interested in these purposes.

Acknowledgment

It is impossible to acknowledge in detail the assistance of the many engineers whose discussions of practical experiences have contributed to these developments. We wish to mention particularly, however, those of R. A. Rockwell of the Foxboro Company, who has throughout the entire development made valuable suggestions, conducted field experiments, and accumulated reliable data pertaining to the practicability of the mathematical analysis. Credit for the preparation of this paper for presentation is due in large measure to the encouragement given by John J. Grebe of the Dow Chemical Company. We are also indebted to A. F. Spitzglass and M. J. Zuerow for helpful discussions and for cooperation in pointing out basic similarities between the present approach and those of earlier, foreign writers.

Discussion

E. S. SMITH[9] AND C. O. FAIRCHILD.[10] This paper presents a valuable and straightforward treatment of a combined controller and plant, i.e., a controlled system for several familiar types of controllers and a relatively uncommon process or plant. While level control is used as a complete analog of temperature control, this does not appear to be adequate since the latter involves the important factor of attenuation due to "distributed capacity and resistance."

Since a process is a method, not an apparatus, the word "plant" should be used instead of "process" when the apparatus for carrying out the process is meant. The use of a volume unit instead of a weight unit as the basic "quantity" unit would seem preferable as appreciably simplifying the dimensional treatment.

The so-called philosophy of control cited in connection with Equation [7] does not appear to be entirely consistent with the essential unity of the plant and its controller implied in footnote,[5] the noted reversal being simply a matter of opposite sign or 180-deg phase difference.

Under two-position control, the conclusions that the intervals and amplitudes progressively decrease with time do not appear to be of value for the common practical case where metering lag exists, in which case the intervals and amplitudes become constant.

The two-position-with-rate control is more commonly known as constant-speed floating control. In Fig. 7 and its context, it is unfortunate that R should be used in another sense than resistance as it was elsewhere used in the paper. The last paragraph of the "Two-Position-With-Rate" section appears to be incorrect or inadequate, since a dead zone or meter friction is necessary to eliminate hunting, and an increase of capacity requires a slowing of the rate R of valve movement to avoid reaching the limits of valve travel.

Under the heading "Proportional Control," the s of Equation [19] might well be explained further as being the ratio of the head T_a for $Q_a = (Q_a)_{max}$ to the head of the throttling band b. Following Eq. [21], the "loss of the control point" is more commonly known as "drift" or "load error." In the absence of further explanation of T_p, T_{cp}, and $(T_a)_{norm}$ the final values of Equation [23] appear to be in error. The generality of the conclusion, "As the numerical value of the constant s is increased toward a value which would produce discontinuity for the particular upset, the period of cycling becomes shorter . . . .," must be questioned, since this does not seem to be so in temperature control, including where attenuation is involved. If the flow scale of Figs. 9 and 10 were inverted as in a paper[11] by one of the writers, a clearer picture of lags for proportional and floating control would be obtained. Thus, it is immediately apparent that the final control element moves in phase with the measured value of the head T_a in Fig. 9 and lags 90 deg behind such head in Fig. 10. The last sentence of this section apparently means that the throttling control simply breaks down into two-position control under unfavorable conditions.

Under the heading "Floating Control" (of a particular kind), a fuller treatment of q in Equation [31] in terms of c would give the reader a needed mental picture of this before he reaches Equation [36]; at least the dimensions of q and c should be stated. The use of the inverse of c, i.e., $1/c$ seems to the writers to be more nearly consistent with the speed of reset as used throughout the latter part of the paper. The reference to transfer lags in the penultimate paragraph of this section might well include a reference to the portion of Fig. 1 which is meant. The last paragraph might likewise state that the lag of a floating valve is 90 deg behind that of a valve with proportional control.

In connection with Equations [34] to [36], it might be worth while to bring out that $1/c$ is simply the speed of reset dimensionlessly expressed in terms of the maximum flow per unit of head departure $T_a - T_{cp}$, and that an increase of r is accompanied by a resultant tendency for the stability to decrease. Exception may be taken on the grounds of overgenerality to the statement, "Except in such applications (averaging level control), however, the adjustments giving aperiodic behavior following a disturbance are not the most favorable," a case cited in an unpublished paper by R. P. Lowe and one of the present writers presented before the Society in 1938 constituting an important exception in which the controller had to follow a storm flow smoothly.

The last paragraph of the first column on page 304 appears to imply that the throttling band b and the reset speed $1/c$ are adjusted together to maintain r, or b/c, constant. In the second paragraph beyond this, a question arises as to whether $1/c$ or r is meant. In the following paragraph, it would seem to be the users' turn next if the progress of the present paper is to be consolidated without the possible loss of anything more than a bit of higher mathematics.

While the addition of a cascaded reservoir A_a enabled the authors to show that their approach was not limited to simple cases, yet it is likely that a somewhat simpler plant would provide a clearer relative picture of the merits of the several sorts of controllers or regulators. This suggestion is borne out by the authors' simplification of the treatment of Figs. 11 and 12.

A somewhat different approach may be more helpful in certain cases. For example, the analysis of Ivanoff for temperature control of plants involving thermal lags and attenuation also led to some fairly general conclusions as to reset speed which have considerable practical justification. For another example, Ivanoff also determined a controlling apparatus to fit a desired law of control for a particular plant which presented unusual difficulties.

Time is of the essence in detecting a change and initiating a movement of a final control valve properly to offset the cause of the change. With a proportional controller, which operates without serious metering lag or dead zone, nonhunting throttling control exists with a single-capacity plant, since any change of head immediately acts to position the valve properly. In level control, it may be noted that the addition of a rate-of-departure component permits the controller to act as though it were governed by the net discharge from the reservoir and hence to set the control valve immediately to the proper position to maintain the set level, after a change in the rate of either inflow or outflow, without waiting for the level itself to depart objectionably. The addition of the rate component implies a high sensitivity which is generally obtainable only by the servo-operation of the portion providing such component, which portion may be actuated by either the meter or the control valve as convenient. This "departure-plus-rate-of-departure" controller thus functions in an entirely different manner from that of a throttling control and tends to be more stable; although theoretically, with a single capacity, the valve of a throttling controller will be stable even though its throttling band be indefinitely reduced. However, it is better in practice from the standpoint of stability to have a reasonably wide "initial throttling band" followed by a gradual reset to the set point.

The addition of one cascaded capacity also requires the addition of a rate component to let the control valve be properly positioned soon after a variable supply has changed, considering that the outflow be controlled.

---

[9] Patent Agent, C. J. Tagliabue Mfg. Co., Brooklyn, N. Y. Mem. A.S.M.E.

[10] Director of Research, C. J. Tagliabue Mfg. Co., Brooklyn, N. Y.

[11] "Automatic Regulators, Their Theory and Application," by E. S. Smith, Trans. A.S.M.E., vol. 58, 1936, PRO-58-4, pp. 291–303.

From the standpoint of promptness of response, the similar addition of a second cascaded capacity seems similarly to require the addition of an acceleration component, and so on. A general rule seems to be that an increase in attenuation in the number of cascaded capacities or in the order of the differential equation for the plant requires the corresponding addition of a higher derivative to the controller to make prompt control with accurate compensation possible. The use of a floating control valve instead of a throttling control valve likewise raises the order and requires the addition of a higher derivative. An increase in the power of time of the law of departure likewise in effect raises the order and necessitates the addition of a higher derivative if control is not to be lost while within the range of the controller. From these particular considerations, it appears that a controller may be straightforwardly selected to give the desired mode of control of a plant instead of trying empirically a number of different sorts of controllers in an effort to find one which has an acceptable performance with the particular plant.

The reset requirements of flow-rate controllers are of a different order from those of temperature controllers. If the authors have space in their closure, they might include a statement as to whether their more general remarks upon the effects of the reset speed on stability apply equally to flow controllers. The effects of cavitation with gassy liquids and of water hammer in long lines may well modify radically some of the general conclusions with flow-rate controllers where a premium may exist on making the flow changes as gradual as possible. This requirement also exists in other cases such as that in which a thermal gradient must be maintained without exceeding a critical temperature.

Since there is no true distinction in a control system between the plant and its controller and the paper includes a comparative treatment of controllers, it seems desirable to call attention briefly to generally related patent literature: Patent No. 2,113,-164 of A. J. Williams, Jr., contains an interesting analysis of a system which involves both the first and the second derivatives; and the C. E. Mason patent No. 1,897,135 (Re. 20,092) is for a device using the first derivative and having a coupling of a differential bellows to its nozzle and flapper. The latter also includes an interesting analysis. It is requested that the author's closure state whether this Mason patent for the "Stabilog" controller should be regarded substantially "proportional-plus-(first derivative) floating control" or as having a significant higher derivative effect due to close coupling, which effect is not included in the mathematical analysis of such patent.

W. D. Wood.[13] In the section of the paper covering "Proportional Control," the authors have used the term "Control band," and have developed from it a dimensionless sensitivity constant s. This proportional sensitivity constant is familiar to the readers of the published works of Ivanoff, who also derived the term "potential temperature." The sensitivity constant s may be simply defined as the potential temperature change caused by unit temperature change as measured by the control instrument. This constant may be aptly termed "proportional overall sensitivity," since it includes the sensitivities of all elements in the control circuit. Ivanoff has pointed out the relation between this sensitivity constant and "loss-of-control point" in proportional control. It is worth repeating since it is not readily apparent from the present paper. If a load disturbance is described in terms of the temperature change which would result if the controller were inoperative, then the actual equilibrium temperature change due to a disturbance during control is $\frac{1}{1+s}$ times the disturbance.

[13] Engineering Research Department, Taylor Instrument Companies, Rochester, N. Y. Jun. A.S.M.E.

One wonders why the authors introduced the auxiliary flow Q_a to effect load changes. In actual installations, load disturbances generally arise through a change in the outlet resistance. From Equation [19], it is seen that the sensitivity constant depends upon the outlet resistance. Thus the sensitivity constant normally changes with load changes. The need for characteristic flow valves, such as percentage or logarithmic valves, arises from this consideration.

In the section dealing with "Floating Control," the authors have introduced a constant c which corresponds to control band b for proportional control. In floating control, the valve travel depends upon the area of temperature deviation and time. The constant c has a real physical significance, namely, that on a time-temperature-deviation graph (which may be a temperature-controller chart) it represents the area necessary to cause complete valve travel.

Corresponding to the proportional sensitivity constant s the authors have derived a floating constant q, which may be termed "floating over-all sensitivity" and defined as the rate of potential temperature change for unit actual temperature change.

To the writer it seems desirable to describe an instrument's action in terms of the ratio of output change to input change. The narrower the control band, the greater should be the proportional effect since more valve action takes place for a given controller input change. Therefore, the proportional effect is proportional to $1/b$ and, correspondingly, the floating effect is proportional to $1/c$. On this basis the authors reset constant r, defined as the ratio b/c, should be called the ratio of the integrating to the proportional effect.

In connection with Fig. 11, it is noted that the reset constant was held unchanged and the control band decreased. It is of interest to note that, for several commercial pneumatic instruments, the mechanism is so designed that a change in the proportional adjustment affects the floating action, whereas a change in the floating adjustment does not affect the proportional action.

The authors' analysis has clarified the control effects of independent adjustments of the proportional and floating components of control. They point out that there is a critical reset rate for every process. Does this mean that there is one best floating adjustment, or one best ratio of floating-to-proportional adjustment, and how is this adjustment arrived at?

The ultimate value of this paper will depend upon its practical application. The authors have made a rational analysis of the control problem from which it is hoped valuable information will be obtained regarding guides to practical rules for industrial use. One might wish that the authors had devoted some space to the constants which arise from consideration of an actual process.

Authors' Closure

Messrs. Smith and Fairchild suggest that the model system shown in Fig. 1 of the paper is a relatively uncommon one. In the interest of clarity, it should be stated that no attempt was made by the authors to select an actual process for treatment. Perhaps the system selected is uncommon in that sense. However, it is both common and relevant in another and more important sense, since it involves and represents types of lag which must frequently be dealt with in the successful industrial application of control. In addition, the model system chosen has the valuable property that it submits gracefully to a relatively simple mathematical analysis, and requires a low-order linear differential equation for its complete dynamic description.

The authors have been particularly careful to avoid dealing with processes, either hydraulic or thermal, which might involve questions as to the practicability of the assumptions necessary to construct their differential equations. Under these conditions, the accuracy of the results may be relied upon to the same de-

gree as the mathematical manipulation, the latter being carried on according to accepted procedures. Until there is a thorough understanding of the behavior of nondistributed or lumped systems as such, the authors see no valid object in precarious generalizations. The possibilities inherent in the use of lumped parameters have been marvelously demonstrated over and over again in the electrical field, where highly complex networks have been represented to an uncanny degree of precision by such practical methods. In these cases, certainly, a complete knowledge of the simpler component systems was already available from previous work extending over many years. The infant science of automatic control can hardly disregard this established method of development.

The differential equation of the thermal process, of which Fig. 11 of an earlier paper[13] was taken to be an analog, was developed in that paper. Reference to that paper will show that the very reasonable assumptions which were made in the development of the thermal system will permit it to be considered as devoid of distributed capacities and resistances. Thus it is not encumbered by these complications; its thermal-lag characteristics are reasonably embodied in the structure of a second-order linear differential equation in terms of heat flow, temperature, and time.

Whether the system under control is called a "plant" or a "process" is a question which loses importance when models are under discussion. A great deal of incorrect but descriptive nomenclature has grown out of common usage in the field. This same usage has given a meaning to the word "plant" somewhat broader than would seem appropriate. The simplification obtainable in the hydraulic model by using a volume unit for quantity rather than a weight unit was foregone because of the attendant loss of vividness in the correspondences between the units of the hydraulic system and those of the various other systems which might be represented (for example, refer to Table 1 of the paper).

With regard to the "philosophy of control," the causal relationships between the manipulated and controlled variables, as pointed out in the paper, are held to be more fundamental than the simple polarity or phase criterion mentioned by Messrs. Smith and Fairchild.

Unless the term "metering lags" is interpreted as including discontinuities such as dead zones, we cannot agree that the addition of metering lag leads necessarily to a continual cycling under two-position control.

"Two-position-with-rate" control was given in the paper as a tentative name. We agree that this method of control is commonly known as "constant-speed-floating," but it was desired to emphasize its similarity to two-position control rather than to floating control. The last paragraph in the section "Two-Position-With-Rate Control" refers to a condition in which there is a predominance of capacity in that part of the process in which the controlled variable is measured. Under such a condition, the rate of corrective action could be materially increased if the variations involved in such action might be disregarded. In practice, however, dead zones are frequently employed to reduce valve activity. As pointed out by Messrs. Smith and Fairchild, this reduction in the valve variation is only accomplished by using extremely slow rates. On the other hand, if the rate of valve movement is increased indefinitely, this type approaches two-position control and the valve occupies its limiting positions practically all of the time. This was not borne out in Fig. 7 of the paper since, in none of the transients shown did the manipulated variable attain a limiting value, although it was shown in that illustration how extremely slow the rates of corrective action must be made to attain small flow variations.

It is certainly worth while to stress the physical meaning of the dimensionless sensitivity constant s, defined in Equation [19] of the paper. Even more generally (as pointed out in Mr. Wood's discussion), s may be identified as the ratio of an immediate change in "potential" level enacted by the controls to the original change in level which initiated such action. Unfortunately, there must be some misunderstanding about Equation [23] and/or the definitions of T_p, T_{cp}, and $(T_a)_{norm}$. In the remarks made in the paper, concerning the effects of an increase in the constant s, the term "period of cycling" was used to denote the cyclic period itself (or 1/frequency) which is invariably decreased by an increase in s. The orientation of the coordinate scales used for plotting control transients is naturally a matter of choice, but the straightforward method employed by the authors bears out graphically the 180-deg phase difference mentioned earlier in the discussion.

The constants q and c were given subordinate roles in the exposition; they were introduced in a natural manner in the development and were used to lend a logical symmetry to the equations. A joint consideration of the symbols used in Equations [19], [31], and [36] will show this symmetry.

In connection with Equations [34] to [36], the term $1/c$ cannot in any sense be considered dimensionless. The reset constant r, however, has the formal dimensions of inverse time. The fact that the value of r may be so chosen that an ultimate point stability is obtained without appreciable loss of oscillatory stability is of prime importance. Rather than being overgeneral, the statement in the paper concerning aperiodic behavior was perhaps not made general enough; further elaboration would have deviated from the main purposes of the paper.

The adjustments, demonstrated under the heading "Proportional-Plus-Floating Control," are summarized in Table 3 of the paper. Changes in the numerical value of b (or of s) have no effect on the numerical value of r, and vice versa. Their joint influence on control performance is implicit in the mathematics. The authors hope that the impression cannot be gained from the paper that the subject has had complete mathematical treatment. Such treatment has scarcely begun. Mathematics itself is only a means to an end. The progress which may be made through cooperation between user and manufacturer has been indicated by a wealth of practical evidence. Although practical experience will be invaluable in continuing the mathematical development toward some stage of practicability, it will be essential to heed the advice of Francis Bacon, given some 300 years ago: "... At the entrance of every inquiry our first duty is to eradicate any idol by which the judgment may be warped."

It is perfectly true that the original two-capacity system could have been employed. On the other hand, a more complex system might be considered necessary if a prototype, having considerable distributed resistance and capacity, were to be represented. The model chosen provided plausibly complete representation of a typical prototype involving some difficulty and, at the same time, was simple enough not to require an unwieldy analytical exposition.

The reference by Messrs. Smith and Fairchild to the work of Ivanoff is interesting and appropriate. That author's approach has been from the frequency standpoint. The two methods of treatment are equally valid and are certainly not incompatible, each having its distinct advantages. They may also serve as a check on one another in practice. The value of any method of analysis must depend upon its ability to yield laws useful in practical applications. In any case, the authors contend that there is a very real advantage in the concreteness of the representation obtainable with the liquid-level method of analogy; the more complex the system to be represented, the greater the desirability of this concreteness.

To obviate the possibility of misunderstanding, it should be

[13] "Quantitative Analysis of Process Lags," by C. E. Mason, Trans. A.S.M.E., vol. 60, 1938, p. 331.

reiterated that the application of a series of controller types to the model process was made in order to demonstrate an analytic procedure found by the authors to be effective, rather than to document a search for a satisfactory controller for the particular model, as implied in the Smith-Fairchild discussion. In practice, any criterion of excellence for control is affected by economic considerations relating to the environing equipment of the controlled system concerned.

As to flow control, the general conclusions of the paper encounter no exceptions in that field. For the most part, however, automatic-flow-control problems are considered to be on a lower plane of difficulty than that dealt with in the paper, an important exception arising in those liquid-flow cases where the mass of moving fluid imparts a momentum seriously restricting the action of the controls.

Reference to the patent literature by Messrs. Smith and Fairchild is acknowledged without comment. The analysis given in the paper was directed to the mathematics of automatic control, and was not intended to refer to the particular instrument designs of any of the various manufacturers. Thus, for example, the proportional-plus-floating controller was merely postulated as a mathematical type in the development.

Mr. Wood's elaboration of the fundamental meaning of the sensitivity constant was acknowledged in a previous statement. This meaning was not directly brought out in the paper since the corresponding portion of the analysis was couched principally in terms of the empirically measurable "throttling band." In an earlier paper[13] by one of the authors, the term "potential temperature" was acknowledged to have been originated by Ivanoff. The expression for equilibrium "loss of control point" is directly evident from Equation [20] of the paper, as

$$\Delta(T_p) = \frac{1}{1 + s}\,\Delta(R_a Q_o)$$

where $\Delta(R_a Q_o)$ represents the load alteration whether originating in the load resistance R_a or in the load supply flow Q_o.

The mathematical method shown by the authors applies equally well to all types of disturbances. Although, for some systems, load changes are more precisely represented by changes in R_a than in Q_o, it might be questioned whether such systems are in the majority. The practical benefits arising from the use of valves having logarithmic characteristics extends far beyond the mere compensation for variation of outlet resistance with load.

Mr. Wood points out the practical significance of the constant c, thereby providing an answer to one of the questions in the Smith-Fairchild discussion.

An answer to Mr. Wood's question on the best floating adjustment may perhaps be provided by the result (indicated by the mathematical analysis of the paper) that the optimum value of the reset constant r, once it is found, is very nearly independent of the value of the throttling band which it might be advisable to employ. A controller equation faithfully describing any particular commercial instrument must be written directly from the detailed mechanics of that instrument and, thus, such an equation may not necessarily take the exact form of any of the mathematically developed types shown in the paper.

The Influence of Crystal Size on the Wear Properties of a High-Lead Bearing Metal

By JOHN R. CONNELLY,[1] BETHLEHEM, PA.

This paper,[2] describes work done to correlate metallurgical aspects of a bearing metal with mechanical testing under conditions existing in a bearing. Previous work by Karelitz and Kenyon (1),[3] and by the author (2) and (3) have concerned effects of different composition of bearing metal and different loading and size of specimen. The present investigation was made to determine the effect on removal of the bearing-metal surface and the pressure at which the oil film breaks down as a result of variations in the crystalline structure of the bearing metal. In this work both the chemical composition of the bearing metal and the size of the specimen were constant. The crystalline structure was varied and the resulting change in properties determined.

The Problem

THE analysis of bearing conditions is usually associated with the hydrodynamic theory of lubrication. This theory has served very well to explain phenomena under conditions where it is applicable, namely, where the trueness of the surfaces, the speed, the load and the fluid are such that the forces which the fluid can develop are sufficient to float the journal and prevent wear. In a number of cases, the hydrodynamic theory is not applicable, at least, as it is understood at present. The fact that most bearings show some wear after service indicates that a fluid film may not be present at all times. Thus, many bearings, which normally are running under conditions quite similar to those assumed in the hydrodynamic theory, may occasionally depart from those conditions. Such departure may be due to loss in viscosity of the lubricant either by reason of high temperature or deterioration of the lubricant.

In addition, very slow speeds or very high loads may cause such departure. Under such extreme conditions, in the presence of a lubricant, the phenomena of dry rubbing surfaces may not appear. Such extreme conditions without dry friction are often referred to as "boundary lubrication" or similar descriptive terms. Some very slow disappearance of the mating surfaces accompanies boundary lubrication. This is called wear. In brief it may be said that the conditions of boundary lubrication are slow removal of one or both mating surfaces in the presence of a lubricant but absence of a lubricant film. It was the purpose of this investigation to determine the effect on removal of the bearing-metal surface or wear and the pressure at which the oil film breaks down as a result of variation in the crystalline structure of the bearing metal.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Method of Investigation

A specimen of bearing material has one side machined to a plane surface. A constant holding force, hereafter referred to as the load, presses the machined surface tangent to a rotating steel cylinder, submerged in a bath of lubricant. For these tests the force was obtained by gravity. The specimen, which can move only in a direction normal to the machined surface, wears a cylindrical groove and the contact changes from line to a progressively larger area. This wearing away continues until equilibrium conditions are established between the forces causing wear and the forces resisting wear. The load divided by the projected area at any instant is referred to as the pressure and the pressure existing at equilibrium is called the final or ultimate bearing pressure or equilibrium pressure. Rate of wear is designated as volume of bearing material removed per length of travel of a point on the surface of the cylinder.

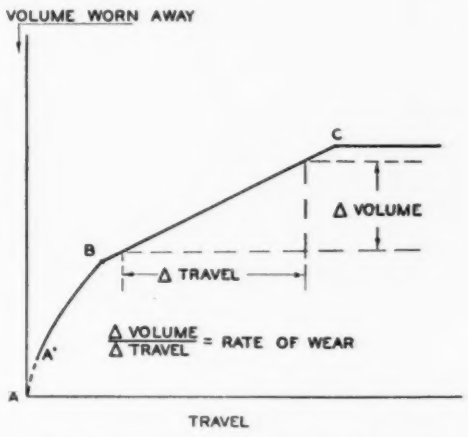

Fig. 1 Determination of Rate of Wear

This wearing away of the bearing material seems to occur in more than one phase, as illustrated in Fig. 1. From A to A' results are in doubt because of the difficulty of measuring the rapid movement. Within a few minutes after the test starts, the rate of wear becomes more stable and proceeds along the path $A'B$. To distinguish $A'B$ from the following phase BC, $A'B$ is referred to as unlubricated wear, although the phrase may not be completely descriptive. Data previously analyzed show rate of wear in phase $A'B$ proportional to the corresponding contact pressure. The phase BC of the rate of wear has a linear relation with travel for all data that have come to the author's attention. This constant rate of wear, for pressures just above the ultimate bearing pressure, fixes the rate of wear in phase BC as independent of the bearing pressure. The phase BC is referred to as lubricated wear.

PREPARING TEST MATERIALS

Bearing-Metal Specimens

The bearing metal selected for this investigation is known as

Cosmos metal and has an approximate composition of lead 76 per cent, antimony 15 per cent, and tin 9 per cent. This composition is in common use in industry. It is often used as a substitute for true babbitt metal because the high lead composition is less expensive. A further reason, for selecting this particular composition for this investigation, is that considerable variation in crystal size can be obtained by varying rates of cooling of the metal just prior to and including solidification.

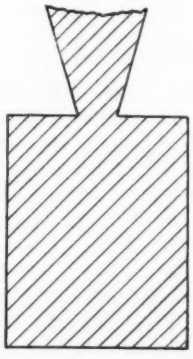

FIG. 2 TEST BAR AND RISER

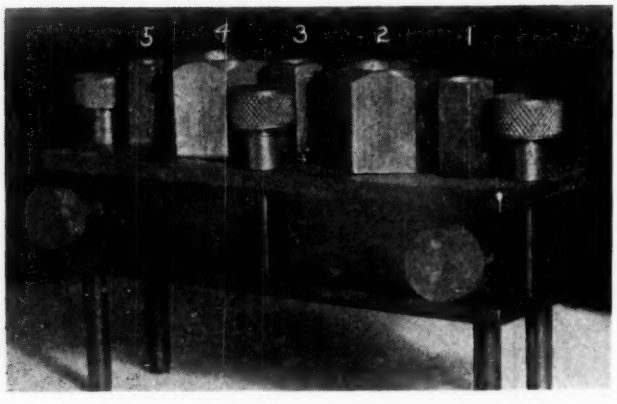

FIG. 3 MOLD FOR TEST BARS AND RISERS

A permanent mold of pieces of steel clamped together was constructed which cast a bar 1¼ in. by 1 in. by 6 in. Fig. 2 illustrates the cross section through a riser. When first made the mold had three risers which are Nos. 1, 3, and 5 in Fig. 3. Specimen bars contained cavities so risers Nos. 2 and 4 were added. Risers Nos. 1, 3, and 5 had a total volume of about 8 per cent of the bar. Risers Nos. 1, 2, 3, 4, and 5 have a column of about 31 per cent of the bar. With these additional risers no cavities appeared in the specimen bars. The risers were constructed as

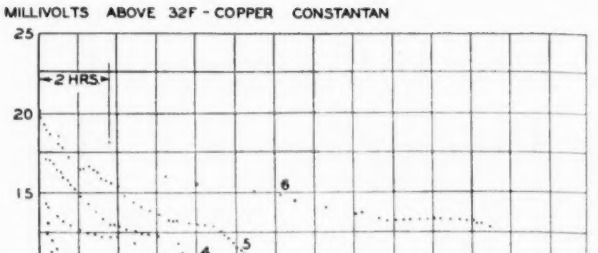

FIG. 5 COOLING OF TEST BARS

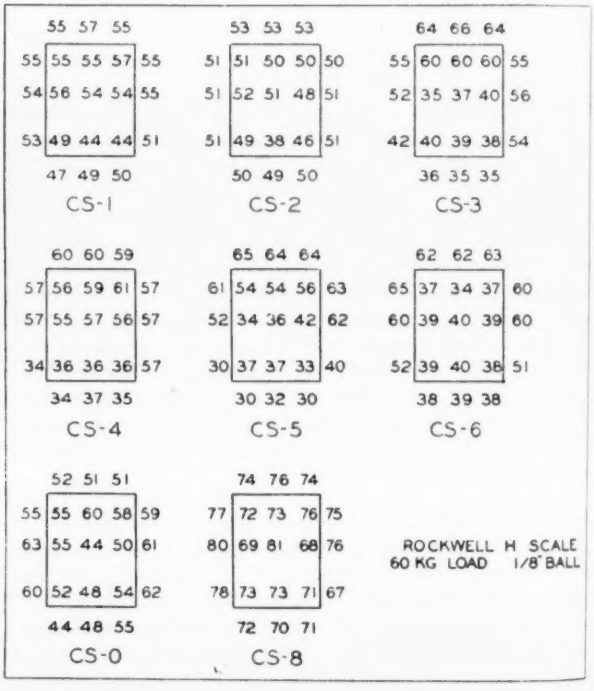

FIG. 6 HARDNESS READINGS; SECTION AND SURFACE OF TEST BARS

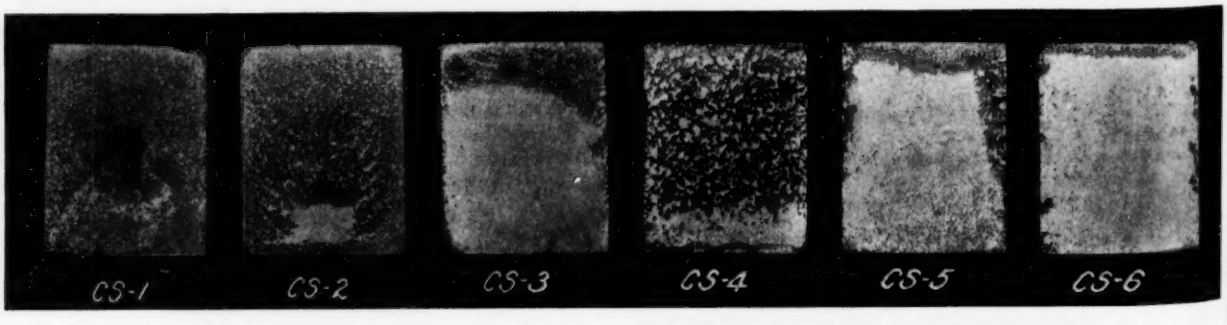

FIG. 4 MACROSTRUCTURE OF TEST BARS FOR INVESTIGATION WITH THEIR DESIGNATIONS

TABLE 1 CRYSTAL DISTRIBUTION IN SPECIMENS

Specimen	Area devoid of crystals
CS-1	4 per cent (estimated)
CS-2	8.4 per cent (by planimeter)
CS-3	71.3 per cent (by planimeter)
CS-4	Unobtainable (by planimeter)
CS-5	78.5 per cent (by planimeter)
CS-6	93.3 per cent (by planimeter)

inverted cones to assist in removing them without damage to the specimen bar. In Fig. 3, riser No. 3 is shown partially unscrewed; the unscrewing breaks the riser at the narrow section.

Six bars, hereafter designated as CS-1, 2, 3, 4, 5, and 6, were poured, Figs. 4 and 5. From these six bars were obtained (*a*) a broken section, (*b*) a polished and etched section to show microstructure, (*c*) a polished and overetched section to show macrostructure, (*d*) a section for hardness survey Fig. 6, and (*e*) a wear-test specimen. Of the above items (*b*), (*c*), and (*e*) were expected to yield the principal data. Items (*a*) and (*d*) are frequently given in metallurgical studies and for completeness were included. Also the value of that property indicated by hardness tests in this field is controversial and further information may be

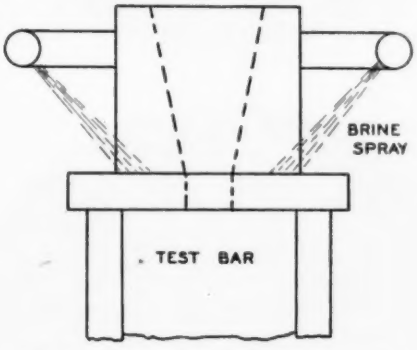

FIG. 7 METHOD OF CHILLING SPECIMEN

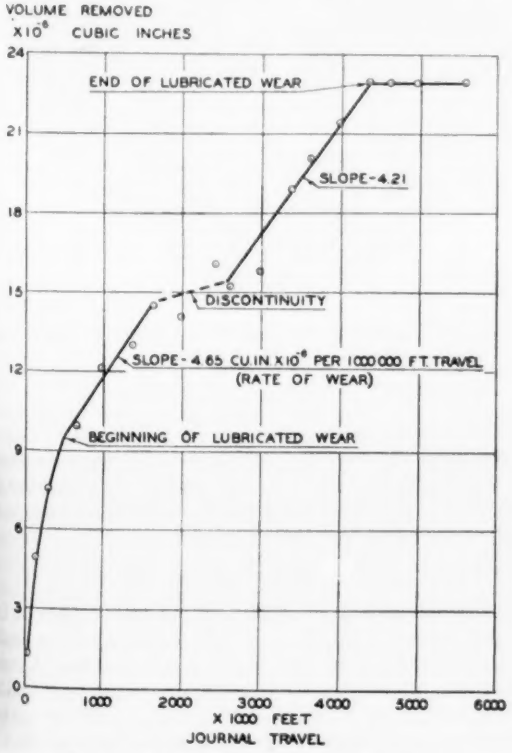

FIG. 8 DETERMINATION OF RATE OF WEAR

of value. The wear specimens were machined to shape by a new milling cutter used exclusively for this work. The $2^1/_2$-in. cutter had a face of 4 in. and 16 teeth. The test surface for each specimen was finished with the cutter rotating at 500 rpm and a linear feed of $^5/_8$ in. per min. Each wear specimen was machined to a length of approximately 0.4 in. Previous investigations indicate this length to be sufficiently beyond the range where end leakage for this type of test is a factor. Tests using the varying-wear method as described were run on these specimens.

Examination of the macrostructure of specimens CS-1, 2, 3, 4, 5, and 6, Fig. 4, shows that except for CS-4 there is a core practically devoid of crystals. The extent of crystalline structure is indicated in Table 1. This core increases in size as the rate of cooling decreases, as indicated in Table 1. The tin-antimony crystals solidify before the lead so that, when the solidification of lead is delayed, the crystals float toward the top of the bar. According to metallurgical explanation this excess of tin and antimony at the top of the bar will cause some of the antimony to crystallize as pure antimony. Antimony being a relatively hard substance, this will give a greater hardness at the surface, as

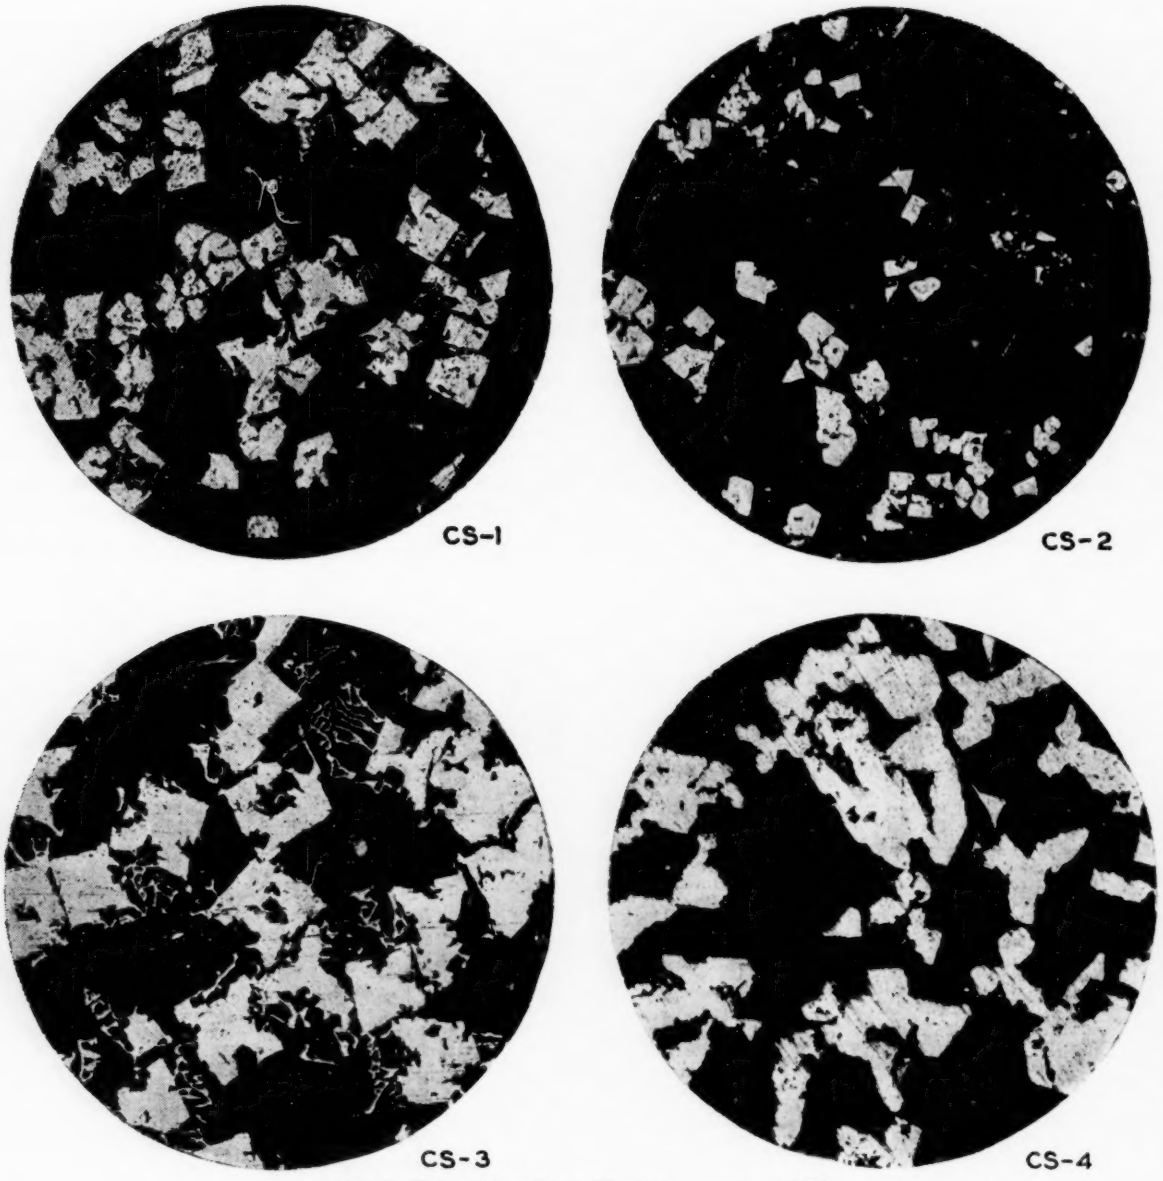

FIG. 9 TOP OF TEST BARS, MICROSTRUCTURE, ×100

shown by the hardness survey, Fig. 6. Such hardness might affect the test results materially and obliterate the effect of crystal size. To investigate this possibility bar CS-7 was poured having reduced percentages of tin and antimony and was allowed to cool overnight in the furnace. The intention was that tin and antimony in floating to the top would give about a normal concentration and composition in that region. Bar CS-7 was so soft that it was damaged in attempting to obtain a broken section. For this reason it was discarded. A new bar CS-8 was prepared in the same manner as CS-7 and packed in dry ice for several hours. A broken section was obtained without difficulty.

It is questionable whether such a broken section is indicative of structure. It was decided to cast additional bars and attempt to secure crystals smaller than previously obtained. CS-0 was poured of the same composition as CS-1, 2, 3, 4, 5, and 6 and chilled by spraying cold brine at 15 F onto the top of the mold, as shown in Fig. 7. The bars CS-8 and 0 were given the same series of tests as were CS-1, 2, 3, 4, 5, and 6. Etching of specimens was by ferric-chloride solution or a 3 per cent solution of nitric acid in ethyl alcohol, Fig. 9.

TEST JOURNAL

The test journal was a piece of $^1/_4$-in-diam drill rod. No treatment was given the rod but it had been in service some months before starting these tests using the same bearing-metal-and-oil combination. This use had polished the drill rod but the change, if any, in diameter was less than 0.0001 in.

LUBRICANT

The lubricant used was D.T.E. light turbine oil secured from the Socony-Vacuum Oil Company. As received it has a Saybolt viscosity of about 169 sec at 100 F. After some use the value rises slightly. This oil had been in use for several years and had a Saybolt viscosity of 173 sec. During the tests the oil was kept at an average temperature of 77 F and fluctuated between 75 F and 80 F.

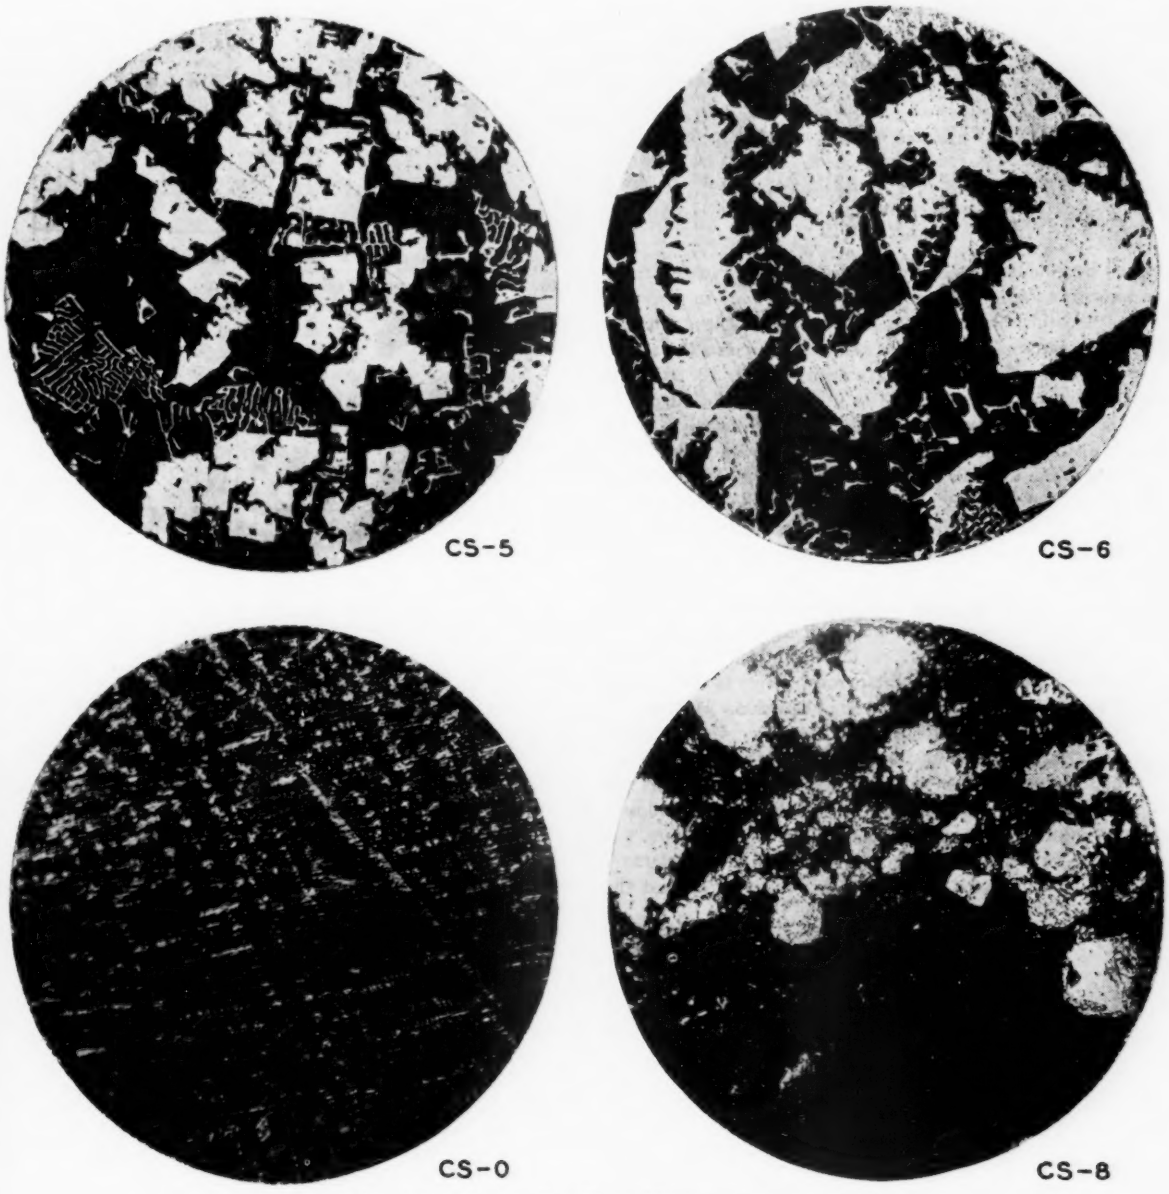

FIG. 9 (*continued*) TOP OF TEST BARS, MICROSTRUCTURE, ×100

SUMMARY OF TEST DATA

As previously described, the rate of wear is obtained by measuring the slope of the volume curve immediately preceding the attainment of equilibrium conditions. The unit of slope is arbitrarily taken as cubic inches of volume removed per million feet of travel of a point on the surface of the journal. Fig. 8 illustrates the method of procedure. Since this bearing metal is heterogeneous, regions of variable properties occur. Discontinuities in the volume removal data evidence that the rotating journal passed through such regions. These discontinuities do not occur in every case and seem to have no regularity when present. The test results are given in Table 2. In each case, the number in parentheses, following tabular values of rate of wear, denotes the number of plotted points which the slope value represents. The larger the number of points the more reliable the rate of wear.

The dimensions of the crystals given in the table were obtained with the aid of professional metallurgists. These values represent the inspection of more areas than would be feasible to present in a report.

A further item included in Table 2, showing results, is the pressure at which the change-over from unlubricated to lubricated wear takes place.

DISCUSSION OF DATA AND RESULTS

GRAPHICAL REPRESENTATION

Figs. 10, 11, 12, and 14 show results taken directly from the tabular values. Figs. 10 and 11 show equilibrium pressure and rate of wear versus the linear dimension of the tin-antimony cubical crystals. Fig. 12 presents rate of wear and equilibrium pressure against each other. Fig. 14 shows the relation between the pressures obtaining at the beginning and end of lubricated wear.

Fig. 13 shows the mass centers of results in Fig. 12. The x and y coordinates of these mass centers, referred to as $\bar{x}$ and $\bar{y}$ are

determined by calculations analogous to those used in determining the location of the centroid of a group of rivets in a riveted joint. In place of the area of a given rivet in the analogous method, the number of slope points minus 2 is used as the multiplier for the coordinates of points shown in Fig. 12. By the number of slope points is meant the number of plotted points which the slope value represents, as described previously. Since the slope is a straight line, it is determined by two points. Subtracting 2 from the number of points which the slope represents gives the number of agreeing values in excess of those required to determine the slope line. The quantity of excess agreeing values, obtained in this way, is a conservative measure of the reliability (4) of the slope line.

Table 3 is a summation of the results showing relation between crystal size and averages of rate of wear and equilibrium pressure. The arithmetic mean, the geometric mean, and the mass centers from Fig. 13 are included. Arithmetic mean refers to the method of dividing the sum of data by the number of values. Geometric mean or logarithmic mean is obtained by taking the antilogarithm of the arithmetic mean of the logarithms of the data values. This method is employed in computations where averages are desired for data in which the nature is such that there is a lower limit to the values but no upper limit. The geometric mean is considered to give a more representative average of such data.

Figs. 15 and 16 show the averages of rate of wear against the

linear dimension of the crystals and against the exposed area of one crystal that is the average crystal area. In passing a curve to represent the data, the mass centers have been favored, since the method of their determination takes account of the presumed relation between equilibrium pressure and rate of wear. The departures of samples CS-6 and CS-8 from the general trends indicated in Fig. 14 are also considered in passing the curve.

Figs. 17 and 18 represent the averages of equilibrium pressure against linear dimension of the crystals and against the average

exposed crystal area. The passing of a curve to represent the data was done in the same manner as that described for Figs. 15 and 16.

COMMENTS

Whatever property of the bearing metal makes for a low rate of wear makes for a high equilibrium pressure and vice versa. On the basis of the mass centers, Fig. 13, it would seem that, below a certain crystal size, rate of wear changes little and the equilibrium pressure increases rapidly.

Fig. 12 shows that each pair of values of rate of wear and its corresponding equilibrium pressure are relatively consistent. The results are believed to give an accurate picture of the material tested, the spread of values for a given test bar being due to the heterogeneous bearing metal.

It is evident that, regardless of the averaging method employed, the general shape of the curves in Figs. 15, 16, 17, and 18 will vary little.

COMPARISON WITH OTHER INVESTIGATIONS

In a paper (1) published in 1937, Karelitz and Kenyon reported

some work by this method of testing on several compositions of bearing metal. In subsequent discussion (1) of this paper some values of rate of wear were worked out which are somewhat comparable to the data presented in the present paper. Karelitz and Kenyon report that according to their photomicrographs the specimens were overchilled. This evidence would place their data in the range of CS-0, although the various hardness values do not agree. For the lead-base specimen of Karelitz and Kenyon, the rate of wear in the same units as used in this paper is 0.92×10^{-6} cu in. per 1,000,000 ft of travel. The equilibrium pressure is approximately 700 lb per sq in. These check very well with the data here reported.

Conclusions

The results are evidence that, for the bearing metal tested, (*a*) crystalline structure is a factor and crystal size an important variable in thin-film lubrication, (*b*) rate of wear and equilibrium pressure are related, and (*c*) pressures at beginning and end of lubricated wear are related. The method of investigation used is a way of determining quantitative values of rate of wear, equilibrium pressure, and the pressure at the borderline condition between unlubricated wear and lubricated wear. Other things being equal a very small crystal size gives optimum values of rate of wear and equilibrium pressure.

In corroboration of the results obtained, it may be pointed out that the motorcar industry at present produces bearing inserts by a technique which gives very small crystals having a linear dimension of the order of 0.001 in. Since this is done deliberately we may infer that gross testing of over-all bearings has indicated the lower rates of wear obtained with small crystals.

Bearings that are poured in place, such as large pillow-block bearings, have crystal sizes in the range where the rate of wear and equilibrium pressure are decidedly not optimum. In the future, such large bearings could be better designed to make use of some type of insert that could be cooled rapidly upon pouring.

Of possibly greater importance than the specific results on the effect of crystal size are certain implications in connection with fundamental analysis of a journal-lubricant-bearing combination. The present concepts of thin-film lubrication take no account either of the material or crystalline structure of the mating surfaces.

In the light of this investigation, it would be appropriate to revise the phrase "hydrodynamic theory of lubrication," to be stated as the "theory of hydrodynamic lubrication." This would indicate correctly that the theory refers to a certain part of the field of lubrication and not to the entire field.

A theoretical explanation of the mechanism of wear should wait on further research in the field of thin-film lubrication. The explanation should be developed independent of the data in the range of thick-film lubrication.

Acknowledgments

The author wishes to express thanks to A. D. Shankland, engineer of tests, and M. W. Dalrymple, metallurgical supervisor, of the Bethlehem Steel Company for advice and help and for photomicrography, photomacrographs, and hardness survey of crystal specimens CS-1, 2, 3, 4, 5, and 6; Professor Allison Butts of Lehigh University for advice in preparation of a crystal specimen of reduced tin-antimony content; J. H. Vail, James Ward Packard Fellow in Mechanical Engineering 1936–1938, for a major part of the data from the varying-wear machine; R. L. Scott, James Ward Packard Fellow in Mechanical Engineering 1938–1940 for the remainder of the data on the varying-wear machine; Professor F. V. Larkin, head of the department of mechanical engineering at Lehigh University, for securing funds to carry on the investigation.

Discussion

B. F. Hunter.[4] Recently our laboratories had occasion to examine a high-lead bearing that had failed in a steam turbine for the purpose of determining the cause of failure of the bearing metal. The bearing was made in two parts each half being composed of a steel shell into which the babbitt metal was cast. In the main portion of the bearing the lining was about $^1/_4$ in. thick, at the edges about $^1/_2$ in. thick.

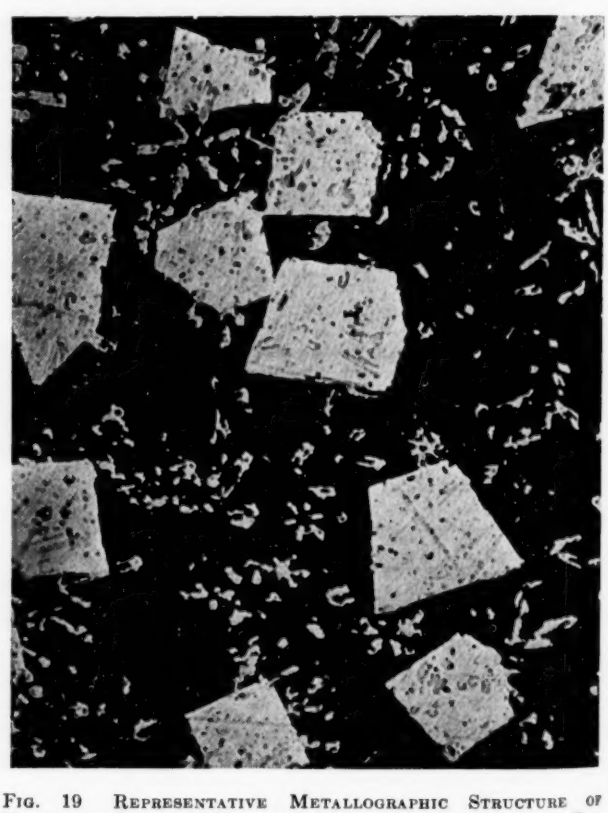

Fig. 19 Representative Metallographic Structure of Defective Bearing Metal, Showing Large Cubes of Tin-Antimony, and Short Thick Needles of Copper-Tin in Combination, ×100 (Etched With Ferric Chloride)

The upper half of the bearing showed only a few slight scores but the lower half was badly scored, in addition to being cracked and pitted. Numerous small particles had fallen out and others were loose and could easily be picked out of the lining.

Chemical analysis was not made since the manufacturer of the bearing material supplied the following specifications:

[4] Chief Lubrication Engineer, Gulf Oil Corporation, Pittsburgh, Pa.

Tin, per cent	84 to 86
Lead, per cent	0.035 max
Antimony, per cent	9.5 to 10.5
Copper, per cent	4.5 to 5.5

Sections from both halves of the bearing were given metallographic examinations. A representative structure is shown in Fig. 19 of this discussion. It contained extremely large cubes of Sn-Sb, and rather short thick needles of Cu-Sn in the alpha-solid solution of Sn and Cu and pseudoeutectic. At the magnification used, this latter constituent could not be resolved, but there was a considerable portion present.

The conditions attending the pouring and cooling of this bearing were not obtained and, since no analysis was made, it was assumed that the composition was correct.

That the pouring temperature was correct is revealed by the relatively short thick needles, some of which are arranged in a starlike shape. Also, the pouring temperature, except in so far as it affects the rate of cooling, is insignificant in its action toward the formation of such large cubes of Sn-Sb.

The size of these cubes, the area of each of which, as shown in Fig. 19, is about 10 times normal and their uneven distribution throughout the matrix are the only conditions present which can conceivably be the cause of the failure. The cause of these very large cubes can be attributed to the bearing alloy being too slowly cooled. The reason for the failure of the lower half was probably due to the much higher loads it had to carry; the absence of failure in the upper half was because of the comparatively light loads to which it was subjected.

The unsatisfactory service secured from this bearing appears to have been due to the presence of extremely large, poorly distributed crystals of tin-antimony compound in the bearing material, resulting from too slow a cooling rate after pouring.

This is one of many similar bearings we have examined and our findings would seem to substantiate very definitely the author's data.

F. C. Linn.[5] The author has presented an enlightening paper upon the crystalline structure and its effect upon wear and load-carrying capacity of the bearing when the operation is within the thin-film region.

Under "Conclusions" he states that "(*a*) crystalline structure is a factor and crystal size an important variable in thin-film lubrication." In reviewing Figs. 15 to 18, inclusive, it would appear that the linear dimension of the crystal has a very critical range, at which the rate of wear is large and the equilibrium pressure low. Outside of this range it is noted that the rate of wear is relatively lov and the equilibrium pressure high. This indicates that the size of the crystal should be held within reasonable limits during the casting cycle.

It is not quite understood how the author arrived at the conclusion (*c*) in which he states that "pressures at beginning and end of the lubricated wear are related." A further discussion of this point would be appreciated.

The writer requests that information be supplied on the following:

1 What effect has hardness upon wear?

2 What effect has hardness on rate of wear and equilibrium pressure?

3 Referring to Fig. 6, on what surfaces were the wear tests made?

R. G. Simard.[6] The scope of this investigation on the relation of bearing-metal wear to structural characteristics is especially commendable and, in this writer's opinion, constitutes a fruitful approach to the problem of wear phenomena. The directness of the method employed appears to have definite worth in fundamental investigations of this nature. Although there is no pretense that the work is in the category of simulated testing, the time is not considered inopportune again to remind ourselves that wear resistance is a consequence of service conditions rather than an inherent property of matter. Application to practice of the results of this or similar investigations should be attended only with extreme caution.

An investigation of the wear quality of lubricating oils in relation to representative bearing metals along lines suggested by the work of Karelitz and Kenyon at Columbia has been under way for the last 3 years in the laboratories of the research division of the Atlantic Refining Company. A battery of 6 identical machines, carefully constructed to eliminate running inaccuracies, was employed for the purpose. The standard metal specimens were prepared under rigid specification of composition and casting procedure. Results soon indicated, however, that reliance could not be attached to micrometer indication of rate of wear, since the depth of the wear groove was of such magnitude that its measurement at the end of a 5:1 lever was seriously disturbed by temperature fluctuations and slight inaccuracies of the shaft. Measurements have accordingly been confined to comparative total wear after an operating period sufficient to insure attainment of equilibrium.

The following data have been singled from our files as illustrative of that which predicated the change in procedure and these comments:

Metal	S.A.E. No. 62 bronze (hard cast)
Oil	S.A.E. No. 30 acetone-benzol dewaxed nitrobenzene refined motor oil (without) film-strength additive) at 130 ± 5 F
Shaft	⅛-in. ground tap and reamer stock
Rpm	1760
Load	60 lb (nominal)

Unit	Time (days)	Measured groove width, in.	Indicated groove depth, in.	Calculated groove depth, in.
1	5	0.0139	0.0003	3.75×10^{-3}
2	7	0.0173	0.0002	5.63×10^{-3}
3	9	0.0149	0.0005	4.37×10^{-3}
4	11	0.0166	0.0004	5.63×10^{-3}
5	13	0.0154	0.0005	4.37×10^{-3}
6	13	0.0143	0.0002	3.75×10^{-3}

Author's Closure

In discussing the photomicrograph of the failed bearing, Mr. Hunter has opened up a field about which comparatively little is known. Since preparing the original paper, the author has investigated several additional methods of etching and is at present of the opinion that no one method gives a complete picture of the metallographic structure for the high-lead metal described in the paper. The electrolytic etch described by Weaver[7] has been quite instructive. Whether the same applies to the high tin metal cannot be stated, but it is entirely possible that some further critical conditions were not revealed by the etching agent employed.

Conclusion (*c*), "pressures at beginning and end of the lubricated wear are related," was made after study of the data shown in Fig. 14 of the paper, where the ordinate is the pressure at the beginning of lubricated wear (see Fig. 8) and the abscissa is the pressure at the end of lubricated wear. Mr. Linn raises the question of the effect of hardness on wear. Referring to Fig. 6, it is seen that CS-0, the specimen having the lowest rate of wear

[5] Turbine Engineering Department, General Electric Company, West Lynn, Mass. Mem. A.S.M.E.

[6] Research and Development Department, The Atlantic Refining Company, Philadelphia, Pa.

[7] "Type Metal Alloys," by F. E. Weaver, *Journal of Institute of Metals*, vol. 56, 1935, pp. 209–233.

and highest equilibrium pressure, has a low but not the lowest hardness value, while CS-8 (which can best be understood by adding 100 to all other hardness numbers), which has the lowest hardness number, is intermediate as to rate of wear and equilibrium pressure. Further examples could be given but no relation seems evident by considering Rockwell numbers. However, present methods of taking hardness may be inadequate to indicate the hardness of certain critical components of the bearing metal.

The experience of Mr. Simard concerning the measurement of groove depth does not seem directly applicable to the present paper. Karelitz and Kenyon reproduced the method reported by the author in his first paper (3) on the subject. However, at that time it was pointed out that the Ames dial had been discarded because of its many failings in favor of an electrically indicated micrometer screw. The use of a substantially different bearing metal and a resulting groove width of quite a different order of size would not seem conducive to comparable results. The author has investigated the effect of temperature fluctuations and found that, while they are of measurable magnitude, the fluctuations resulting from the controlled oil temperatures are insufficient to vitiate the results. Further, on the basis of work done, since the original paper was prepared, the author is extremely cautious about accepting the phrase "specimens were prepared under rigid specifications of composition and casting procedure." This is no reflection on those who prepared the specimens, but is simply a warning that, present knowledge of nonferrous compounds of three components and higher being in such a state, we cannot be absolutely sure that a set of specimens is exactly as intended.

It seems that metallographic work will have to be done in parallel with work on wear of bearing materials and, as this is done, we must, as Mr. Simard suggested, be most careful of interpreting results. If others would care to work in the high-lead bearing metals, the author would gladly share his troubles.

Calculation of the Elastic Curve of a Helical Compression Spring

By H. C. KEYSOR,[1] CHICAGO, ILL.

Equations for the elastic curve of a helical compression spring are developed, without making the usual assumption of axial loading. The load is found to be eccentric, in general, being axial only under certain conditions. Elastic curves are given for both axial and eccentric loading. These curves are sinusoidal, showing that deflection along the bar is not linear, as is customarily assumed. A reversed deflection is found to occur in the closed end, back of the tip contact point, which increases the deflection of the spring as a whole, and shows that it is not correct to consider the entire closed end as inactive. An axial load is theoretically possible under certain conditions, but practically axial loading is difficult to obtain and cannot be counted on with any certainty. The effect of load eccentricity on stress is considered, and an approximate formula for estimating this effect is given. Reference is made to laboratory tests by another investigator[2] which are in good agreement with the theory here presented.

AN ANALYSIS of helical-spring deflection has been made by the author which yields three results:

1 The load is, in general, eccentric with consequent increase in stress.

2 The correct deduction for inactive end turns is shown to be approximately 1.2, based on the usual practice of taking the total turns as solid height divided by bar diameter.

3 The deflection at any point along the bar is obtained, thus permitting the elastic curve to be drawn.

The first two items have been discussed in a previous paper[3] by the author. The third item forms the subject of the present paper.

Fig. 1 shows the lower portion of a helical compression spring with ends closed and squared. Assume that the spring is compressed between parallel plane surfaces, as this is the usual condition of loading. Let P be the load. Any point on the bar, as point a', must therefore sustain the direct load P, a torque T, and a vertical bending moment M, the line of action of P being at some point Q. It is apparent that Q must be on a radial line through a, the longitudinal center point of the bar, for otherwise the forces and reactions on the top and bottom halves of the spring would not be symmetrical and the necessary condition of static equilibrium would not obtain. We do not restrict the position of point Q on the radial line through a; that is, we consider the load to be eccentric by some variable amount e, leaving the magnitude of e to be determined by the conditions of the problem.

The load P can be replaced by two component loads, P_1 at a and P_2 diametrically opposite a. If $P_1 + P_2 = P$ and the center of pressure of P_1 and P_2 is at point Q the torque, moment, and direct load at the general point a' will not be affected. The reactions which balance P are P_3 at the tip contact point b, and $(P - P_3)$, distributed in some manner in the vicinity of point O where the bar makes contact with the loading plane. There is also a torque reaction at point O. The angular distance v between b and O is roughly 180 deg for most springs; the determination of v will be explained later.

The location of the contact point b is subject to variation due to the manner of forming the tapered end, and due also to the load, for it is evident that, with increasing load, b will move away from the tip so that the angular distance between contact points will diminish. Consideration must be given to this fact in interpreting the following analytical results in their relation to actual springs.

From the foregoing discussion, it is evident that we require the deflection equations for a helix fixed at the origin and sustaining

Contributed by the Special Research Committee on Mechanical Springs and presented at the Annual Meeting, Philadelphia, Pa., December 4–8, 1939, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

a vertical load at any point along its length. The effects of bar curvature, direct shear, and angularity of the bar with the horizontal, are neglected, as these factors do not appreciably effect the results in the case of close-coiled springs.

Let O be the origin in Fig. 2 and W the load applied at the angle θ_0. At any point θ the deflection is y and the slopes in the circumferential plane and the radial plane are σ and λ, respectively. These three quantities, expressed as functions of θ_0 and θ, will completely define the position of the bar under load. They are obtained by the strain-energy method. It is shown in texts on elasticity that

$$y = \int \frac{Mm}{EI}\,dl + \int \frac{Tt}{GH}\,dl$$

where

M = bending moment, T = torque } due to applied load
m = bending moment, t = torque } due to unit load applied at the point whose deflection is y
EI = flexural rigidity
GH = torsional rigidity

Referring to Fig. 3, let θ be the coordinate of the point whose deflection y is required, and ψ be the coordinate of any point

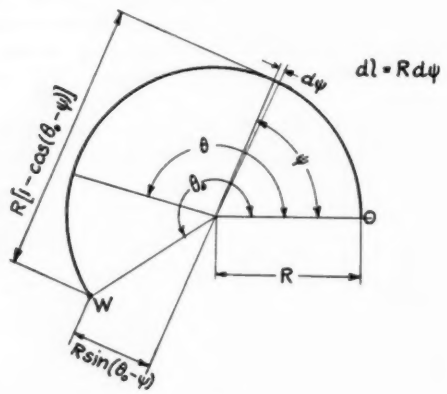

FIG. 3

between the origin O and θ. The load W is applied at θ_0, perpendicular to the plane of the figure.

At the point whose coordinate is ψ we have

$$M = WR\sin(\theta_0 - \psi)$$
$$T = WR[1 - \cos(\theta_0 - \psi)]$$
$$m = R\sin(\theta - \psi)$$
$$t = R[1 - \cos(\theta - \psi)]$$

$$y = WR^3\left\{\frac{1}{GH}\int_0^{\theta}[1 - \cos(\theta_0 - \psi)][1 - \cos(\theta - \psi)]\,d\psi + \frac{1}{EI}\int_0^{\theta}\sin(\theta_0 - \psi)\sin(\theta - \psi)\,d\psi\right\}$$

Reducing, we obtain

$$y = WR^3\left\{\frac{1}{GH}\left[\theta + \frac{1}{2}\theta\cos(\theta_0 - \theta) + \sin(\theta_0 - \theta) - \sin\theta_0 - \sin\theta + \frac{1}{2}\cos\theta_0\sin\theta\right] + \frac{1}{EI}\left[\frac{1}{2}\theta\cos(\theta_0 - \theta) - \frac{1}{2}\cos\theta_0\sin\theta\right]\right\} \quad [1]$$

The circumferential slope σ is found by differentiating Equation [1] with respect to $Rd\theta$ since

$$\sigma = \frac{dy}{dl} = \frac{1}{R}\frac{dy}{d\theta}$$

$$\sigma = WR^2\left\{\frac{1}{GH}\left[1 + \frac{1}{2}\theta\sin(\theta_0 - \theta) - \frac{1}{2}\sin\theta_0\sin\theta - \cos\theta\right] + \frac{1}{EI}\left[\frac{1}{2}\theta\sin(\theta_0 - \theta) + \frac{1}{2}\sin\theta_0\sin\theta\right]\right\} \quad [2]$$

The radial slope λ is shown in Fig. 2, and it is apparent that the originally horizontal radial axis X—X will slope upward toward the coil axis, while the circumferential Y—Y axis slopes downward. Therefore, if we take σ in Equation [2] as positive, λ will be negative. Let $d\phi$ be the angle of twist in the element dl at ψ, and di be the change in slope due to vertical bending, in the length dl at ψ. Projecting $d\phi$ and di upon the plane of θ, which makes the angle $\theta - \psi$ with the plane of ψ, we obtain

$$d\lambda = d\phi\cos(\theta - \psi) - di\sin(\theta - \psi)$$

It can be seen that the torque T which causes $d\phi$, tends to give a positive value of λ at θ, but the moment M would make $d\lambda$ negative. Since

$$d\phi = \frac{Tdl}{GH} \quad \text{and} \quad di = \frac{Mdl}{EI}$$

then

$$\lambda = WR^2\left\{\frac{1}{GH}\int_0^{\theta}\cos(\theta - \psi)[1 - \cos(\theta_0 - \psi)]\,d\psi - \frac{1}{EI}\int_0^{\theta}\sin(\theta - \psi)\sin(\theta_0 - \psi)\,d\psi\right\}$$

which reduces to

$$\lambda = -WR^2\left\{\frac{1}{GH}\left[\frac{1}{2}\theta\cos(\theta_0 - \theta) - \sin\theta + \frac{1}{2}\cos\theta_0\sin\theta\right] + \frac{1}{EI}\left[\frac{1}{2}\theta\cos(\theta_0 - \theta) - \frac{1}{2}\cos\theta_0\sin\theta\right]\right\} \quad [3]$$

The deflections and slopes at the load point θ_0 are obtained by making $\theta = \theta_0$

$$y_0 = WR^3\left\{\frac{1}{GH}\left[\frac{3}{2}\theta_0 - 2\sin\theta_0 + \frac{1}{4}\sin 2\theta_0\right] + \frac{1}{EI}\left[\frac{1}{2}\theta_0 - \frac{1}{4}\sin 2\theta_0\right]\right\} \quad [1a]$$

$$\sigma_0 = WR^2\left\{\frac{1}{GH}\left[\frac{3}{4} - \cos\theta_0 + \frac{1}{4}\cos 2\theta_0\right] + \frac{1}{EI}\left[\frac{1}{4} - \frac{1}{4}\cos 2\theta_0\right]\right\} \quad [2a]$$

$$\lambda_0 = -WR^2\left\{\frac{1}{GH}\left[\frac{1}{2}\theta_0 - \sin\theta_0 + \frac{1}{4}\sin 2\theta_0\right] + \frac{1}{EI}\left[\frac{1}{2}\theta_0 - \frac{1}{4}\sin 2\theta_0\right]\right\} \quad [3a]$$

These equations can be checked by observing that they must satisfy the condition

$$y_0 = y + \bar{y} + R\sigma\sin(\theta_0 - \theta) + R\lambda[1 - \cos(\theta_0 - \theta)] \quad [4]$$

where $\bar{y}$ is the deflection at θ_0 referred to θ as an origin, and is obtained from Equation [1a] by replacing θ_0 with $(\theta_0 - \theta)$. Reduction of the right-hand member of Equation [4] shows that it becomes identical with Equation [1a], thus proving that Equations [1] to [3] are correct.

The deflection and slopes of a point beyond the load point are required as shown in Fig. 4.

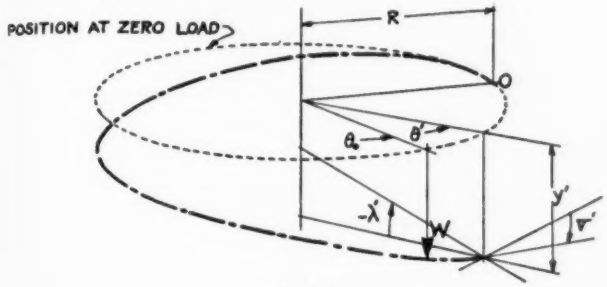

FIG. 4

Letting θ' be the coordinate of the desired point we obtain y' from Equation [4] by making $\bar{y} = 0$, $y_0 = y'$, $\theta_0 = \theta'$, and $\theta = \theta_0$:

$$y' = y_0 + R\sigma_0 \sin(\theta' - \theta_0) + R\lambda_0[1 - \cos(\theta' - \theta_0)]$$

Projecting the orthogonal slopes σ_0 and λ_0 on the plane of θ', that is, through the angle $(\theta' - \theta_0)$, we obtain

$$\sigma' = \sigma_0 \cos(\theta' - \theta_0) - \lambda_0 \sin(\theta' - \theta_0)$$

$$\lambda' = \lambda_0 \cos(\theta' - \theta_0) - \sigma_0 \sin(\theta' - \theta_0)$$

Substitute y_0, σ_0, and λ_0 from Equations [1a], [2a], and [3a]; reducing we get

$$y' = WR^3 \left\{ \frac{1}{GH} \left[\theta_0 + \frac{1}{2}\theta_0 \cos(\theta' - \theta_0) + \sin(\theta' - \theta_0) - \sin\theta' - \sin\theta_0 + \frac{1}{2}\cos\theta' \sin\theta_0 \right] + \frac{1}{EI} \left[\frac{1}{2}\theta_0 \cos(\theta' - \theta_0) - \frac{1}{2}\cos\theta' \sin\theta_0 \right] \right\} \quad \ldots\ldots [5]$$

$$\sigma' = WR^2 \left\{ \frac{1}{GH} \left[\frac{1}{2}\theta_0 \sin(\theta' - \theta_0) + \frac{3}{4}\cos(\theta' - \theta_0) - \cos(2\theta_0 - \theta') + \frac{1}{4}\cos(3\theta_0 - \theta') \right] + \frac{1}{EI} \left[\frac{1}{2}\theta_0 \sin(\theta' - \theta_0) + \frac{1}{4}\cos(\theta' - \theta_0) - \frac{1}{4}\cos(3\theta_0 - \theta') \right] \right\} \quad \ldots\ldots [6]$$

$$\lambda' = -WR^2 \left\{ \frac{1}{GH} \left[\frac{1}{2}\theta_0 \cos(\theta' - \theta_0) + \sin(\theta' - \theta_0) - \sin\theta' + \frac{1}{2}\cos\theta' \sin\theta_0 \right] + \frac{1}{EI} \left[\frac{1}{2}\theta_0 \cos(\theta' - \theta_0) - \frac{1}{2}\cos\theta' \sin\theta_0 \right] \right\} \quad \ldots\ldots [7]$$

The method of applying the equations to the calculation of the elastic curve will now be given. Fig. 5 shows the lower half of the spring, a being the longitudinal center of the bar. The angle $u - v$ is known, since it is one half the angle between tip contact points. Point O, which is taken as the origin, is the same as in Fig. 1, and its position must be left to be determined, that is, angle v is an unknown. The two load components, P_1 and P_2, and the reaction P_3, are all unknown, so that, with v, we have four quantities to determine. The four necessary conditions are:

1 $P_1 + P_2 = P$ where P is the given load on the spring.

2 The combined deflection at point b is zero, since the tip prevents downward movement of the adjacent coil.

3 The combined radial slope at point a must be zero to suit the imposed condition of parallel loading planes.

4 The combined vertical bending moment at point O must be zero, for the bar is not fastened to the loading plane and is, therefore, free to move upward, which it actually does. Suppose that at some point O' between O and b the bar were forced back to its no-load position by a force F. The reaction to F would be upward at b resulting in a vertical moment at O', which point would be the origin. Therefore, a moment at the origin would necessitate a downward force at that point to hold the bar against the plane, obviously a physical impossibility. It will be shown later that the torque at the origin is not zero, and that this condition is consistent with a zero bending moment.

The combined circumferential slope at a is not required, for whatever value it may have, the condition of parallel loading planes will be satisfied due to the symmetry of the top and bottom halves of the spring.

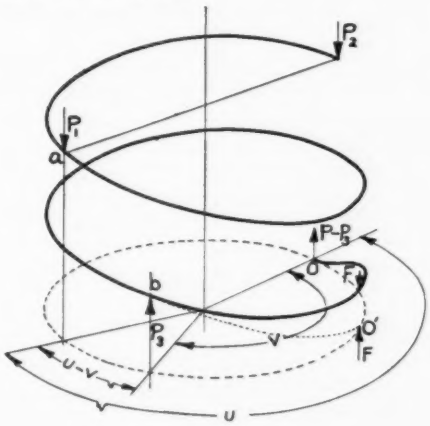

FIG. 5

To express the conditions (2) and (3), and to find the deflection at a, the component deflections are written from Equations [1] to [7]. Taking P_1 at a, we have $\theta_0 = u$ and $\theta = v$. From Equation [1a]

$$(y_a)_1 = P_1R^3 \left\{ \frac{1}{GH} \left[\frac{3}{2}u - 2\sin u + \frac{1}{4}\sin 2u \right] + \frac{1}{EI} \left[\frac{1}{2}u - \frac{1}{4}\sin 2u \right] \right\}$$

From Equation [1]

$$(y_b)_1 = P_1R^3 \left\{ \frac{1}{GH} \left[v + \frac{1}{2}v\cos(u - v) + \sin(u - v) - \sin u - \sin v + \frac{1}{2}\sin v \cos u \right] + \frac{1}{EI} \left[\frac{1}{2}v\cos(u - v) - \frac{1}{2}\sin v \cos u \right] \right\}$$

From Equation [3a]

$$(\lambda_a)_1 = -P_1R^2 \left\{ \frac{1}{GH} \left[\frac{1}{2}u - \sin u + \frac{1}{4}\sin 2u \right] + \frac{1}{EI} \left[\frac{1}{2}u - \frac{1}{4}\sin 2u \right] \right\}$$

Taking P_2 diametrically opposite a, we have $\theta_0 = u + \pi$ and $\theta = u$ for point a. From Equation [1]

$$(y_a)_2 = P_2R^3\left\{\frac{1}{GH}\left[\frac{1}{2}u - \frac{1}{4}\sin 2u\right] + \frac{1}{EI}\left[-\frac{1}{2}u + \frac{1}{4}\sin 2u\right]\right\}$$

From Equation [3]

$$(\lambda_a)_2 = -P_2R^2\left\{\frac{1}{GH}\left[-\frac{1}{2}u - \sin u - \frac{1}{4}\sin 2u\right] + \frac{1}{EI}\left[-\frac{1}{2}u + \frac{1}{4}\sin 2u\right]\right\}$$

For point b, $\theta = v$ and we have from Equation [1]

$$(y_b)_2 = P_2R^3\left\{\frac{1}{GH}\left[v - \frac{1}{2}v\cos(u-v) - \sin(u-v) + \sin u - \sin v - \frac{1}{2}\sin v\cos u\right] + \frac{1}{EI}\left[-\frac{1}{2}v\cos(u-v) + \frac{1}{2}\sin v\cos u\right]\right\}$$

Taking P_3 at point b and using the negative sign because P_3 acts upward, we have $\theta_0 = v$ and $\theta' = u$. From Equation [5]

$$(y_a)_3 = -P_3R^3\left\{\frac{1}{GH}\left[v + \frac{1}{2}v\cos(u-v) + \sin(u-v) - \sin u - \sin v + \frac{1}{2}\sin v\cos u\right] + \frac{1}{EI}\left[\frac{1}{2}v\cos(u-v) - \frac{1}{2}\sin v\cos u\right]\right\}$$

From Equation [7]

$$(\lambda_a)_3 = P_3R^2\left\{\frac{1}{GH}\left[\frac{1}{2}v\cos(u-v) + \sin(u-v) - \sin u + \frac{1}{2}\sin v\cos u\right] + \frac{1}{EI}\left[\frac{1}{2}v\cos(u-v) - \frac{1}{2}\sin v\cos u\right]\right\}$$

From Equation [1*a*]

$$(y_b)_3 = -P_3R^3\left\{\frac{1}{GH}\left[\frac{3}{2}v - 2\sin v + \frac{1}{4}\sin 2v\right] + \frac{1}{EI}\left[\frac{1}{2}v - \frac{1}{4}\sin 2v\right]\right\}$$

Combining the above results we have:

$$(y_b)_1 + (y_b)_2 + (y_b)_3 = 0 \ldots \text{Condition (2)}$$
$$(\lambda_a)_1 + (\lambda_a)_2 + (\lambda_a)_3 = 0 \ldots \text{Condition (3)}$$
$$y_a = (y_a)_1 + (y_a)_2 + (y_a)_3$$

This last equation is not required for the elastic-curve calculation, but is used in calculating the deflection of the spring as a whole and, hence, the deduction for inactive end turns. The condition equations can be simplified by the usual trigonometric transformations, and for round steel bars, a further simplification is made by putting $\frac{1}{EI} = 0.770\,\frac{1}{GH}$.

Simultaneous solution of the equations for conditions (1), (2), and (3) gives the results

$$\left.\begin{aligned} P_1 &= P\,\frac{BF + EC}{F(A+B) - 2C^2} \\ P_2 &= P - P_1 \\ P_3 &= P\,\frac{E(A+B) + 2BC}{F(A+B) - 2C^2} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [8]$$

$$y_a = \frac{PR^3}{GH}\left[K\frac{P_1}{P} + L\frac{P_2}{P} - D\frac{P_3}{P}\right]$$
$$A = 0.885u - \sin u + 0.0575\sin 2u$$
$$B = 0.885u + \sin u + 0.0575\sin 2u$$
$$C = 0.885v\cos(u-v) + \sin(u-v) - \sin u + 0.115\sin v\cos u$$
$$D = C + v - \sin v$$
$$E = -C + v - \sin v$$
$$F = 1.885v - 2\sin v + 0.0575\sin 2v$$
$$K = 1.885u - 2\sin u + 0.0575\sin 2u$$
$$L = 0.115u - 0.0575\sin 2u$$

The angle v is now determined from condition (4) which is

$$\left[BF + EC - \frac{1}{2}F(A+B) + C^2\right]\sin u - \left[\frac{1}{2}E(A+B) + BC\right]\sin v = 0 \ldots\ldots\ldots [9]$$

This equation can be solved by trial. If we assign a numerical value to v, the terms containing only trigonometric functions of u can be grouped into one member, and the other member of the equation becomes merely a constant times u. To illustrate, let $v = 188$ deg, and the condition (4) equation becomes

$$\sin^2 u - 0.5494\sin u[2.9039\cos(u - 8°) + \sin(u - 8°) + \sin u + 0.0160\cos u] + 0.004226\sin 2u = -0.06502\,u$$

The left-hand member contains only sine and cosine functions of u and its graph will therefore be sinusoidal with waves of constant amplitude. The right-hand member is merely an inclined straight line, and since it is negative, we need consider only the negative portions of the sinusoidal curve. This curve repeats at intervals of π, therefore only the first negative wave is required, and we obtain the roots by drawing a series of inclined parallel lines separated by a vertical distance of $0.06502\,\pi$ as

FIG. 6

shown in Fig. 6. The first two roots, points (1) and (2), have no significance since they are less than v. The other seven roots are as shown.

Values of u and v obtained in this manner are plotted in Fig. 7. It is seen that v fluctuates about 180 deg as a mean and that, except for short springs, it differs but little from this value.

We can now work out any desired numerical case from Equations [8] and the graph of Fig. 7. It is found, in general, that $P_1 \neq P_2$ or the resultant load P is eccentric. The loading is axial, $P_1 = P_2$ only when

$$u - v = \text{integer} \times \pi + 92 \text{ deg}$$

and the eccentricity is maximum when

$$u - v = \text{integer} \times \pi \text{ (approximately)}$$

The maximum eccentricity diminishes with increase of u, as shown in Fig. 7. The abscissas are shown in terms of u and also the number of turns between tip contact points.

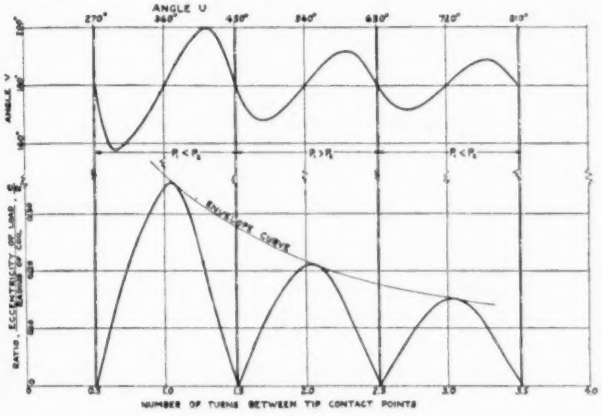

FIG. 7

The reactions between the coil end and the loading plane must now be considered, to show that the necessary conditions of static equilibrium are satisfied. The tapered tip which contacts the loading plane is shown in Fig. 8.

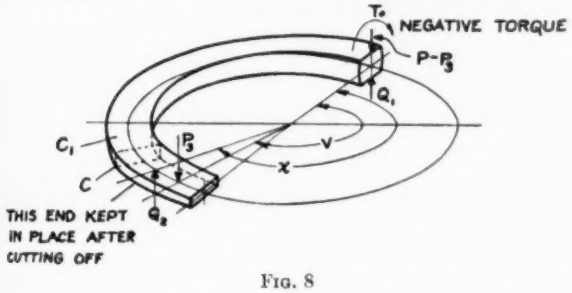

FIG. 8

A numerical calculation of P_1, P_2, and P_3 for various values of u shows that there is always a negative torque T_0 at the origin, as shown in Fig. 8, which would cause the tapered end to rise from the loading plane if it were not held down by the reaction P_3. The reactions between the tapered end and the loading plane are Q_1 and Q_2. Static equilibrium requires that the sum of torques, and the sum of bending moments at O must each be zero, and sum of reactions equal to the load on the spring:

$$P_3R(1 - \cos v) - Q_2R(1 - \cos x) - T_0 = 0$$
$$P_3R \sin v - Q_2R \sin x = 0$$
$$Q_1 + Q_2 = P$$

The terms P_1, P_2, and P_3 are calculated as previously explained, and T_0 from the equation

$$T_0 = R[-P_3(1 - \cos v) + P - (P_1 - P_2) \cos u]$$

Q_1, Q_2, and x can then be found from the foregoing three equations. The results of a sample calculation are as follows:

u = 387 deg 7 min	
v = 193 deg	x = 193 deg 55 min
P_1 = 0.32407 P	Q_1 = 0.33362 P
P_2 = 0.67593 P	Q_2 = 0.66638 P
P_3 = 0.71284 P	
T_0 = —0.09423 PR	

To test the truth of the foregoing reasoning, a test was made, cutting off the tapered ends at C (in Fig. 8) and using a spring with ends ground accurately parallel (to within 0.0005 in. in 6½ in.), and employing ground-steel plates for loading planes. Upon application of the load it was found that the end C_1 moved upward from the loading plane, thus proving that there is a negative torque at O if the ends are not cut.

The elastic curve can now be calculated for any desired length of spring. Taking first a case of approximately maximum eccentricity (u = 1080 deg and v = 180 deg) we obtain from Equation [8]

$$P_1 = 0.4520\ P$$
$$P_2 = 0.5480\ P$$
$$P_3 = 0.5755\ P$$

Letting θ be the coordinate of any point, we write the component deflections from Equation [1] using

$$\theta_0 = \begin{cases} 1080 \text{ deg for } P_1 \\ 1260 \text{ deg for } P_2 \\ 180 \text{ deg for } P_3 \end{cases} \quad \text{and } 0 < \theta < 180 \text{ deg}$$

Adding these deflections, in terms of P, we obtain

$$y = \frac{PR^3}{GH} \times 0.4245\ [\theta(1 + \cos\theta) - 2\sin\theta] \ldots\ldots [10]$$

which gives the elastic curve for points between the origin O and the tip contact point b.

For values of $\theta > v$ we require another equation because P_3 now comes between θ and the origin. Using Equation [5], and replacing θ' with θ, and θ_0 with v (180 deg) we obtain the component deflection for P_3. The component deflections for P_1 and P_2 are the same as used in the preceding paragraph. Combining

$$y = \frac{PR^3}{GH}\ [\theta(1 - 0.08489\cos\theta) - 1.8081 + 1.6175\sin(\theta + 81°37')] \ldots [11]$$

which applies between the tip contact b and the bar center point a.

The consistency of these results can be seen by noting that Equation [10] gives $y = 0$ for $\theta = 0$ or $\theta = 180$ deg, and Equation [11] gives $y = 0$ for $\theta = 180$ deg. Also the derivatives of Equations [10] and [11], taken with respect to θ, are equal for θ = 180 deg, thus satisfying the necessary condition of continuity.

The graph of Equations [10] and [11] is the required elastic curve and is shown in Fig. 9, deflections being plotted in terms of the deflection of the entire spring. It is seen that the deflection is reversed between the origin and tip contact point, which fact makes the deflection of the whole spring more than it would be if the bar were held fixed at the tip contact. The elastic curve has sinusoidal waves, the amplitude of which diminishes as the center of the spring is approached.

Taking the case of axial loading, we have

$$P_1 = P_2 = 0.5\ P \qquad u = \text{integer} \times \pi + 92 \text{ deg}$$
$$P_3 = 0.5305\ P \qquad v = 180 \text{ deg}$$

The method of calculation is the same as for the previous case, and we find

$$y = \frac{PR^3}{GH} \times 0.4695\ [\theta(1 + \cos\theta) - 2\sin\theta] \ldots\ldots [12]$$

$$0 < \theta < v$$

$$y = \frac{PR^3}{GH}\left[\theta - 1\frac{2}{3} + 1.4763\sin(\theta + 87°38')\right] \ldots [13]$$

$$v < \theta < u$$

Equations [10] and [12] are identical except for a small difference in the numerical coefficient, showing that the deflection back of the tip-contact point is practically unaffected by load eccentricity. The graph is shown in Fig. 10; it has sinusoidal waves of constant amplitude as can be seen from the form of Equation 13, whereas, with eccentric loading the amplitude diminishes at the bar center point. This is the distinguishing feature between axial and eccentric loading as far as the elastic curve is concerned.

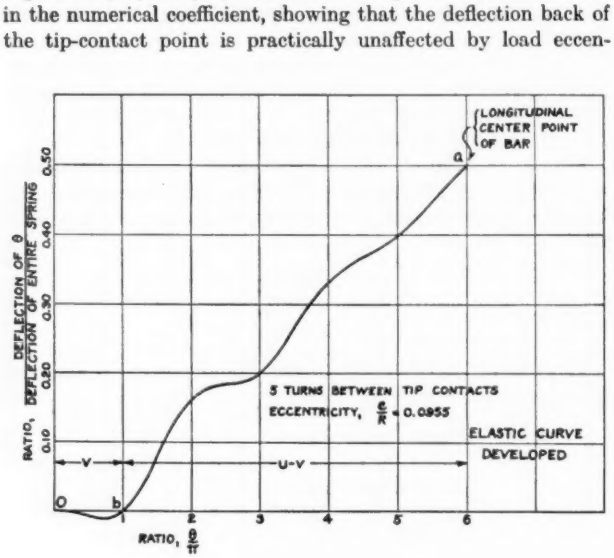

FIG. 9

An experimental determination of the elastic curve, covered in a current paper[2] by D. H. Pletta and F. J. Maher of the Virginia Polytechnic Institute, furnishes proof of the essential correctness of the analytical results.

Load eccentricity increases stress because the maximum torque is increased, the direct load being unchanged. If we let Z be the eccentricity stress factor, the relation between Z and the eccentricity e is given by

$$e = 1.123\,R(Z - 1) \quad \text{or} \quad Z = 1 + \frac{e}{1.123\,R}$$

Axial loading is theoretically possible, but actually it cannot be realized. This point is discussed in more detail in Professor Pletta's paper.[2] His experiments showed close agreement between the test and theoretical elastic curves in cases of maximum load eccentricity. For the theoretical number of turns corresponding to axial loading, the agreement between test and theory was not as close, indicating that axial loading was not realized in the tests in spite of all the precautions taken to obtain it. In actual springs the chances of getting axial loading would be even less, and it would therefore appear best for conservative design to calculate the eccentricity stress factor Z from the envelope of the e curves shown in Fig. 7. It can be shown that on this basis the envelope formula for Z would be

$$Z = 1 + \frac{0.5043}{N} + \frac{0.1213}{N^2} + \frac{2.0584}{N^3}$$

N = solid ht ÷ bar diameter

In order to use the foregoing analytical results in calculation, it is necessary to relate the angle $u - v$ to the number of turns in the spring. The actual average location of the tip-contact point b, as shown in Fig. 1, is somewhat advanced from the extreme tip, say about $^1/_{20}$ turn or 18 deg. Since the bar-tip thickness is $^1/_4$ of the bar diameter, the number of closed turns at one end is

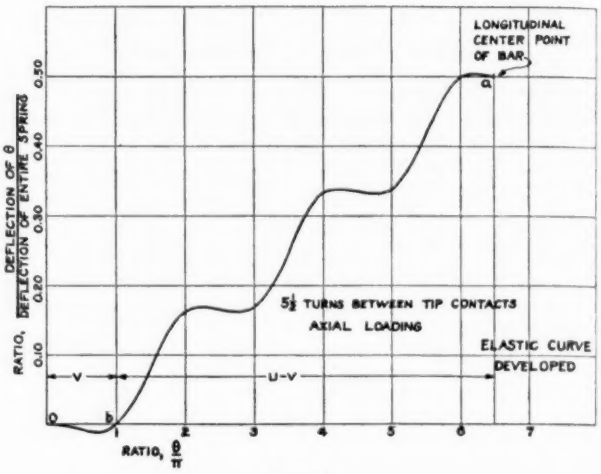

FIG. 10

$^1/_2 + ^1/_4 + ^1/_{20} = 0.8$, or 1.6 for the whole spring. Therefore

$$2(u - v) = 2\pi(N - 1.6)$$

$$\frac{u - v}{\pi} = N - 1.6 = \text{number of turns between tip-contact points.}$$

Using this equation in connection with any desired value of N, we can find the eccentricity from Fig. 7, or the envelope stress factor Z from the equation in the preceding paragraph.

The deflection for the whole spring is

$$y = \frac{PD^3\pi(N - 1.2)}{4GH}$$

$$y = \frac{8PD^3(N - 1.2)}{Gd^4}$$

for round bars, where $N - 1.2$ is the number of effective turns. The deduction of 1.2 for inactive end turns is obtained from the foregoing analysis by calculation of y_a.

Discussion

H. C. PERKINS.[4] Elastic curves of helical compression springs, as computed by the author, check so well with the experimental results[2] reported by Pletta and Maher that the essential validity of his theory seems definitely established. He is to be congratulated upon the success of his analysis and the accuracy of his calculations. Nevertheless, his formulas are inconvenient, especially in case his Fig. 7 is inapplicable.

Since the author's theory seems to be of sufficient interest and value to warrant an attempt to simplify the analysis and reduce its results to more convenient form, the following discussion of his paper has three objects:

1 To check the author's theory
2 To simplify his analysis
3 To derive formulas which could be used in design.

Fig. 11 of this discussion represents the lower half of a compression spring stressed and deflected by a force P with eccentricity e and supported by reactions P_3 and P_4 at the lower end coil as shown. Since the bending moment does not, in general, vanish at the point $V = \pi$, but is small and changing rapidly, the author chose to take the origin O at the cross section of zero bending moment and to regard V as undetermined.

[4] Assistant Professor of Mechanical Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

It therefore follows that the stress resultant at O (including any reaction between O and b) is a vertical force P_4 with action line intersecting a coil diameter through O, at an unknown distance C from the axis of the coil. If f represents the number of free turns of wire between end contacts b, then half the free length of the wire is equal to $Rf\pi$ as suggested in Fig. 11 of this discussion.

Three independent equations of equilibrium may be written. Thus, summing forces

$$P_3 + P_4 - P = 0 \quad [14]$$

Summing moments about a coil diameter through a

$$P_3 R \sin f\pi + P_4 C \sin U = 0 \quad [15]$$

Summing moments about a coil diameter through b

$$Pe \sin f\pi - P_4 C \sin V = 0 \quad [16]$$

But a moment sum about the coil diameter perpendicular to the one through a is also useful in case $\sin f\pi$ and $\sin V$ vanish as they do when f = integer. Thus

$$Pe + P_3 R \cos f\pi + P_4 C \cos U = 0 \quad [17]$$

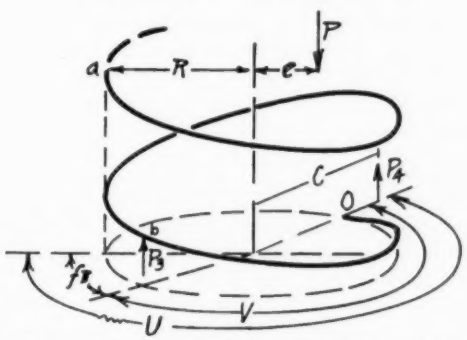

FIG. 11 LOWER HALF OF COMPRESSION SPRING STRESSED AND DEFLECTED BY FORCE P AND SUPPORTED BY REACTIONS P_3 AND P_4 AT THE LOWER END COIL

Before proceeding with the general analysis, consider two special cases.

In case 1, when $2f$ is an odd integer, the end contacts b are at opposite ends of a coil diameter. In this case, by symmetry of the upper and lower halves of the spring $e = 0$, since P must be equidistant from the two end contacts. Then by Equation [16] of this discussion, since $f\pi = 0$ and $P_4 C$ does not vanish, it follows that $\sin V = 0$, so $V = \pi$ and U = (integer) (π) + 90 deg. This is 2 deg smaller than the author's value. The error is not one of calculation but seems to follow from the assumption that the radial slope λ vanishes at the origin. This assumption is, in general, inconsistent with the fact that, as shown by the author, there are torques on most cross sections of the "dead end coil" of an actual spring, but the tests[3] of Pletta and Maher indicate that the consequent errors are probably smaller than those introduced in the manufacture of the spring.

In case 2, when f is an integer, $\sin f\pi = 0$, and since $P_4 C$ does not vanish, Equation [16] of this discussion requires that $\sin V = 0$, so $V = \pi$.

Given the value of V as in cases 1 and 2, the corresponding value of C/R is found from the condition that the deflection y must vanish at b. The deflection y at any point of the elastic curve may be formulated as follows.

The bending and twisting moments on any cross section located by angle θ from 0 or angle ϕ from b are

$$M = P_4 C \sin \theta + P_3 R \sin \phi \quad [18]$$

$$T = P_4 (C \cos \theta - R) - P_3 R (1 - \cos \phi) \quad [19]$$

and corresponding values for unit downward force on the elastic curve at angle α from O or β from b are

$$m = -R \sin (\alpha - \theta) = -R \sin (\beta - \phi) \quad [20]$$

$$t = -R [1 - \cos (\alpha - \theta)] = -R [1 - \cos (\beta - \phi)] \quad [21]$$

Substituting these values in the strain-energy formula

$$y = \int \frac{M m dL}{EI} + \int \frac{T t dL}{GH} \quad [22]$$

and integrating $dL = Rd\theta = Rd\phi$ from $\theta = 0$ to $\theta = \alpha$ or from $\phi = 0$ to $\phi = \beta$, the result is

$$y = P_4 R^3 \frac{c}{2R}\left[\frac{1}{EI} + \frac{1}{GH}\right](\alpha \cos \alpha - \sin \alpha) + \frac{P_4 R^3}{GH}(\alpha - \sin \alpha) + \frac{P_3 R^3}{2EI}(\beta \cos \beta - \sin \beta) + \frac{P_3 R^3}{2GH}(2\beta - \beta \cos \beta - 3 \sin \beta) \quad [23]$$

Note that by taking $\beta = \theta$, $P_3 = W$, $P_4 = 0$, and $\theta_0 = 0$, or taking $\alpha = \theta$, $P_4 = W$, $P_3 = 0$, $C = R$, and $\theta_0 = 0$, Equation [23] and the author's Equation [1] are reduced to the same form.

Since P_4 is the only reaction if the angle θ is less than V, the zero deflection at b is formulated by letting $P_3 = 0$ and $\alpha = V$ in Equation [23] of this discussion. It follows thus that

$$\frac{C}{R} = \frac{2EI}{EI + GH} \cdot \frac{V - \sin V}{\sin V - V \cos V} \quad [24]$$

or if $\frac{GH}{EI} = 0.77$

$$\frac{C}{R} = 1.13 \frac{V - \sin V}{\sin V - V \cos V} \quad [25]$$

In cases 1 and 2, $V = \pi$ and $C/R = 1.13$. In general, however, before C/R can be evaluated, V must be computed from the condition that, by symmetry, the radial slope λ must vanish at the mid-section. Thus, bending and twisting moments on any cross section are given by Equations [18] and [19] of this discussion and corresponding values for unit torque at mid-section a are

$$m = -\sin (U - \theta) = -\sin (f\pi - \phi) \quad [26]$$

$$t = \cos (U - \theta) = \cos (f\pi - \phi) \quad [27]$$

Substituting these values in the strain-energy equation

$$\lambda_a = 0 = \int \frac{M m dL}{EI} + \int \frac{T t dL}{GH} \quad [28]$$

integrating $dL = Rd\theta = Rd\phi$ from $\theta = 0$ to $\theta = U$ or from $\phi = 0$ to $\phi = f\pi$, solving for $\frac{-RP_3}{CP_4}$ and equating it to the corresponding ratio from Equation [15] of this discussion

$$\frac{-RP_3}{CP_4} = \frac{U \cos U - A \sin U}{f\pi \cos f\pi - \sin f\pi} = \frac{\sin U}{\sin f\pi} \quad [29]$$

in which $A = \dfrac{EI\left(2\frac{R}{C} - 1\right) + GH}{EI + GH}$

To check, let $\frac{GH}{EI} = 0.77$, and take $f = 1/2$ which comes under case 1. Then $\frac{C}{R} = 1.13$, $A = 0.87$, $\sin f\pi = 1$, $\cos f\pi = 0$, $\sin U = -1$, $\cos U = 0$. These values do not satisfy the equation. To estimate the error, regard $f\pi$ as undetermined. Then

$$\cot f\pi = \frac{0.13}{f\pi}$$

Solving by successive approximations, $f\pi = 94$ deg 30 min. The author found that $e = 0$ when $U - V = (\text{integer})\ (\pi) + 92$ deg. In general, by taking $A = 1$ in Equation [29] of this discussion, the error is eliminated in case 1 and perhaps in other cases as well. If this change is effected, the equation can be written in the form

$$\cot U = \frac{f\pi \cot f\pi}{U} \quad \ldots\ldots\ldots\ldots\ldots\ldots [30]$$

which is easily solved by successive approximations.

For example: let $f = 3.25$ so $\cot f\pi = 1$. Substitute $U_0 = 585 + 180$ deg on the right and solve for U_1 on the left. Thus

$$\cot U_1 = \frac{585\ (1)}{765} = 0.764$$

so $U_1 = 772.6$. Substitute U_1 on the right and find $U_2 = 772.9$ deg on the left. This completes the solution, since further refinement is useless for slide-rule computation. Now $V = 772.9 - 585 = 187.9$ deg, which seems to check with the corresponding ordinate in the author's Fig. 7.

Using this value of V in Equation [25] of this discussion, $C/R = 1.238$

Equations [14] and [15] of this discussion may now be solved to find $P_4 = 0.583P$ and $P_3 = 0.417P$ and Equation [16] solved to find $e/R = 0.101$ which is about 10 per cent less than the corresponding ordinate in the author's Fig. 7. Finally, the over-all deflection of the spring is obtained by doubling the deflection at mid-section, the latter being found from Equation [23] by taking $\alpha = U$ and $\beta = f\pi$.

A formula approximating the author's "envelope curve" may be found by taking $f =$ an integer and solving Equations [24], [14], [17], and [29] to find

$$\frac{e}{R} = \frac{-2}{f\left(3 + \frac{GH}{EI}\right) + 2} \quad \ldots\ldots\ldots\ldots [31]$$

Disregarding sign and taking $\frac{GH}{EI} = 0.77$, the results check the author's values of e/R for $f = 1$, 2, and 3 free turns, respectively. Increasing the numerator 5 per cent and, changing sign, the "envelope formula" is

$$\frac{e}{R} = \frac{2.1}{f\left(3 + \frac{GH}{EI}\right) + 2} \quad \ldots\ldots\ldots\ldots [32]$$

Since e, in Fig. 11 of this discussion, is alternately positive and negative as f is alternately odd and even, and passes through zero when $2f$ is an integer, the curve e versus $f\pi$ is periodic. It may be approximated by the formula

$$\frac{e}{R} = \frac{-2 \cos f\pi}{F\left(3 + \frac{GH}{EI}\right) + 2} \quad \ldots\ldots\ldots\ldots [33]$$

in which F is the integer nearest to the given value of f.

In the foregoing example, in which $f = 3.25$ and $\frac{GH}{EI} = 0.77$, $F = 3$ and the approximate eccentricity ratio is

$$\frac{e}{R} = \frac{1.414}{3 \times 3.77 + 2} = 1.06$$

This discussion seems to support the conclusion that, although simplifying assumptions have introduced some errors, the errors are probably small. The author's calculations also seem to be highly accurate despite their complication. However, as shown, the analysis need not be complicated and, judging by the illustrative example near the close of this discussion, the formulas therein derived could easily be used in the design of helical compression springs.

Author's Closure

Professor Perkins' discussion is of much interest as showing a different method of approaching the problem. His treatment is admittedly shorter than the author's, and possibly simpler, but it has been compressed to such an extent that it is more difficult to follow. For instance, Equation [23] is given for the elastic curve, but no equations expressing P_3 and P_4 directly in terms of P are given. Apparently it would be necessary to use Equation [15] which involves U, finding U from Equation [30]. The author admits frankly that the assumption of zero λ at the origin is not exactly true. However, it is very nearly true, physically, as is the case with many assumptions commonly accepted in elasticity calculations. It is not clear why the reaction P_4 has been taken as acting outside the coil.

The paper is concerned primarily with the determination of the elastic curve, as the subject indicates. No attempt was made to give working formulas for practical spring calculation. For such purposes, neither the author's paper nor Professor Perkins' discussion is suitable. A further simplification is necessary and the results must be put in tabular form so that the use of formulas is eliminated. Such tables have been prepared by the author and used for several years in routine spring calculation. They have proved to be rapid and accurate, containing the proper allowance for inactive end turns and load-eccentricity effect, as expressed in the envelope curve.

Helix Warping in Helical Compression Springs

By D. H. PLETTA[1] and F. J. MAHER,[2] BLACKSBURG, VA.

When helical springs are compressed between parallel planes, the load is usually eccentric with the longitudinal axis and the helix, in its deflected position, is no longer truly helical but assumes a sinusoidal or warped shape. The magnitude of the eccentricity and of the warping is a function of the number of turns in the spring.

The research reported on here illustrates this warping for a heavy helical spring, whose length was varied for the series of tests, and it also compares the test results with the theoretical behavior as outlined in the accompanying paper of H. C. Keysor. In general, the actual and theoretical behavior were in excellent agreement, thus apparently substantiating the theory. An analysis of the data also emphasizes the need of always assuming some eccentricity of load in practical design, to allow for the lack of perfect concentricity of the individual turns.

THE TESTS reported on in this paper were undertaken to determine the correlation between the actual behavior of loaded helical compression springs and the theoretical behavior as outlined in the companion paper[3] by H. C. Keysor. The theory indicates that helical springs, when compressed between parallel planes, are usually subjected to an eccentric rather than a concentric load, and that this eccentricity causes the helix to warp under load. The term warping, as used here, indicates that the deflected helix assumes a sinusoidal shape and does not remain truly helical in its deflected position as the ordinary spring formula leads one to believe. Fig. 1 illustrates this phenomenon. Curve *A* shows the unloaded helix "unwound" and projected on a vertical plane. Curve *B* indicates the deflected position of this helix after application of the load, the solid curve showing actual behavior, and the dotted line showing the commonly assumed position. The shaded area between curves *A* and *B* represents deflection and is replotted in curve *C* for only half of the helix.

The actual and theoretical behavior of compression springs may then be checked by measuring the actual eccentricity of load or by measuring the warping of the helix, and comparing these observations with the theoretical values. The tests as carried out included only observation of helix warping, mainly because apparatus capable of determining warping already existed and because it would have been somewhat difficult to measure eccentricity accurately on the heavy stiff spring used.

A single spring was used in this project. Hence, all variables such as differences in heat-treatment, moduli of elasticity, coil-and-bar diameter, etc., common to any series of separate specimens were eliminated or at least minimized. The bar as coiled consisted originally of about seven turns from each end of which equal lengths were cut as the spring was shortened for the series of tests. The spring had an outer diameter of 6.42 in. and a bar diameter of 1.336 in. A plain carbon steel (0.9 to 1.05 per cent C) was used, coiled hot on a slightly tapered mandrel, and subjected to an oil quench from 1525 F and a subsequent drawing to 850 F.

The spring lengths, as tested, were placed between special helical end blocks mounted to the base and movable head of a testing machine, Fig. 2. Very thin plaster of Paris cappings, as cast in place under load, insured continuous contact for the first 270 deg of the dead turn. The balance of the apparatus to measure the warping consisted essentially of a collar, concentric with and free to rotate about the lower end block, to which a vertical post was attached. An Ames dial reading to 0.001 in. was fastened to a sleeve which was free to slide up and down the post. A tapered pin, which fits through the sleeve and post simultaneously, could be inserted in any one of a series of holes in the post spaced 1 in. apart. The cantilever arm attached to the lower end of the Ames-dial plunger rested on the top side of the wire of the spring. With this arrangement, it was possible to determine the elevation of any point on the coil to 0.001 in. above a datum for any given load. A subtraction of two successive elevations at any given point gave the net deflection for that increment of load.

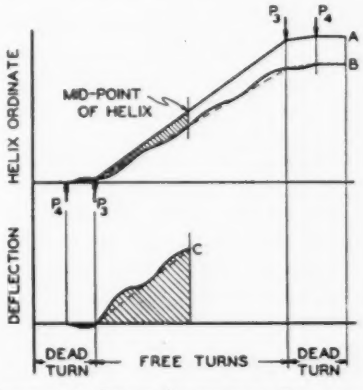

FIG. 1 SINUSOIDAL SHAPE ASSUMED BY DEFLECTED HELIX

During a test run, readings were taken at points spaced 30 deg apart along the helix for loads of 500 and 8000 lb. The cantilever arm was used to eliminate the error that could possibly result if points on the outside of the wire had been used. Any twist in the wire, when the coil was loaded, would have caused these points to deflect more or less than the helical axis, whereas any measurement made on a horizontal tangent to the top of the wire would always remain half a wire diameter above the axis. At each load the deflection of the whole spring was also observed by noting the movement of the head of the testing machine.

At the 8000-lb load, the upper and lower split wedge blocks were adjusted so that the deflection of the end of the dead

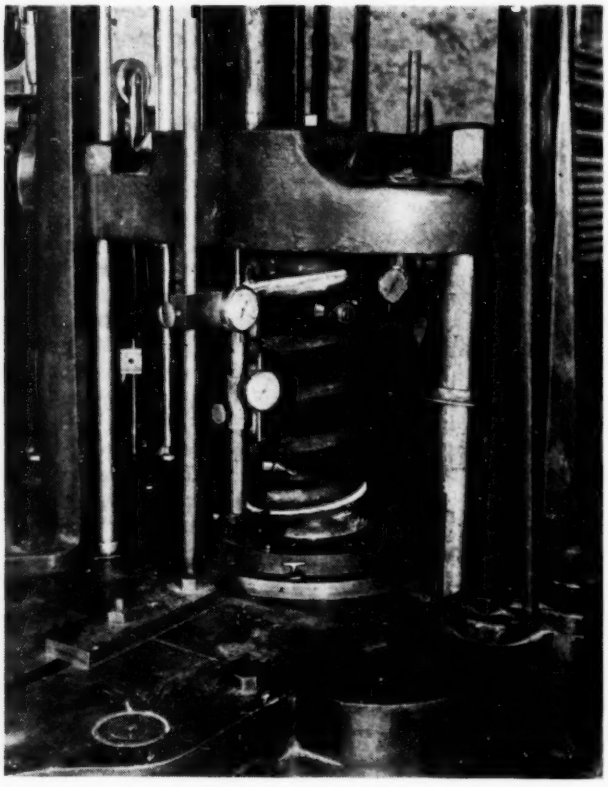

FIG. 2 METHOD OF MOUNTING SPRING LENGTHS IN TESTING MACHINE

turn (point 13) was reduced to zero relative to its seat. The wedges can be seen in Fig. 2 and are also illustrated in detail in Fig. 3. They resemble a bolt with the circular head of the bolt and washer tapered. Under the 8000-lb load the two ends of the dead turn closed several hundredths of an inch allowing point 13 to deflect. This movement was reduced to zero by tightening the nut, thus separating the ends of this turn. Various other nonadjustable supports were tried but all of them allowed some deflection due to the localized contact deformation. It was thought best to have this deflection zero in keeping with the theory, but it should be added that the small movement allowed by these other supports was not critical, for the deflections of points along the helix were only slightly affected.

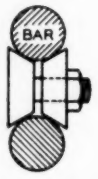

FIG. 3 SPLIT WEDGE BLOCK

Table 1 indicates the scope and some of the results of the tests. Seven tests were made, the bar length varying from 6 to 3.511 total turns. Three of these lengths were such that the eccentricity of the load was theoretically zero; whereas the others, with the exception of case 2, were such that the eccentricity was the maximum attainable. The theoretical spring deflection was calculated, using a shearing modulus of elasticity of 11,600,000 lb per sq in.

Fig. 4 shows the helix warping up to mid-length of the spring for the seven tests outlined in Table 1. The other half of the spring should, of course, be identical and tests indicated that it was, but there seemed little need of plotting the curves for the entire spring. The load increment was 7500 lb. The solid line represents theory. No attempt was made to draw a curve through the data points. In four of the tests the correlation between theoretical and actual behavior was almost perfect, whereas in the other three cases it was only fair. There are

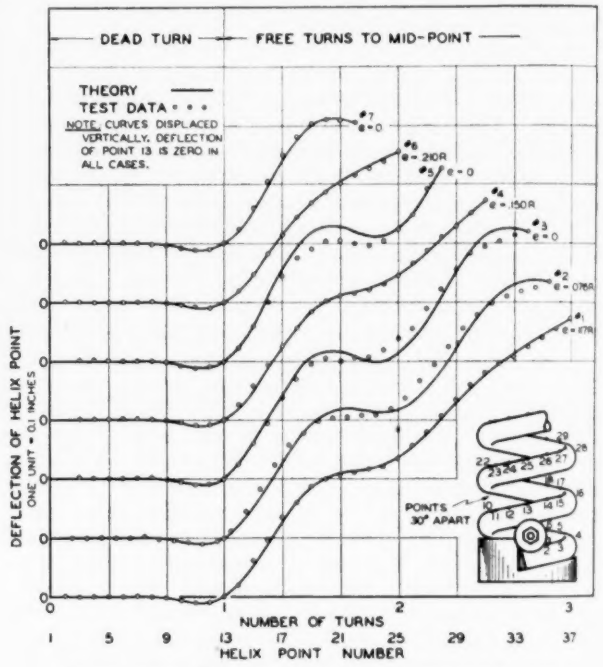

FIG. 4 HELIX WARPING UP TO MID-LENGTH OF SPRING

several reasons why the agreement in these last three cases should not be perfect. The measurement of the deflection on the top of the bar rather than along the neutral axis; the slight rocking of the bar on the split wedge blocks, tending to shorten the spring; the imperfect seating on the helical end seats; and the lack of perfect concentricity for the individual turns of the spring, all tended to modify perfect behavior. The last condition is the most important. It is practically impossible to coil heavy bar so that all turns are identical in diameter, pitch, and concentricity. If only one turn is displaced laterally, an axial load on the spring would be eccentric on this coil. Theoretically the warping decreases near the center of the spring as the ec-

TABLE 1 SCOPE AND RESULTS OF COMPRESSION TESTS ON HELICAL SPRINGS

Test no.	Number of turns: Free[a]	Number of turns: Active (theoretical)	Number of turns: Excess	Deflection in in.: Actual	Deflection in in.: Theoretical	Variation from theoretical, per cent	Theoretical eccentricity
1	4	4.415	0.415	0.947	0.938	+0.96	0.1171R[b]

7	1.511	1.979	0.468	0.416	0.421	—1.19	0

[a] All test springs had two dead coils in addition.
[b] R = mean coil radius.

centricity of load increases. Hence the sinusoidal effect would tend to be damped out especially at the center of the spring. The measured eccentricity of individual turns on the spring amounted to several hundredths of an inch, which corresponded approximately to $e = 0.02R$ rather than zero. Naturally the magnitude of this error was relatively larger in cases 3 and 5 when the eccentricity should have been zero than in cases 1, 4, and 6 when e was appreciable. Yet in case 7, with $e = 0$ theoretically, the correlation is very good. The reason for this is that this spring had only 1.511 free turns and was therefore too short to be affected by any lateral displacement of a full turn, the short length practically requiring concentricity with itself.

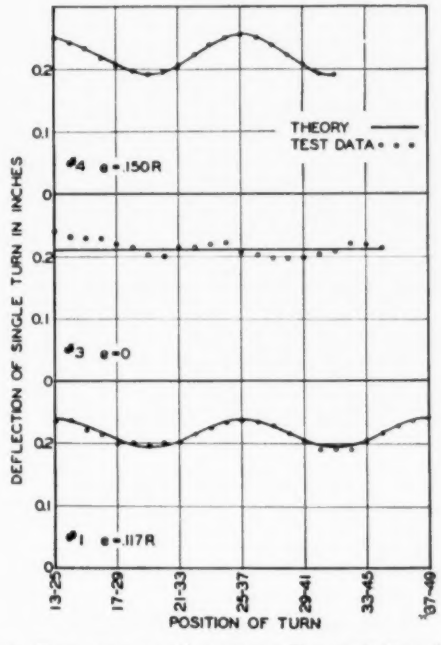

FIG. 5 DEFLECTION OF INDIVIDUAL TURNS 30 DEG APART

The actual eccentricity of individual turns in cases 3 and 5 was actually determined, but its existence would also be suspected when studying Fig. 5. Here the deflection of individual full turns 30 deg apart is plotted for cases 1, 3, and 4. The sinusoidal nature of the test data for case 3 is possible only when the load is eccentric. When considering this variation, it should be remembered that the total load on the spring, considered as a concentrated force, acts perpendicular to the diameter through the mid-point of the spring, and that it is generally displaced from the longitudinal axis of the spring.

Some objection to these tests and the theory might be raised because of the difference in the end conditions between these tests and those in commercial springs with their tapered ends ground square. Fig. 6 illustrates helix warping in a commercial spring tested and reported on previously.[4] Here again the sinusoidal effect is quite evident.

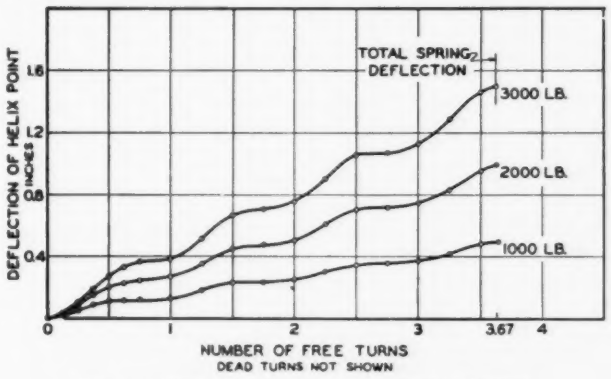

FIG. 6 HELIX WARPING OF A COMMERCIAL SPRING

It is the belief of the authors that the tests reported in this paper substantiate Mr. Keysor's theory on spring behavior and also emphasize the absolute necessity of always assuming some eccentricity for the load in commercial design to be on the safe side. In other words, an eccentricity based on the envelope of the theoretical cyclic variation in eccentricity,[5] rather than the theoretical eccentricity itself, should be used to allow for the lack of concentricity arising in the practical manufacture of springs. In the commercial design it should, of course, be remembered that eccentric loads produce greater shearing stress than the commonly assumed axial loads.

Boundary Film Investigations

By SYDNEY J. NEEDS,[1] PHILADELPHIA, PA.

This paper describes attempts made in Dr. Kingsbury's laboratory to detect the influence of boundary surfaces on the viscosity of thin films of lubricant between two optically plane parallel disks. Investigations included both mineral and vegetable oils. Details of two testing machines are given and typical results with each machine are described.

Introduction

THE MANNER in which a liquid in contact with a solid surface is influenced by that surface has been the subject of considerable study in this country and abroad. It appears obvious that the molecules of the liquid actually in contact with and adhering to the surface, or to adsorbed layers on the surface, must necessarily behave differently from adjacent molecules of the liquid in bulk. But the nature of this surface phenomenon and the distance from the surface to which its influence extends are not well understood and experimental studies have given rise to widely divergent opinions on these particular points. Kingsbury (1)[2] pointed out some 37 years ago that the nature of this surface property was probably "an intensified viscosity in that part of the fluid within the region of attraction of the surface molecules of the metal." Hardy and Nottage (2) offer proof "that the attraction field of the solids modify the state of the lubricant throughout a layer many hundreds or thousands of molecules in thickness;" and they place the limit of boundary lubrication (3, 4) at a distance of 0.007 to 0.010 mm (0.0003 to 0.0004 in.), that is, the film must be of that order of thickness if any of the liquid is to be beyond the range of surface influence. Wilson and Barnard (5) found that capillaries as large as 0.3 mm (0.01 in.) diam would gradually clog up under the flow of oils and would close completely if a small percentage of oleic or stearic acid were added to the oil. This clogging was attributed to the gradual building up of adsorbed films on the walls of the capillaries.

In a carefully conducted series of experiments with capillaries of approximately the same diameter as those used by Wilson and Barnard, Bulkley (6) was able to show that the clogging was due to the fact that the oil had not been thoroughly filtered. From further experiments with highly filtered oils in fine glass and platinum capillaries having diameters of the order of 0.01 mm to 0.03 mm, Bulkley concluded "that the thickness of any fixed layer adjacent to the walls is not in excess of two or three hundredths of a micron, or approximately a millionth of an inch." Confirming results have been published by Bastow and Bowden (7), who conclude from measurements of the flow of liquids between optically polished flat plates that no sign of induced rigidity is to be detected in liquids at a distance of 1000 Å [$4(10)^{-6}$ in.] from the surface. There are many other reports in the literature which form, as pointed out by Bowden (8), "a large body of conflicting evidence and opinion as to the range of surface forces."

The present paper reports some of the results of a 4-year study of thin films of vegetable and mineral oils conducted in Dr. Kingsbury's laboratory under his direction. Aside from the problems of filtration, selection of the proper metal for the test surfaces and the preparation of the surfaces, the experimental work divided itself into two distinct parts. Part I of this paper describes attempts to discover indications of increasing viscosity in thin films of oil formed by two plane disks approaching each other under loads of the order of 0.20 lb per sq in. with no tangential motion. Part II describes experiments with plane surfaces approaching under loads up to 800 lb per sq in. with continuous relative rotation of the surfaces. It also describes a method of measuring the minimum film thickness reached under these conditions. Experiments reported in part II are extremely simple and may be readily reproduced. They add clarity to the results of part I and appear to show that steel surfaces have a profound influence on the behavior of lubrication films up to thicknesses greater than 60 millionths of an inch (0.0015 mm); the thickness depending somewhat upon the lubricant. These films have great mechanical strength and are capable of supporting loads at least as great as 800 lb per sq in. Under such loads, the film thickness quickly reaches a constant minimum value which remains unchanged indefinitely even with continuous relative rotation of the surfaces.

The influence of the surfaces on the film manifests itself in what might be termed "directional rigidity," a property, which to the author's knowledge, has not been previously observed. As mentioned, the condition of constant minimum film thickness is indicated by constant torque at a given rpm, provided the rpm is above some minimum value. As long as the film is under continuous shear at a rate above this minimum, it behaves as a purely viscous liquid in the circumferential direction and the torque is proportional to the rpm. In the radial direction, however, the liquid exhibits remarkable plasticity or rigidity since, under heavy loads, it will not flow radially from between the surfaces. Building up of an apparently similar rigidity in the circumferential direction may be observed by stopping rotation and running at infrequent intervals only long enough for a torque observation to be made. The torque will increase rapidly at first and then more slowly, finally reaching an upper limit within 1 to 3 days. This upper limit will be several times greater than the constant torque when the film is free from circumferential rigidity. During the rigid stage, the film will resist considerable circumferential stress without appreciable deformation. If continuous rotation is again resumed, the circumferential rigidity will be gradually removed; the torque will decrease rapidly at first and then more slowly until finally the same constant value is reached when rigidity has entirely disappeared, thus indicating no change in film thickness. In any particular test this cycle may be repeated as often as desired.

Oils used in the earlier tests were rotated for periods up to 50 hr in a clinical centrifuge. A small ultracentrifuge, operating at extremely high speeds, was next constructed and used. In the later tests the samples of oil were removed by pipette from near the centers of containers that had remained undisturbed for several months. It may therefore be assumed that the oils were used in the same condition as commerically produced. Centrifuging of the oils made no apparent difference in test results.

Theoretical

Formulas for two plane, circular, parallel plates, approaching each other under the action of an external force and with the space between the plates filled with a viscous liquid, may be readily developed from Reynolds' (9) basic equation

$$\frac{\partial}{\partial x}\left(h^3\frac{\partial p}{\partial x}\right)+\frac{\partial}{\partial z}\left(h^3\frac{\partial p}{\partial z}\right)=6\mu\left\{(U_0-U_1)\frac{\partial h}{\partial x}+2V_1\right\}\quad[1]$$

Geometry of the surfaces is shown in Fig. 1. The notation used is as follows:

- a = radius of plane circular plates
- f = shear stress in liquid at surfaces of plates due to relative rotation
- f_r = shear stress in liquid at surfaces of plates due to radial pressure flow
- h = film thickness or uniform distance between parallel plates
- N = revolutions per unit time of rotating plate
- p = pressure at any point s in film above atmospheric or uniform ambient pressure
- r = radial distance from centers of surfaces to point s. Rectangular coordinates of s are x, z
- T = torque due to relative rotation of plates
- t = time required for any given decrease in film thickness
- U = $2\pi rN$ = linear velocity at s due to relative rotation of surfaces
- $U_0 - U_1$ = relative tangential velocity of surfaces
- V_1 = relative normal velocity of surfaces
- W = external load acting on surfaces
- μ = viscosity of the liquid between the surfaces; assumed constant and uniform.

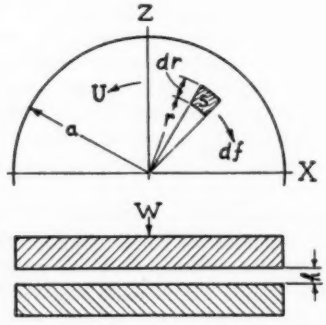

Fig. 1 Mathematical Notation; Plane Circular Plates

Since there is no relative tangential velocity of the surfaces in the case under consideration, $U_0 - U_1 = 0$; and, since the plates are parallel, there is no variation of film thickness; hence, $\partial h/\partial x = 0$. By definition $V_1 = dh/dt$; hence Equation [1] reduces to:

$$\frac{\partial^2 p}{\partial x^2}+\frac{\partial^2 p}{\partial z^2}=\frac{12\mu}{h^3}\frac{dh}{dt}$$

a solution of which is

$$p=\frac{3\mu}{h^3}\frac{dh}{dt}(x^2+z^2-a^2)\quad[2]$$

The pressures are symmetrical with respect to the centers of the plates; hence, the total load W will be four times the integrated pressure over each quarter. Therefore

$$W=\frac{12\mu}{h^3}\frac{dh}{dt}\int_0^a\int_0^{\sqrt{a^2-x^2}}(x^2+z^2-a^2)\,dx\,dz\quad[3]$$

Successive integration gives

$$W=-\frac{3\pi\mu a^4}{2h^3}\frac{dh}{dt}\quad[4]$$

and

$$t=\frac{3\pi\mu a^4}{4W}\left(\frac{1}{h_2^2}-\frac{1}{h_1^2}\right)\quad[5]$$

the time required for the surfaces to fall from h_1 to h_2. If h_2 is small compared with h_1, the initial film thickness may be neglected and Equation [5] becomes

$$t=\frac{3\pi\mu a^4}{4Wh^2}\quad[6]$$

from which

$$h=\frac{a^2}{2}\sqrt{\frac{3\pi\mu}{W}}\sqrt{\frac{1}{t}}\quad[7]$$

Equations [5] and [6] were first developed by Stefan (10) in his studies of the approach of plane, circular disks separated by a viscous liquid. Reynolds' Equation [1], published 12 years later is of great general utility since, in addition to the present case, it is also the basis of modern theoretical treatment of plane and cylindrical bearings.[3]

From (9) the shear stress at the surfaces of the plates, due to outward radial flow of the liquid, is

$$f_r=\frac{h}{2}\frac{dp}{dr}\quad[8]$$

and this stress will be the same on any radius passing through the common axis of the plates. Since $x^2 + z^2 = r^2$, we have from Equation [2]

$$\frac{dp}{dr}=\frac{6\mu}{h^3}\frac{dh}{dt}r$$

and from Equation [4]

$$\frac{dh}{dt}=-\frac{2h^3W}{3\pi\mu a^4}$$

Substituting in [8]

$$f_r=-\frac{2hWr}{\pi a^4}\quad[9]$$

the negative sign indicating that the shear stress opposes flow from between the surfaces. Since the shear stress is maximum when $r = a$

$$f_{r(\max)}=-\frac{2hW}{\pi a^2}\quad[10]$$

The film thickness may also be calculated by rotating one of the plates relative to the other at a known rate and measuring the required torque.

Referring to Fig. 1, the frictional drag opposing rotation at the differential area $2\pi r dr$ is df, and the moment is rdf. If N is expressed in revolutions per minute, the linear velocity U is $2\pi rN/60$. Then for a simple Newtonian liquid

$$df=\frac{2\pi\mu U r dr}{h}$$

[3] Reynolds' original paper contains many misprints, which unfortunately also appear in his "Collected Papers." His expression, similar to Equation [5], for the approach of parallel elliptical plates should have the coefficient 3/2 instead of 3.

and

$$r df = \frac{\pi^2 \mu N}{15h} r^3 dr$$

The total torque

$$T = \frac{\pi^2 \mu N}{15h} \int_0^a r^3 dr$$

from which

EXPERIMENTAL

I—The Disk Viscometer

The disk viscometer, shown in Fig. 2, was constructed to measure the rate of approach of two plane disks under conditions that would enable a comparison to be made with theory. It consists essentially of two disks A with plane surfaces and the balanced beam B, with a micrometer screw C to measure the movement of a pin fastened in the end of the beam. The upper plane is $^7/_8$ in. diam and is firmly attached to the upper bar D of the rugged steel frame by means of a fitting electrically insulated from the frame. The lower plane is $^3/_4$ in. diam and has a steel ball placed so that the lowest point on its surface is located as near as possible to the center of gravity of the disk. The ball rests on a plane support attached to the beam, thus locating the disk and permitting its plane surface to adjust itself to the upper plane. A thin-steel cup E is provided to prevent loss of liquid flowing from between the approaching surfaces. The beam is supported by the knife-edge F. Load is applied by the $^1/_{10}$-lb sliding weight G and may be varied by changing the position of the weight. When the weight is against the knife-edge fulcrum H, the center of gravity of the beam and all its parts is brought as close to the knife-edge as possible by adjustments of the counterweights J. The cam K is used to raise the loaded end of the beam, thus keeping the surfaces separated until the start of an experiment.

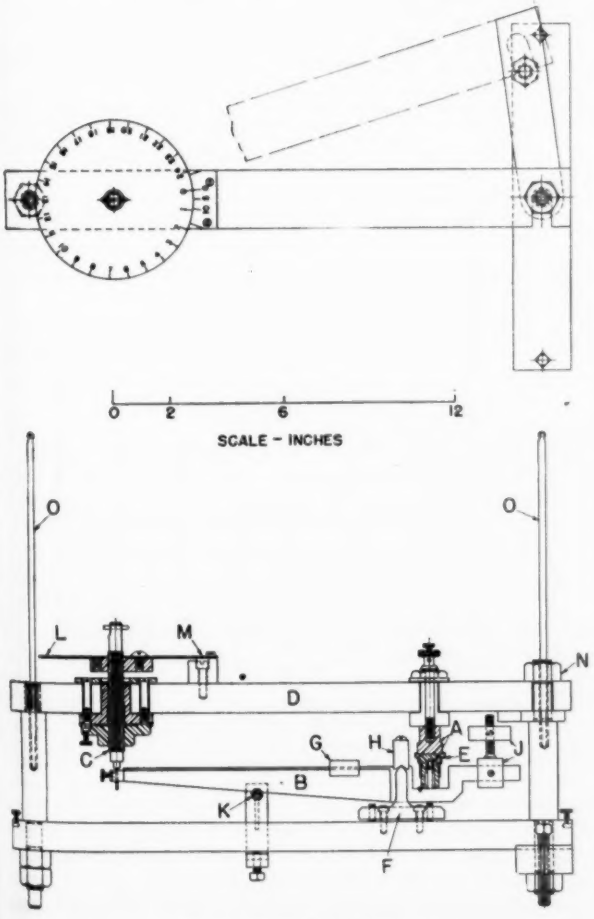

Fig. 2 Disk Viscometer

The micrometer-screw nut is fastened to the upper bar by four screws and electrically insulated with sheet mica. A lower nut is provided to eliminate lost motion in the screw. The micrometer screw is $^1/_2$ in. diam and carefully cut with 40 threads per in. Smooth operation is obtained by lapping the screw and nuts together. After assembly, the spindle in the end of the micrometer screw was lapped optically flat. A disk L, $5^1/_2$ in. diam and graduated into 25 equal numbered divisions, is attached to the upper end of the micrometer screw. Each division is subdivided into tenths and a vernier M is provided for reading to $^1/_{10}$ of each subdivision or $^1/_{100,000}$-in. vertical movement of the screw. The distance from the micrometer screw to the knife-edge is 10 times greater than the distance from the knife-edge to the center line of the plane disks. Each vernier division therefore represents a change in film thickness of one millionth of an inch. Contact between micrometer and beam is indicated by a milliammeter in a circuit closed when the micrometer spindle touches the pin in the beam. A similar circuit is provided to indicate contact between the plane surfaces. By loosening the frame nut N, the upper bar may be swung to one side permitting insertion of the lower disk or removal of the beam.

The viscometer is operated in a wooden box (not shown) covered with aluminum foil and heavy paper for heat insulation. Curtained inspection windows are fitted in the box and the necessary controls are provided for external operation of the instrument. The box is electrically heated by coils operated through a relay and a differential-expansion thermostat capable of holding the temperature constant to within 0.1 F. Viscometer temperatures are measured by thermometers O located in mercury wells in the vertical supports at each end of the instrument and also by a thermometer suspended in the atmosphere near the plane surfaces.

The plane disks were first made of normalized low-carbon steel and later a second pair was made of hardened tool steel. The surfaces were optically polished and flat to better than one millionth of an inch, including the edges. Turned edges were avoided by cementing the otherwise finished disk with beeswax in a ring about $2^1/_4$ in. diam made from the same bar of steel as the disk, and finishing the two as a single piece. The turned edge will then be on the ring and, if the diametral clearance between the disk and ring is of the order of 0.001 in., the plane surface of the disk will be continuous to its edge. After cementing the disks in the rings, the surfaces were ground flat, lapped on lead, and finally polished with optical rouge on pitch. Supports were then placed under the unpolished sides of the disks and the rings gently heated until melting of the beeswax permitted them to drop free, leaving the edges of the disks untouched.

Most of the difficulties encountered in polishing the surfaces to the required flatness proved to be simply questions of technique; eventually the point was reached where the scratching of a pair of surfaces, instead of actually threatening the success of the investigation, occasioned merely a relatively short interruption in the experimental program. However, researches for a

EXPERIMENTAL

I—The Disk Viscometer

The disk viscometer, shown in Fig. 2, was constructed to measure the rate of approach of two plane disks under conditions that would enable a comparison to be made with theory. It consists essentially of two disks *A* with plane surfaces and the balanced beam *B*, with a micrometer screw *C* to measure the movement of a pin fastened in the end of the beam. The upper plane is $^3/_8$ in. diam and is firmly attached to the upper bar *D* of the rugged steel frame by means of a fitting electrically insulated from the frame. The lower plane is $^3/_4$ in. diam and has a steel ball placed so that the lowest point on its surface is located as near as possible to the center of gravity of the disk. The ball rests on a plane support attached to the beam, thus locating the disk and permitting its plane surface to adjust itself to the upper plane. A thin-steel cup *E* is provided to prevent loss of liquid flowing from between the approaching surfaces. The beam is supported by the knife-edge *F*. Load is applied by the $^1/_{10}$-lb sliding weight *G* and may be varied by changing the position of the weight. When the weight is against the knife-edge fulcrum *H*, the center of gravity of the beam and all its parts is brought as close to the knife-edge as possible by adjustments of the counterweights *J*. The cam *K* is used to raise the loaded end of the beam, thus keeping the surfaces separated until the start of an experiment.

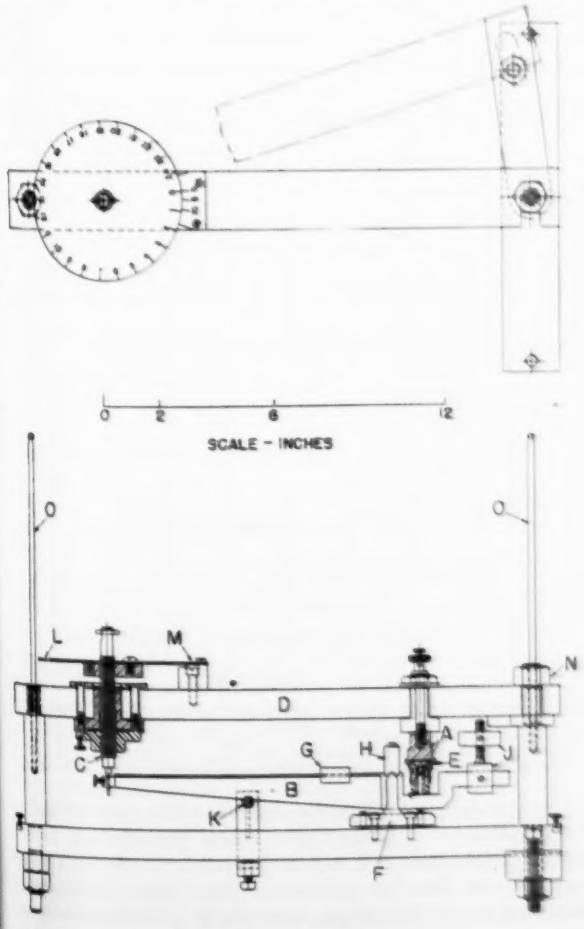

Fig. 2 Disk Viscometer

The micrometer-screw nut is fastened to the upper bar by four screws and electrically insulated with sheet mica. A lower nut is provided to eliminate lost motion in the screw. The micrometer screw is $^1/_2$ in. diam and carefully cut with 40 threads per in. Smooth operation is obtained by lapping the screw and nuts together. After assembly, the spindle in the end of the micrometer screw was lapped optically flat. A disk *L*, $5^1/_2$ in. diam and graduated into 25 equal numbered divisions, is attached to the upper end of the micrometer screw. Each division is subdivided into tenths and a vernier *M* is provided for reading to $^1/_{10}$ of each subdivision or $^1/_{100,000}$-in. vertical movement of the screw. The distance from the micrometer screw to the knife-edge is 10 times greater than the distance from the knife-edge to the center line of the plane disks. Each vernier division therefore represents a change in film thickness of one millionth of an inch. Contact between micrometer and beam is indicated by a milliammeter in a circuit closed when the micrometer spindle touches the pin in the beam. A similar circuit is provided to indicate contact between the plane surfaces. By loosening the frame nut *N*, the upper bar may be swung to one side permitting insertion of the lower disk or removal of the beam.

The viscometer is operated in a wooden box (not shown) covered with aluminum foil and heavy paper for heat insulation. Curtained inspection windows are fitted in the box and the necessary controls are provided for external operation of the instrument. The box is electrically heated by coils operated through a relay and a differential-expansion thermostat capable of holding the temperature constant to within 0.1 F. Viscometer temperatures are measured by thermometers *O* located in mercury wells in the vertical supports at each end of the instrument and also by a thermometer suspended in the atmosphere near the plane surfaces.

The plane disks were first made of normalized low-carbon steel and later a second pair was made of hardened tool steel. The surfaces were optically polished and flat to better than one millionth of an inch, including the edges. Turned edges were avoided by cementing the otherwise finished disk with beeswax in a ring about $2^1/_4$ in. diam made from the same bar of steel as the disk, and finishing the two as a single piece. The turned edge will then be on the ring and, if the diametral clearance between the disk and ring is of the order of 0.001 in., the plane surface of the disk will be continuous to its edge. After cementing the disks in the rings, the surfaces were ground flat, lapped on lead, and finally polished with optical rouge on pitch. Supports were then placed under the unpolished sides of the disks and the rings gently heated until melting of the beeswax permitted them to drop free, leaving the edges of the disks untouched.

Most of the difficulties encountered in polishing the surfaces to the required flatness proved to be simply questions of technique; eventually the point was reached where the scratching of a pair of surfaces, instead of actually threatening the success of the investigation, occasioned merely a relatively short interruption in the experimental program. However, researches for a

satisfactory metal of which to make the disks were not so successful. There appears to be no metal which, when polished and examined even under low powers of the microscope, will present a surface of uniform appearance even remotely approaching that of well-polished glass. The metal surfaces invariably contained pits or nonmetallic inclusions, iron carbides or traces of manganese in the form of gray spots with well-defined but irregular edges. At times traces of corrosion were also visible somewhat resembling nonmetallic inclusions. No one steel of good enough grade to be considered for optical flats is likely to contain all the above flaws, but, by the very nature of the constituents of steel and its method of production, nonhomogeneous structures are to be expected on any plane. Experience finally seemed to indicate that the best surfaces were produced by high-speed tool steel or a high-chrome tool steel. The chrome steel is corrosion-resistant and will hold its shape over long periods of time but it warps badly during the hardening process and is somewhat difficult to polish. High-speed tool steel gave the most uniform surface of all metals investigated, and it was therefore used in the later experiments.

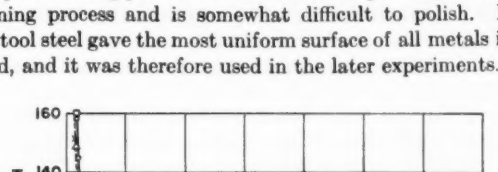

FIG. 3 APPROACH OF PLANE CIRCULAR PLATES; TESTS WITH CASTOR OIL

(Plates, 3/4 in. diam; oil temperature, 92.2 F; $\mu = 50.8(10)^{-6}$ lb sec per sq in.; load, 0.199 lb. The four tests were made under identical conditions.)

After polishing, the disks were prepared by washing with pads of absorbent cotton moistened with carbon tetrachloride. When all visible traces of contamination had been removed the disks were gently rubbed with dry absorbent cotton and finally touched with a fine camel's hair brush to remove any tiny pieces of lint left by the cotton or other contamination deposited from the air. The disks were then placed in the viscometer and the upper bar locked in position. Two carefully cleaned platinum wires approximately 0.001 in. diam were placed parallel across the lower plane approximately equidistant from its center. The beam was gently lowered until the surfaces were separated only by the wires. The box was then closed, outside operating attachments were connected, and the heat turned on.

When the temperature had reached the desired constant value, a micrometer reading was taken with the wires in place. If the diameter of the wires is known, it is then a simple matter to compute the micrometer zero, which is the micrometer reading when the disks are in actual contact. This seems to be the only practicable method of determining the zero reading. If the surfaces were brought together without the wires, a false reading would probably result due to possible surface contamination or to adsorbed air or moisture films on the surfaces. Attempts to obtain optical contact of the surfaces by wringing them together would doubtless result in scratches and would also introduce the problem of separation after the zero reading had been made. It is probable that the small-diameter wires cut through any adsorbed layers on the surfaces and came into actual contact with the metal. Assuming this to happen, it then became necessary to measure the diameters of the wires in order to establish

FIG. 4 APPROACH OF PLANE CIRCULAR PLATES; TESTS WITH OLIVE OIL

(Plates, 3/4 in. diam; oil temperature, 92.2 F; $\mu = 7.02(10)^{-6}$ lb sec per sq in.; load, 0.199 lb. The four tests were made under identical conditions.)

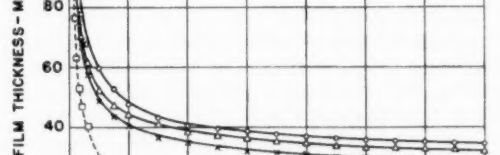

FIG. 5 APPROACH OF PLANE CIRCULAR PLATES; TEST WITH DTE LIGHT MINERAL OIL

(Plates, 3/4 in. diam; oil temperature, 92.3 F; $\mu = 5.23(10)^{-6}$ lb sec per sq in.; load 0.199 lb. The four tests were made under identical conditions.)

the micrometer zero. This was done by a filar micrometer used with a microscope. Many measurements were made at various magnifications with ordinary and monochromatic illumination and the wire diameter determined from these measurements. Assuming perfect microscopy, however, the limitations of the microscope would leave the final result open to an uncertainty of the

order of $^1/_2$ wave length of light and this is considerably greater than the film thicknesses it had been hoped to investigate.

After noting the zero reading, the micrometer screw was raised so that the beam could be lifted by the cam. The wires were then removed and oil introduced between the separated surfaces from a pipette. This was done with but slight temperature disturbance through a hole in the top of the box. When the temperature had again reached the constant value, the time was noted, the cam moved from beneath the beam, and the surfaces began to approach.

Observed rates of approach of the planes are compared with theory in Fig. 3 for the case of castor oil, and for olive oil and DTE light in Figs. 4 and 5, respectively. Calculations of rates of fall are based on the known bulk viscosities of the three oils and are shown by the broken lines. In general, the observed rates of approach are a fair approximation to theory but excepting the experiments with castor oil the film thicknesses at the end of 1 to 2 hr are found to be considerably greater than the calculated values. Satisfactory duplication of tests was found impossible, even though the lubricants were carefully centrifuged before using. After 8 hr, little if any reduction was observed in film thickness and, at the end of 24 hr, the film thickness was invariably found to have increased slightly above the reading at 8 hr. It is interesting to note that after a few hours the measured film thicknesses were of the same order regardless of the differences in bulk viscosities of the oils. Apparently the films were not behaving strictly according to theory. The probable causes of these discrepancies will appear from the results described under part II.

It was also observed that, when the films reached a thickness of approximately $(10)^{-4}$ in., they began to show indications of carrying current under a voltage of 0.025 volts. At thicknesses of about 60 $(10)^{-6}$ in., the resistance of the film had dropped to the point where it carried small currents as readily as the copper wire of the circuit, that is, the ammeter showed the same current flowing with and without the film in the circuit.

With loads of about 0.2 lb per sq in., the final film thicknesses were of the order of 30 to 40 millionths of an inch, subject to errors of approximately 10 millionths of an inch. Because of this high percentage of uncertainty, these figures are not entirely satisfactory. Nevertheless the above experiments indicate that there is some limiting film thickness reached by plane surfaces approaching under load. The limits of boundary lubrication placed by Hardy are considerably greater than those observed in the foregoing experiments.

II—Continuous Rotation

It is obvious from the results cited that loads much greater than a fraction of a lb per sq in. are required to bring the surfaces to within a few millionths of an inch of actual contact. The apparatus shown in Fig. 6 was therefore constructed and mounted in the same drill press used with the tapered-plug viscometer and the journal-bearing testing machine (11, 12). The lower disk A is located by the fitting B, and held against rotation by a set screw. This assembly is located by the ball bearing C and supported by the torsion rod D. Angular twist of D, measured by a graduated curved scale E, gives an accurate measure of the torque, due to rotation of the upper disk A'. The torsion rod is supported against buckling by a split bushing F set in a ball bearing to avoid binding at the support. The torque-indicating arm is counterbalanced by the weight G and vibrations of the arm are damped by a pan of oil H. At extremely low speeds, the movement of the indicating arm may be very small; hence a microscope has been found convenient for detecting minute deflections. The upper disk is held central and rotated by the sleeve J, the bore of which has been lapped to a close sliding fit on the spindle K. Load is applied by compression of the spring L which is held

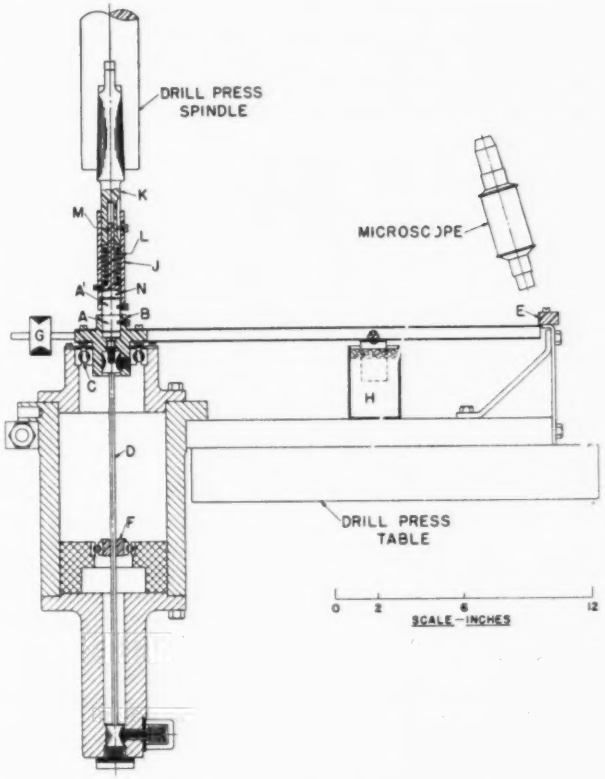

Fig. 6 Torsional Disk Viscometer

central by the plunger M. The lower surface of the plunger is hardened and ground flat to form a contact surface for the hardened conical point of the disk support N, thus providing for adjustment of the upper disk. Both plane disks are supported on annular rings, turned on the backs of the supports. Assuming a parabolic pressure distribution in the oil film, the diameter of the ring is such as to provide support at a point directly under the center of gravity of each radial half section of the parabola. The spindle K is fitted into the drill-press spindle in the usual manner and electrically insulated by paper.

The drill press is driven by a $7^1/_2$-hp, 1200-rpm synchronous motor through a chain-and-change-gear transmission. Friction clutches are provided for starting, stopping, and reversing. An independent drive for low speeds is furnished by a small synchronous motor through a speed reducer. Speeds as low as 0.0016 rpm are thus obtained. The loading springs were calibrated in position and the spindle graduated at the top of the sleeve. A spring is provided to cover the range up to 100 lb per sq in.; a second spring is used for loads from 100 to 400 lb per sq in.; and the heaviest spring possible with the present apparatus gives loads up to 800 lb per sq in.

The hardened plane disks, $^7/_8$-in. diam, were prepared as previously described, except that the final polish was made on lead instead of pitch. After cleaning, they were covered with a heavy film of oil, placed in the machine, and brought together until the oil formed a single film approximately $^1/_{16}$ in. thick. At zero time, rotation was begun and load applied. Almost immediately most of the oil was pressed from between the surfaces, forming a thick ring around the edge of the film as shown in Fig. 7; thus protecting the film from external contamination. The meniscus of this ring introduced a slight negative pressure at the edge of the film.

Assuming that the plane disks remain coaxial, it may be assumed that the rate of approach is independent of relative rota-

tion. A test was therefore made with olive oil at a load of 100 lb per sq in. with the upper surface continuously rotating at 11.06 rpm. Results of the test are shown in Fig. 8. The broken line represents torque calculated on the basis that the planes are approaching at the rate indicated by Equation [7], and the circled

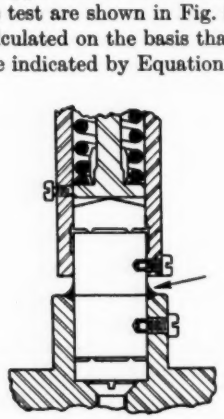

FIG. 7 OIL MENISCUS AT EDGES OF PLANE DISKS; TORSIONAL DISK VISCOMETER

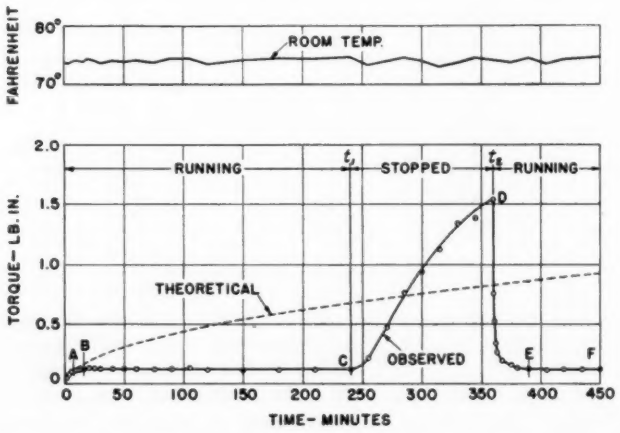

FIG. 8 TEST WITH OLIVE OIL; TORSIONAL DISK VISCOMETER
(Plane disks, 3/8 in. diam; 11.06 rpm; load, 100 lb per sq in.; average temperature, 77 F; $\mu = 10.1(10)^{-6}$ lb sec per sq in.)

points are actual torque observations. During the first 8 min, over the range *OA*, the observed torque agrees with theory. This indicates that, while the film is relatively thick, the rate of approach is the same as calculated. It is interesting to note, however, that after 16 min the torque becomes constant over the range *BC*, showing that the film thickness has reached a minimum value and approach of the surfaces has ceased. If rotation is stopped at time t_1 and resumed at stated intervals only long enough to take a torque observation, it will be found that the torque is progressively increasing. After rotation has been stopped for some time, it will also be found that a slight angular movement of the upper test surface will move the torque indicator from zero and it will not return, thus showing rigidity in the film. That the rigidity increases is shown by the continuous increase in torque with time over the range *CD*. If at time t_2, continuous rotation is resumed, the torque will drop rapidly at first and then more slowly until the previous constant value is reached at *E*. Rotation may be continued indefinitely over the range *EF* with no variation in torque, unless there is a change in film viscosity, due to variation of room temperature.

Fig. 9 shows the results of a continuous run of 52 hr with olive oil at 11.06 rpm and 40 lb per sq in. load, followed by periods of building up and removal of rigidity. Observations of torque versus speed at any time during the constant-torque period fall on a straight line passing through the origin, provided the speed range is low enough to avoid frictional heating of the film. Fig. 10 shows such a curve taken at 50 hr in the test shown by Fig. 9. When rigidity has not been entirely removed by rotation, the torque-speed curve may be a straight line or a curve which, at zero speed, gives a value of torque proportional to the rigidity. It is obvious that torque observations with rigidity present will not be consistent since shear reduces rigidity, thus reducing the torque. There is, however, some minimum speed below which rigidity will not be entirely removed. No attempts were made to discover this limiting speed, but it was observed with olive oil at 40 lb per sq in. load that rigidity would build up very slowly indeed at 0.9 rpm.

After these tests the surfaces appeared to be exactly the same as at the start. There were no traces of scratching or metallic contact even at high magnifications. The first indication that the film will carry small electrical currents occurs at calculated film thicknesses of about $(10)^{-4}$ in. Before constant-torque conditions are reached, the circuit with the film in series carries the same current as when the film is short circuited by a copper wire. Rigidity does not appear to influence the resistance of the film.

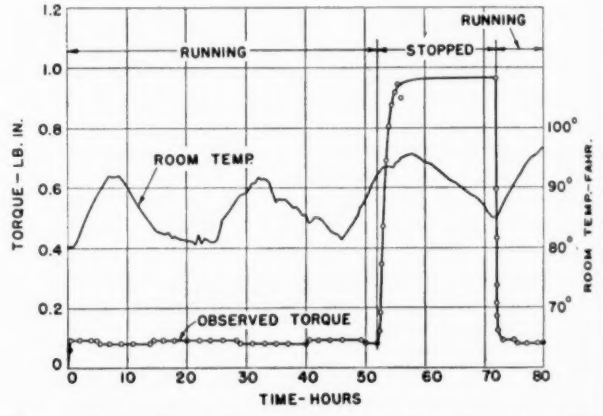

FIG. 9 EIGHTY-HOUR TEST WITH OLIVE OIL; TORSIONAL DISK VISCOMETER
(Plane disks, 3/8 in. diam; 11.06 rmp; load, 40 lb per sq in.; average temperature, 87.9 F; $\mu = 7.80(10)^{-6}$ lb sec per sq in.)

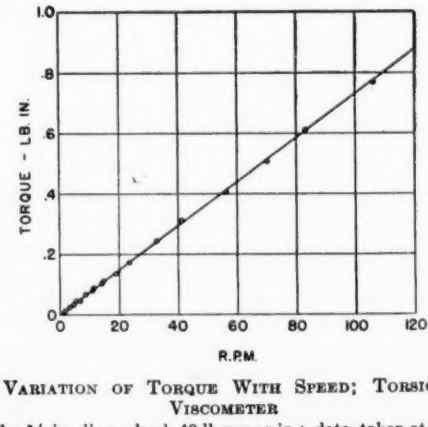

FIG. 10 VARIATION OF TORQUE WITH SPEED; TORSIONAL DISK VISCOMETER
(Plane disks, 3/8 in. diam; load, 40 lb per sq in.; data taken at 50 hr in test shown in Fig. 9.)

Previous reference has been made to the excess oil from the very thick starting film, flowing out under the applied load and forming a seal around the edge of the film. The meniscus of this seal is in such direction as to cause a slight tension at the edge of the film. This is of little importance except to point out that

there is no pressure restricting flow; in fact, the results are the same if all excess oil is removed.

To measure the final film thickness a $^3/_{32}$-in-diam pin with a spherical babbitt tip was fitted into a hole in the lower disk, as shown in Fig. 11. The descending upper plane forces the pin into the hole and the height of its tip above the lower plane is measured after the test by counting the interference fringes (13) between the surface and a small optical flat in intimate contact with an edge of the plane surface and the pin. Film thicknesses thus measured after tests with several oils at loads up to 800 lb per sq in. are shown in Fig. 12. For example, with Atlantic superheat cylinder oil and a load of 300 lb per sq in., the torque reached

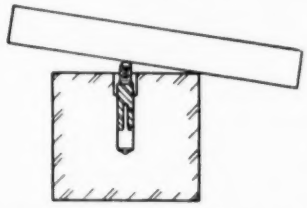

FIG. 11 PIN METHOD OF MEASURING MINIMUM FILM THICKNESS

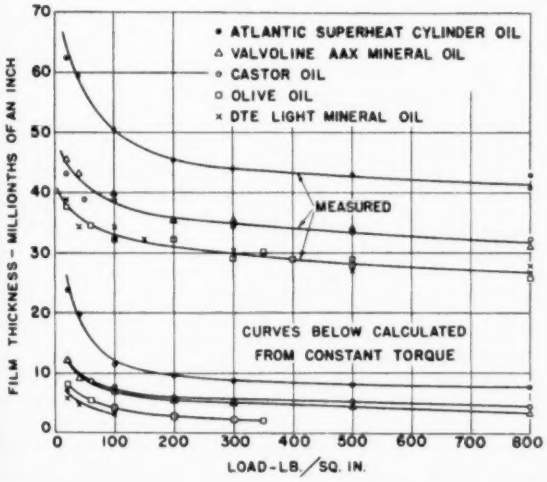

FIG. 12 MEASURED AND CALCULATED MINIMUM FILM THICKNESS WITH VARIOUS OILS; TORSIONAL-DISK VISCOMETER

(Plane disks, $^7/_8$ in. diam; 11.06 rpm. Atlantic superheat cylinder oil; average temperature, 72.4 F; $\mu = 670(10)^{-6}$ lb sec per sq in. Valvoline AAX mineral oil: average temperature, 71.2 F; $\mu = 113(10)^{-6}$ lb sec per sq in. Castor oil: average temperature, 72.2 F; $\mu = 115(10)^{-6}$ lb sec per sq in. Olive oil: average temperature, 73.6 F; $\mu = 11.04(10)^{-6}$ lb sec per sq in. DTE light mineral oil: average temperature, 72.4 F; $\mu = 9.42(10)^{-6}$ lb sec per sq in.)

a steady condition one hour after the load was applied and remained constant during the next hour. The test was then discontinued, the surfaces separated, washed with carbon tetrachloride and finally with alcohol. The optical flat showed the central pin to be $44(10)^{-6}$ in. high and this is the final constant film thickness under the test conditions. From the known bulk viscosity of the oil and the observed torque, the calculated film thickness from Equation [11] is found to be $8.8(10)^{-6}$ in. Variation of speed shows the torque to be directly proportional to the speed and there is no rigidity in the film in the direction of motion as long as rotation is continued. The lubricant is therefore behaving as a purely viscous fluid in so far as the direction of rotation is concerned. From the observed torque and the measured film thickness, the effective viscosity in the direction of motion has been increased 44/8.8 or five times the ordinary bulk viscosity. In the radial direction, however, the effective viscosity has been apparently increased to infinity, since no oil will flow from the film $44(10)^{-6}$ in. in thickness supporting a load of 300 lb per sq in. This may be explained by the fact that rigidity will build up unless the rate of shear is above some critical value. The speed of rotation is sufficient to prevent the formation of rigidity in the direction of motion except perhaps to a small distance from the center. The rate of shear in the radial direction, however, is due to radial oil flow only and this decreases as the surfaces approach. Apparently when the rate of shear in the radial direction falls below the critical value, rigidity rapidly builds up, thus stopping further radial flow from the film. The surfaces are therefore unable to approach and a minimum film thickness is established.

Preparations for the foregoing tests were made under ordinary room conditions; hence, we may not exclude the possibility of contamination from the atmosphere. It is also probable that the commercial lubricants used were not chemically clean. A mass of particles of undefined nature would hold the surfaces apart, but the experimental evidence is against this possibility. If the particles were hard enough to hold the surfaces a definite distance apart the intensity of pressure on the larger particles undoubtedly would be great enough to cause scratching. If the particles were soft enough to change shape under load, they would also be expected to break down under continuous motion and permit closer approach of the surfaces. This would be evidenced by increasing torque. The presence of particles would also tend to increase friction to values well above those observed. Probably the most convincing argument against surface separation by foreign particles is the fact that, immediately after rotation has ceased and before rigidity has become appreciable, if the torque indicator is moved from its zero position, it will immediately spring back. This would be impossible if the surfaces were separated by particles under sufficient pressure to support the load. It seems beyond question that the surfaces are not held apart by particles in the film and any particles present must be smaller than the distance between the surfaces.

The fact that time is required to build up rigidity in the film and time is also required to remove it by motion suggests molecular rearrangements in the film. In such cases, it is reasonable to expect that both building-up and tearing-down actions would be rapid at first and then proceed more slowly as constant conditions are approached. Torque observations indicate that some such phenomenon actually occurs. It would also be expected that the building up and removal of rigidity would be more rapid in the less viscous fluids where molecular motion is more free. This is also observed to be the case. But the less viscous the oil the thinner the film under a given load, and presumably surface influence would become more pronounced as the film thickness is reduced.

Referring again to Fig. 12, the calculated values of film thickness were based on the known bulk viscosity of the oil and the constant torque along the range *BC* or *EF* of the curve in Fig. 8. At loads up to 350 lb per sq in., constant-torque conditions with olive oil were reached in which the friction coefficients were of the order of 0.007. At loads above 350 lb per sq in. with olive oil, and above 100 lb per sq in. with DTE light, no constant-torque conditions could be found. For the first few minutes of the test, the torque followed the theoretical law and then gradually increased to comparatively high values where it remained unsteady, fluctuating between values giving friction coefficients from 0.15 to 0.30. Measured film thicknesses under these conditions, however, fell on a smooth curve consistent with previous measurements at lower loads and constant-torque conditions. It is interesting to note that lard oil, which has about the same viscosity as olive oil, carried a load of 800 lb per sq in. under constant-torque conditions. Oleic acid and a mineral oil of somewhat higher viscosity than DTE light also carried the 800-lb per sq in.

load under constant-torque conditions. This is also true of white Russian mineral oil, the latter presumably nonpolar. Addition of 2 per cent of an ester of phosphoric acid to the above mineral oil made no difference whatever in torque or final film thickness.

Upon separation of the surfaces after a test under constant-torque conditions, the residual films appeared to be evenly spread over the entire area and of variable color depending somewhat upon the angle of view. Immediately after separation, castor- and olive-oil films showed the effects of surface tension by drawing up into tiny circular droplets. These arranged themselves in a geometrical pattern not unlike honeycomb but lacking its regularity of shape. About 10 min were required for the complete formation of the pattern. The final appearance was that of a piece of spider web dropped over the surface. Russian

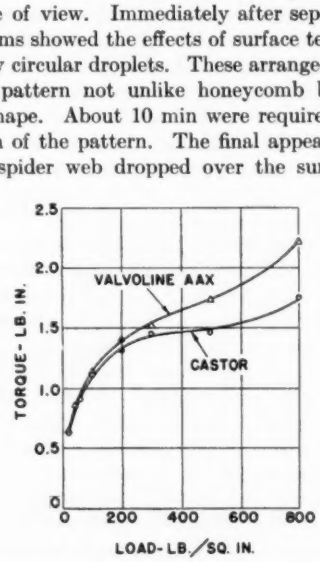

FIG. 13 VARIATION WITH LOAD OF CONSTANT TORQUE AT A GIVEN LOAD; TORSIONAL DISK VISCOMETER
(Plane disks, 7/8 in. diam; 11.06 rpm; $\mu = 115(10)^{-6}$ lb sec per sq in.)

mineral oil and lard oil displayed similar tendencies. The pattern formed by oleic-acid film was much finer than the others and much more rapidly arranged. The commercial mineral lubricating oils showed no similar tendencies; the residual films remaining fixed in the presence of air and thoroughly wetting the surfaces.

In tests with olive oil at the heavier loads, where no constant-torque conditions could be found, the forces set up by rotation were strong enough to tear the films away from the surfaces and break them up into tiny white fragments. These fragments were so small that in some cases the separated surfaces had the appearance of being streaked with paraffin wax. At high magnification, the tiny white fragments were seen to be spots of oil exhibiting characteristic color fringes at their edges, but instead of being spherical segments like the droplets formed by surface tension, they were of irregular shapes with three to eight sides. Generally some round droplets were also present. Even though the film had broken up, the surfaces invariably showed no signs of scratching or wear. Apparently metallic contact had not occurred even though the friction coefficients were as high as would be expected with unlubricated surfaces. Similar tests with DTE light mineral oil generally resulted in faintly scratched surfaces or circular bands visible because of a higher polish than the remainder of the surfaces. Apparently the mineral oil was not as clean as the olive oil and the particles present were hard enough to scratch in the former case and soft enough to give a polishing effect in the latter. The films showed no tendency to break away from the metal as in the case with the olive oil.

Since the ordinary bulk viscosities of castor oil and Valvoline AAX are closely the same at the test temperature, and the measured film thicknesses are about the same, it would be expected that the same torque would be found at the same loads and speeds with the two oils. From Fig. 13 this is seen to be true at low loads but, as the load is increased, the mineral oil gives greater friction than castor oil. At 800 lb per sq in. the friction with the mineral oil is approximately 27 per cent above that with castor oil. Increased viscosity due to film pressure (12) would account for about 8 per cent greater friction with the mineral oil. Corrections have been made for the slight differences in room temperature at which the various tests were made.

DISCUSSION AND CONCLUSION

Results of part I indicate that under very light loads a minimum film thickness is reached which is about 30 to 40 millionths of an inch. The order of these measurements is substantiated by the direct measurement at heavier loads described in part II. It now appears that the apparent increase in film thickness observed overnight in part I might possibly be due to the building up of film rigidity. From the results of part I, it appears that, at film thicknesses of about $(10)^{-4}$ in., the electrical resistivity of the film began to decrease. At thicknesses of about $60(10)^{-6}$ in. the film carried small currents as readily as the copper wire in the circuit. This also agrees with similar observations in part II.

The comparatively simple technique of the experiments described in part II and the ease with which results may be reproduced, offer an attractive method for further study of friction in thin films. The method is free from the complications and uncertainties introduced by abrasion and wear. An improved method of measuring film thickness is desirable.

It has been shown that, when two optically smooth plane steel surfaces are brought together in the presence of oil in such manner that the formation of a parallel film is possible, the distance between the surfaces will reach some definite minimum value depending upon the viscosity of the oil and the external force acting upon the surfaces. At room temperature, with surfaces 7/8 in. diam, this minimum film thickness varies from about $30(10)^{-6}$ in. with olive oil to about $60(10)^{-6}$ in. with a heavy cylinder oil. The minimum film thickness is not greatly changed by loads up to 800 lb per sq in. of surface area.

The nature of this separating film is not known but experimental evidence indicates that the proximity of the metal surfaces has a profound influence upon the forces normally acting between the molecules of the liquid. This gives the film a high degree of mechanical stability, as evidenced by its ability to support considerable load without radial flow. The film also assumes the curious property of directional rigidity which seems to depend upon the direction, rate, and duration of shear.

At the present time there is no direct experimental evidence that rigidity is due to oriented molecules. But the rate at which rigidity builds up and the rate at which it is removed by shear points to the possibility of molecular rearrangement. If molecular orientation is due to surface influence it would be expected that the plane of least influence would be midway between the surfaces. The molecules at the center would be the first dislodged by shear thus causing a rapid reduction in friction. Resistance to dislodgment would increase with each molecular layer removed since the orientating forces would become stronger as the surfaces are approached. This would be evidenced by a decrease in the rate of torque reduction. Eventually a level would be reached where the orientating forces holding the molecules in place would be sufficiently strong to balance the shearing forces and dislodgment of molecules would cease; hence, the observed condition of constant torque at calculated film thicknesses well below the actual distances between the surfaces.

From the foregoing may be visualized a film composed of a fixed layer or layers of molecules firmly attached to each surface, and a central layer in which the molecules are kept free of surface influence by continuous shear. The central layer is there-

fore in the same molecular state as the liquid in bulk as far as the circumferential direction is concerned. Direct experimental proof of the existence of rigidity in the radial direction is lacking. But the fact is that, if the liquid in the central part of the film is free, as indicated by absence of circumferential rigidity, it does not flow radially under the external load. Hence, there must be some restraining radial force.

It was found that at loads above 350 lb per sq in. with olive oil and above 100 lb per sq in. with DTE light, no constant low-torque conditions could be established at 11.06 rpm. It would be interesting to investigate the effect of speed on these limiting loads. In fact, an explanation of the breaking up of films under loads too great to permit constant low-torque conditions would be most interesting indeed.

Liquids other than lubricants should be investigated for film-forming characteristics. Olive oil and DTE light should be highly filtered and the experiments repeated. Filtering should be done by the methods employed by Bulkley and also by centrifugal methods, since there is a possibility that Bulkley's methods might remove the components responsible for rigidity. It would also be interesting to discover if the diameter of the plane surfaces has any influence on final film thickness.

Finally, a study of polished metal surfaces would undoubtedly result in improved methods of producing smoother and truer finishes.

Acknowledgments

This study was made possible through Dr. Kingsbury's generous interest in the fundamental problems of lubrication. The author feels himself most fortunate in having his advice and encouragement during the entire course of the study, as well as his active leadership during its earlier stages. Constructive criticism of the manuscript by Mayo D. Hersey is also greatly appreciated.

Discussion

C. H. Bierbaum.[4] After reading the paper, the thought seems to persist that the oils tested were oxidized, at least so in a limited degree and that, therefore, the researches of Langmuir[5] seem to have a direct bearing. His findings are that the oil molecules are columnar in form and that, in the oxidizing process, one end remains hydrophobic and the other end to which the oxygen is attached becomes hydrophilic or metallophilic, so that these molecules will orient themselves perpendicularly upon a metal surface.

It was the writer's observation that by oxidizing an ordinary motor oil by bubbling pure dry air through it at the temperature of boiling water, for say 2 hr, the ultimate load-carrying capacity of this oil was increased by more than 4000 lb per sq in. of projected bearing area. This effect seems entirely due to the increased tenacity with which the oriented oil molecules attached themselves to the metal surfaces, an adsorbed effect.

Oils oxidized in the foregoing manner have a distinctly corrosive[6] action, in varying degrees, upon the different metals ordinarily used for bearing purposes. It seems safe to assume that the chemical affinity of such modified oils is greater for the more corrosive materials than for the less corrosive; as an illustration, silver, a more noble metal, is not corroded in this manner, which is one reason why in the pure state it has not given a better account of itself for bearing purposes.

Fortunately, it has been found that the full benefit of this oxidizing of oils can be taken advantage of without having the deleterious corrosive effect and, at the same time, be made into a positive inhibitor of corrosion, by the elimination of the corrosive by-product.

It would be interesting to know whether any oxidized oil molecules were present in the tests described in the paper; especially so with the mineral oils, since "the residual film remained fixed in the presence of air and thoroughly wetted the surfaces." Very interesting results can be expected in future tests with different materials for the two bearing surfaces.

The electrical conductivity of the film seems in keeping with the experience in the breaking down of polarized oil in electric transformers, a strong suggestion that oxidized molecules were present.

The fact that the addition of 2 per cent of ester of phosphoric acid had no effect either on the torque or film thickness in the experiments described seems in itself unaccountable, except for the possible presence of an oxidized oil film. The results seem to show that boundary film lubrication may be divorced completely from the properties of the lubricant as a whole.

High-power photomicrographs of the bearing surfaces before and after the tests would have been desirable.

Mr. Needs is certainly to be congratulated upon the accuracy and refinement of his tests. His paper shows distinct progress on the subject of lubrication.

thicknesses shown in Fig. 12 of the paper is attractive, but not wholly convincing. We should expect the extent to which the molecules were detached from their static positions to be dependent upon the force with which they were held, and upon the distorting force applied to them. This latter will in turn be proportional to the rate of shear at the boundaries of the active portion of the film. If we assume that the viscosity of the oil in the active portion is the same as that of the oil in bulk, we may then take the distorting force as inversely proportional to the ordinates of the curves of calculated film thickness. It would be greatest at heavy loads and least at light loads. We should, therefore, expect the static, oriented portions to be thickest at the light loads and thinnest at the heavy.

An examination of the curves shows that this is true. The difference between the measured and calculated thicknesses, which we may take as representing twice the thickness of the oriented, static layer, is greatest at the light loads and least at the heavy. We should, however, expect the orientation to be more vigorous with a substance which is decidedly unsymmetrical in molecular structure, than one with greater symmetry.

The observations recorded in Fig. 12, do not sustain this expectation, for curves for Valvoline, a mineral oil and castor oil are almost identical, while that for Atlantic superheat cylinder oil shows a markedly greater difference between the measured and calculated thicknesses. Apparently viscosity is still associated in some way with these phenomena.

Figs. 8 and 9, showing marked increases in the torque if the apparatus is allowed to stand, suggest that the orientation takes time to form, but that it breaks down quite rapidly.

F. J. Villforth and the writer repeated the stop-and-start experiments, using a tapered-plug viscometer and olive oil. Clearances much greater than those mentioned in the paper were employed, in order to get some idea of the distance to which these surface effects were felt.

With a clearance of 0.0055 in. an increase in torque of about 10 per cent was found when the apparatus was allowed to stand for several hours. When the clearance was reduced to 0.0033 in. the increase was found to be about 20 per cent. A further reduction to 0.00164 in. raised the increase to about 25 per cent. These results were obtained with rates of shear of 786, 978, and 1950 reciprocal sec, respectively. There was also some indication that after a rest the torque first increased and then decreased to a value below that at the start.

If the foregoing results can be validated by subsequent and more extensive experimental work, they would indicate that surface effects extend to distances which are truly enormous in terms of molecular dimensions.

RONALD BULKLEY.[8] The methods of test described in this paper are refreshingly novel and possess great possibilities for the further elucidation of thin-film phenomena. In attacking related problems in the past, several investigators have drawn conclusions regarding the nature of liquid films as close as a few millionths of an inch to a solid wall, but in most cases their actual experiments have been made on films whose thickness has been perhaps 200 times this amount. Now, the author has been able to work with actual films only 0.00002 or 0.00003 in. in thickness and truly this is a great stride forward in the art of thin-fiim experimentation. His conclusions, however, are not in accord either with classical theory or with the conclusions of several previous experimenters in the field.

The concept of long-range forces which increase the viscosity of liquids out to distances of 0.0001 in. or more was championed 15 or 20 years ago by Sir Wm. B. Hardy. In 1922, Wilson and Barnard published experiments purporting to show that oily liquids of polar characteristics, e.g., oleic acid, could be solidified by these forces clear out to distances of 0.005 or 0.006 in. from a solid wall. For 8 or 10 years these results were accepted and widely quoted by many lubrication engineers. Orthodox physicists and chemists pointed out, however, that on the basis of their theoretical calculations, molecular influence can extend outward to not more than about 0.0000005 in.

In 1931, the writer repeated Wilson and Barnard's experiments and discovered that the clogging of capillaries which they attributed to solidification of the liquid was due to lint and foreign matter in the oil. In the same year two of Hardy's own students, Bastow and Bowden, published a paper,[9] giving the same explanation for Hardy's anomalous long-range results, namely, dust and lint in the liquid. In a paper 2 or 3 years later, the same men described viscosity experiments conducted in an apparatus not too different from the author's disk viscometer. These experiments completely confirmed the writer's earlier work, indicating, as he had claimed, that no rigid layer existed on a solid wall out to distances greater than 0.000001 or 0.000002 in.

It is difficult indeed to reconcile these results with those now found by the author. Another difficulty arises from the fact that even Hardy and Wilson and Barnard did not postulate or find any orientating influence for ordinary hydrocarbons or pure petroleum oils, but only for polar materials or materials possessing good oiliness, such as lard oil or oleic acid. The author, however, finds just as pronounced an effect for a mineral oil as for castor oil and olive oil.

Moreover, his conclusions do not seem always to be justified by the data he presents. For example, of the 12 runs he made on 3 oils in the disk viscometer, 5 agreed closely with the theoretical curves. The other 7 were wide of the theoretical curves and the author notes as a general comment that "satisfactory duplication of tests was found impossible." Yet notwithstanding the narrow margin between the number of curves which did and those which did not agree with theory he concludes, contrary to theory, that "the above experiments indicate that there is some limiting film thickness reached by plane surfaces approaching under load." He places the thickness of the limiting film reached under these conditions at about 0.00003 or 0.00004 in.

In the second viscometer, much higher loads are used and the limiting film thickness is, therefore, reached in a much shorter time. The thickness of the film, however, is substantially the same as in the first viscometer, notwithstanding the fact that the loads may be some 4000 times as great. It is hard to imagine what kind of material the oil has been converted into in this relatively thick layer to permit the layer to remain as thick under 800 lb per sq in. attempting to squeeze the oil out as under only 0.2 lb per sq in. The picture the author draws calls for the intensification of viscosity to be greatest at the wall where the forces are greatest and to diminish as the distance from the wall is increased until at last out in mid-stream, 0.000015 or 0.00002 in. away, the viscosity is the normal bulk viscosity. Would we not expect heavy loads to squeeze out more of these partially solidified layers than light loads and thus to give a thinner film? Maybe we could not expect the light load to give a film 4000 times as thick as the load which is 4000 times as great, but should we not expect the film under the light load to be, say, 1000 times as thick or maybe 100 times as thick or at least 10 times as thick? In the author's experiments, the films are of the same thickness regardless of load. This seems to suggest some limitation, not yet discovered, inherent in his apparatus or method

[9] "On the Contact of Smooth Surfaces," by S. H. Bastow and F. P. Bowden, *Proceedings* of the Royal Society, vol. 134, 1931, pp. 404–413.

of experimentation which leads him to erroneous conclusions.

Failing, to date, to find any such limiting conditions, the author's only other recourse, naturally, has been to invent a new concept to explain his data. This has taken the form of a layer of material some 500 or 1000 molecular lengths in thickness which possesses the surprising property of being a solid in one direction and a simple viscous liquid at the same time in another direction.

Regarding this revolutionary concept of directional rigidity, it should be observed that every investigator has a right to invent new concepts when his data are incapable of explanation in terms of old concepts. The author has found it necessary to invent the concept of directional rigidity in liquids which up till now have been regarded as possessing uniform properties in all directions. Until some one can explain his results in a more simple or more conventional manner his new concept must stand.

J. R. CONNELLY.[10] The first part of this discussion will deal with specific matters mentioned in the paper and the second will be a brief statement concerning some of the larger questions in the field in which this investigation exists. In the course of the writer's comments some questions will be raised that cannot be answered and some techniques of the author questioned where an improvement cannot be suggested at present. The specific discussion follows:

1 The method of indicating contact between the micrometer and the beam is open to question because of the possible unevaluated constant and variable errors. The writer and his associates have struggled with this problem for some years and do not feel they have a satisfactory solution, although this method has been tried.

2 Which results were obtained using normalized low-carbon steel and which using hardened tool steel? It is often contended that a low-carbon steel, work-polished against a soft bearing, will react differently from a hardened tool steel which is not work-polished. It seems that some future investigation by this method should endeavor to compare a work-polished (probably burnished is a better term) low-carbon steel with a hardened tool steel. It might also be worth while to prepare two highly polished flat glass disks, since the surfaces exposed would not furnish recesses for the lubricant.

3 In the section devoted to disk-viscometer experiments the author mentions that "satisfactory duplication of results was found impossible." For the castor oil, the variability of results is explainable and, for the olive oil, the extreme variation of one determination is more of quantity than kind. However, in the case of the DTE light mineral oil, it may be said that agreeing data are definitely in the minority. It raises the question of whether all the variables are under even approximate control.

4 In Fig. 10, the author shows a plot of torque taken during the constant-torque period, against rpm. In discussing this plot, the statement is made that the relation is a straight line passing through the origin, provided the speed range is low enough to avoid frictional heating of the film. Now the writer does not wish to contend whether the relation is a straight line or not but to infer that a rotative speed of 100 rpm does not produce frictional heating of the oil film seems far-fetched indeed. Some other explanation would be more satisfactory.

In discussing the method used in the investigation, the author states that it "is free from the complications and uncertainties introduced by abrasion and wear." This statement is true as far as it goes, but to it could be correctly added, "and gives no information on abrasion and wear."

[10] Assoc. Professor, Industrial Engineering, Lehigh University, Bethlehem, Pa. Mem. A.S.M.E.

It would seem that our knowledge has advanced to a state where we can recognize a number of different classes of conditions in bearing operation, as follows:

Class A dry rubbing contact, resulting in reduction of contact surfaces (abrasion).

Class B rubbing contact in the presence of a lubricant, resulting in reduction of contact surfaces (wear).

Class C relatively thin film separating the surfaces (present paper).

Class D relatively thick film separating the surfaces (hydrodynamic theory).

The term boundary film or boundary lubrication would seem to apply to both classes B and C in the sense that they are intermediate between dry-rubbing and thick-film lubrication. For purposes of study it would seem wise, however, to keep these classes separate in our thinking since the variables give evidence of being quite different.

M. D. HERSEY.[11] While a variety of new phenomena are reported in these experiments, they can be harmonized somewhat by noticing the close analogy which they bear to the more familiar phenomena of plastic deformation in everyday tests of greases, and many other types of plastic material, particularly materials that are strongly thixotropic. This analogy might be made more complete if the author could supply a typical curve for torque against speed, taken during the recovery period after rigidity has set in.

It would seem that the possibility has not been entirely ruled out that the observations may, in part, be explained as due to a slight degree of plasticity caused by suspended particles; not necessarily foreign particles. Such plasticity might be present in commercial oils without becoming noticeable until the film is sufficiently thin.

Two experiments might be suggested for the future: (1) Repetition of some of the rotation tests, substituting annular surfaces to simplify the mathematical analysis; and (2) observations of thixotropy of any convenient plastic material in bulk to see if the properties in one direction are influenced by motion at right angles.

G. B. KARELITZ.[12] The work reported in this paper is so extraordinary that one is tempted to look for signs of experimental error. It seems, however, that none of the measurements or techniques can be objected to. Yet it is difficult to believe that the influence of steel on oil molecules would penetrate to a depth of 0.00002 to 0.00003 in. It would mean that the effect of the contact surface may be felt at a distance of 200 to 500 molecular dimensions from the steel surface. In a number of experimental bearings, such as tested by McKee at the Bureau of Standards, the minimum film thickness was of the order considered in the paper, 40×10^{-6} to 60×10^{-6} in. It appears that these bearings should have shown a high coefficient of friction, but they did not. It may be that the agitation in an actual bearing, together with higher speed, would prevent the stratification of the lubricant into an orientated layer.

If the orientation of the molecules extends that far into the film, the several layers near the metal surface must be lined up rather well. It should then be comparatively easy to detect this quasi-crystalline structure by X rays, if pyrex-glass disks are used instead of steel. Reasonably flat disks could be pressed together, with an oil film trapped between them and a pencil of X rays played through the assembly. Of course, it may be that

[11] Research Director, Morgan Construction Company, Worcester, Mass. Mem. A.S.M.E.

[12] Professor Mechanical Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

glass does not produce the same orientation as does steel. A number of observations with techniques different from that used by the author would be required before the existence of directional rigidity could be accepted. This is said not to minimize in any way the importance of the contribution but rather to emphasize the significance of the report.

The low electrical resistance of the film is also very disturbing. It is very unusual that a film 10^{-4} in. thick and only a fraction of a square inch in area, should pass a detectable electric current with an imposed voltage of 25 mv.

One can only hope that this investigation will be followed up by other experimenters who will have the opportunity to study the physics of a thin oil film. The painstaking manner in which the work was performed and reported by the author speaks for itself and adds further credit to the laboratory of Dr. A. Kingsbury.

MELVIN MOONEY.[13] Regardless of what the explanation may be for the formation of a stable thin film of oil, the facts established in the author's experiments are of fundamental importance in problems of lubrication. The explanation given for the facts observed is not very convincing. The data can readily be explained on the assumption of a layer of foreign particles between the parallel plates. Such particles would not be eliminated by centrifuging if they have approximately the same density as the oil. When the upper plate is rotated, the particles roll and form effectively a ball or roller bearing. If they are irregular in shape or slightly compressible, they would tend to increase the separation between the plates when the upper plate is rotated at a fixed pressure. This appears to be in agreement with the experimental facts. (The data on this point are not quite conclusive, for they require an extrapolation of the thickness-pressure curves under rotation back to 0.2 lb per sq in. pressure.) On the other hand, if the strength and rigidity of the final film depend upon a special arrangement of the molecules of the oil, it would be anticipated that the shearing action, when the plates are rotated, would disturb the arrangement and cause a decrease in the thickness of the film. This is contrary to the observed facts. The rigidity to rotation developed on standing may be ascribed to yielding and flattening of the foreign particles.

The difficulty of reconciling the author's explanation of his own experiments with the results obtained by Bulkley with fine capillary tubes is suggested but not discussed by the author.

It is to be hoped that the work with the parallel plates will be continued as planned. There is a variation in the experimental procedure which might be adopted to determine definitely whether the rigidity of the film is due to properties of the oil itself or to fine particles suspended in the oil. The variation here suggested is that one of the test plates be drilled through its center. Then, after a stable film has been produced, it would be possible to test whether oil under pressure can be forced through the central hole and out between the two plates. If so, the rigidity must be due to isolated points of support, presumably foreign particles. If not, the entire film is a rigid structure involving all the oil.

M. MUSKAT AND F. MORGAN.[14] Whether one agrees or disagrees with the observations presented in this paper, the importance of its implications in all problems of the flow of liquids near solid boundaries as well as in boundary lubrication must be recognized. In view of the perhaps almost universal opinion, based largely on the researches of Bulkley and of Bowden and his colleagues, that no such effects exist, the author and Dr. Kingsbury should certainly be commended for their activity in a field in which the possibility of obtaining positive results must have appeared very small.

Before all the previous results are discarded, however, or at least explained on the basis of different experimental conditions, it is perhaps worth asking if the results of this paper can be interpreted in any other way. For instance, the possibility that dust particles may contribute to the experimental results has already been considered, but apparently no great pains have been taken to remove this unknown factor from the experiments. The elaborate precautions necessary to obtain clean surfaces and purified air or liquids relatively free from dust particles have been described by Bastow and Bowden.[9] In spite of the methods used, however, they report that, under the ultramicroscope, purified alcohol still showed occasional dust particles. In fact the presence of some sort of contamination in the author's experiments seems almost to be postulated from the observation in part I that the micrometer zero could only be set by bringing the surfaces together with platinum wires between them, since a false reading would probably be obtained due to surface contamination or adsorbed films if they were brought together without the wires.

In any case, even though the author does feel that dust particles were not present, it is interesting to observe that if we do assume their presence practically all of the experimental results can be explained without invoking the peculiar rigidity properties proposed in the paper. Thus the linearity of the friction-versus-speed curve would simply be the result to be expected of a normal viscous film. As the dust particles would be supporting the load, the surface-tension forces at the edge of the surfaces would more than suffice to keep the liquid in without requiring any rigidity characteristics. The increase in torque observed after the rotation has been stopped might be due to a flattening of the dust particles on standing and subsequent return to approximately spherical shape upon rolling between the rotating disks.

Admittedly, the discrepancy between the directly measured film thicknesses and equivalent film thicknesses calculated from the torque observations must then be ascribed to errors in the pin method of direct thickness measurement. But, until there are other independent confirmations of the accuracy of this method, it is difficult to have sufficient faith in it to compel acceptance of the rigidity hypothesis. As to the lack of wear and scratches, this might be explained if the dust particles act in a manner similar to that of a polishing agent, even though they apparently do not become broken up.

While this picture is presented only as a working hypothesis, the alternative interpretation of the author requires that the film have a tremendous anisotropy. Thus in the direction of rotation the rigidity is equivalent only to a viscosity 5 times its normal value, whereas its radial viscosity is practically infinite. Furthermore, when the disks are at rest, the film apparently has an isotropic rigidity. Moreover, if rotation tends to remove the rigidity, it is surprising that, over the entire range of speeds of 120 rpm practically to zero, the effective viscosity remains so strictly constant.

If these properties are substantiated, the author will certainly have established a most remarkable phenomenon. It is felt, however, that just because this phenomenon would have such a profound bearing upon the general problem of lubrication, it is highly important that all factors which may permit alternative explanations of the experiments be positively eliminated before what are generally believed to be well-established physical concepts are discarded.

B. L. NEWKIRK.[15] In this paper, the observed effects are so

[13] U. S. Rubber Products, Inc., Passaic, N. J.

[14] Gulf Research & Development Company, Pittsburgh, Pa.

[15] Rensselaer Polytechnic Institute, Troy, N. Y. Mem. A.S.M.E.

striking that they call for careful study and further efforts to check them experimentally from new angles if possible. Particularly impressive is the consistency of measurements of the individual curves of Figs. 3, 4, and 5. The departures of individual points from smooth curves are only a few millionths of an inch. In Fig. 3 agreement with theory is close. Figs. 4 and 5 show discrepancies which would be reduced materially if some reason could be found for a change in the zero reading from one test to another. These curves show some apparently real diversities in shape that could not be so explained. For example, the curve marked by crosses in Fig. 5 would not fit the theoretical curve even after displacement. In view of the author's remarks about the difficulty of the zero measurement, it is not surprising that vertical displacements of the curves appear. A wave length of sodium (yellow) light is nearly 0.000024 in. On the other hand, it would certainly not be wise to dismiss these discrepancies in the view that they may be due to zero errors, for it is possible that some important fact would be brought to light if we could find the real cause. If means could be found to check the zero measurements independently, something further of importance might be discovered.

The experiments of part II also turn to a considerable extent on the measurement of distance between the plates. The method used in this case to measure the distance seems admirable but an independent check of a factor of such critical importance would be desirable if it could be managed. The measured distances between the plates are of the order of 400 times the length of the long polar molecules. The apparent fluidity for circular motion and rigidity for radial motion and the rigidity developing during periods of no rotation are very remarkable. If the surfaces had bumps and hollows or if they were distorted by pressure or the mounting, this might account for some of the observations, but the author's statement that the surfaces were flat to better than 0.000001 in. and the care taken in the design and mounting of the disks seem to exclude these possibilities.

K. Terzaghi.[16] The personal experience of the writer concerning the subject of the paper is limited to the physical properties of boundary films in clay-water mixtures. Therefore the writer was much impressed by the similarity between his own experience with water films and that of the author with oil films.

The findings of the writer can be condensed into the following statements: If the average width of the voids in a clay-water mixture is smaller than about 0.1μ the average effective viscosity of the water increases rapidly and, at the same time, the water assumes more and more the characteristics of a solid substance.[17] The increase in viscosity is apparently due to the restraining influence of the proximity of the solid surface on the movement of the molecules of the liquid.[18] The existence of an almost perfectly constant ratio between the normal pressure and the corresponding shearing resistance of the boundary film seems to be due to an orientation of the molecules of the liquid within the boundary film.

In 1933, B. Derjaguin published the results[19] of investigations concerning the elastic properties of water films between an optically plane and a curved surface of glass. The thickness of the film was determined by observing the Newtonian rings around the point of minimum distance between the two surfaces. The data required for computing the modulus of shear of the boundary film were obtained by recording the period of oscillations produced by the application and subsequent release of a torque. The following table contains the results of the investigation, quoted from the paper:

Thickness of film in microns	Modulus of shear in absolute units
0.089	190×10^6
0.093	170×10^6
0.137	4×10^6
0.150	0.0

This table shows that the thickness at which the film began to exhibit a measurable modulus of shear (0.14μ) is of the same order of magnitude as the thickness at which the writer noticed a marked increase of viscosity (0.1μ). However, as soon as the water acquires elastic properties, one can no longer call it a liquid and the physical meaning of the term viscosity changes. The transition from the liquid to the solid state, which takes place if the thickness of the film is decreased, also requires a corresponding progressive departure from Stefan's equation for the relation between the time and the thickness of the film (Equation [6] in the paper). In order to bring this departure more clearly into prominence, it would be advisable to plot the value $h\sqrt{t}$ against $\sqrt{t}$, because according to Equation [6] the value $h\sqrt{t}$ should be a constant, which appears in such a graph as a horizontal line. The departure from a horizontal line is more easily detected than that from a hyperbolic curve.

As h approaches a final constant value h_e the empirical curve approaches an asymptote through the origin $\sqrt{t} = 0$ and the value h_e is determined by the slope of this asymptote. The writer would appreciate it if the author would present such a graph in his final discussion.

The rapid increase of the torque after stopping, as shown in Figs. 8 to 10 of the paper reminds the writer of the thixotropic phenomena in the clay-water mixtures. The increase of stiffness with time under unaltered external conditions, characteristic of thixotropic phenomena seems to be due to the gradual building up of a molecular structure within the boundary films. Such an internal change may also account for the ultimate increase in the thickness of the films in the tests illustrated by Figs. 3 to 6.

As soon as the rotation ceases, the resistance against sliding approaches the value determined by the coefficient of static friction for lubricated surfaces, which is normal pressure per unit of area times coefficient of friction.

The coefficient of static friction for olive oil (Figs. 8 and 9) seems to be of the order of 0.14. For castor oil W. B. Hardy[20] gives a value of 0.10. In this connection, it is interesting to note the extraordinary difference between the rate at which the sliding resistance approaches the static value under a pressure of 40 lb per sq in. (Fig. 9, very rapid) and under 100 lb per sq in. (Fig. 8, very slow). Noticing this difference one feels tempted to consider whether an increase of the pressure may not increase the resistance against re-establishing the molecular structure within that part of the film which is kept by rotation in a liquid state.

Regarding the rigidity of the film during rotation, the writer is inclined to believe that the rigidity existed throughout the films, except within a layer with a thickness equal to the diameter of a few molecules along a plane half way between the solid surfaces. This may also account for the failure of the oil to flow out in a radial direction, in spite of liquid behavior with respect to rotation. Finally it may eliminate the apparent contradiction be-

tween the measured and the calculated values of film thickness (Fig. 12 of the paper), because the calculation seems to be based on assuming that during rotation the film is liquid throughout its thickness. The writer would appreciate an expression of opinion by the author as to whether he considers this hypothesis compatible with his observations. In every other respect his conceptions regarding the structure of the oil films are practically identical with those of the writer, derived from a very different realm of empirical evidence.

Author's Closure

Many interesting points have been brought out in the discussion. Some of these points may be clarified, but in most cases the information is not available at present to answer the questions raised.

Attempts by Professor Bradford and Mr. Villforth to detect indications of film rigidity by means of a tapered-plug viscometer are most interesting. Since the rate of approach of the surfaces appears to be in agreement with theory, until the film thickness is close to its minimum value, it would be indeed surprising if surface influence were detected in such comparatively thick films as 0.005 to 0.006 in.

Dr. Bulkley passed highly filtered fluids through fine capillaries and arrived at the conclusion that there was no surface influence sufficient to produce a rigid layer out to distances greater than 0.000001 or 0.000002 in. from walls of platinum or glass. The author worked with films of oil of the order of 0.00003 in., bounded by two plane steel surfaces, and found unmistakable evidences of unexpected behavior. This behavior he attributed to surface influence. Aside from questions of preparation and purity of the liquids, technique, and others, which become apparent when reading the papers and comparing the findings, the two following important facts stand out: A single surface, such as the wall of a capillary tube, has little or no influence on a contiguous liquid. Two steel surfaces in close proximity exert an appreciable effect on the oil between them. These two findings are not essentially in conflict. All the experiments on which the present paper is based indicated that, when the films were relatively thick, their behavior could be calculated from simple theory. It was only when the two steel surfaces came close to each other that their influences became apparent. It was also found that there appeared to be an appreciable change in electrical resistivity as the films became thinner. This point was not investigated to the extent warranted by its importance, but it was noted that the beginning of the change in resistivity occurred at approximately the same time as the departure of the rate of approach from Stefan's law. Investigation along these lines might be fruitful.

Professor Connelly has pointed out that the work done in shearing the oil film must cause heating of the film. At low speed and low torque, however, the rate at which heat is generated is so small that its influence on the film cannot be detected with the present apparatus. The rate at which heat is generated depends upon work done in shearing the film, and not upon rotative speed alone. For example, in the test shown by Fig. 10 of the paper, the rate at which heat is generated at 100 rpm is about the same as at 30 rpm in the test shown by curve 2 in Fig. 14 of this discussion. Data are available to show that, under these respective conditions, heat is generated at a rate sufficient to cause a 10 per cent drop in torque in 1 min. Only a few seconds are required for a torque observation and, between observations, the speed is reduced to 11 rpm or less where heating of the film is not appreciable. During the constant-torque period in the test shown by Fig. 9 of the paper, the reduction in torque due to shearing of the film is probably not in excess of 2 per cent.

No difference in test results could be detected by using hardened tool steel in place of normalized low-carbon steel. Preference of one steel over another for making the test surfaces was due only to the reasons stated.

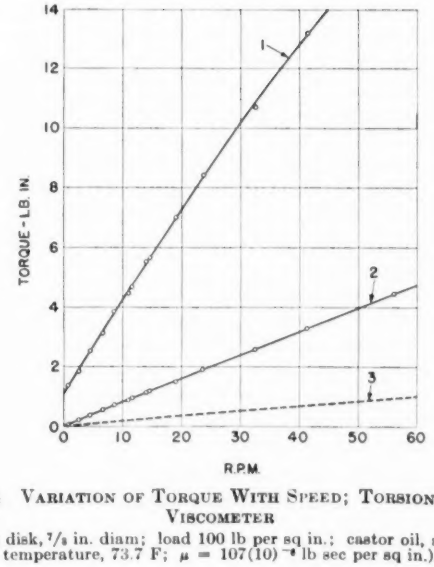

Fig. 14 Variation of Torque With Speed; Torsional Disk Viscometer

(Plane disk, 7/8 in. diam; load 100 lb per sq in.; castor oil, average temperature, 73.7 F; $\mu = 107(10)^{-6}$ lb sec per sq in.)

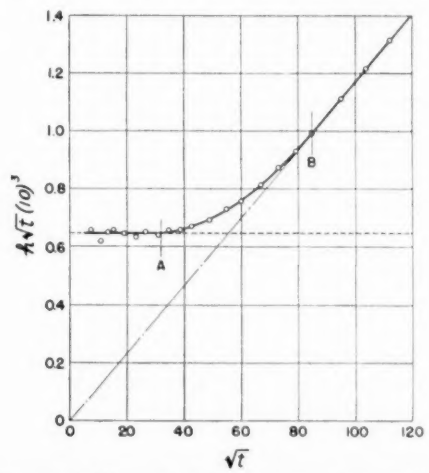

Fig. 15 Terzaghi's Method of Determining Time of Departure From Stefan's Equation; Torsional Disk Viscometer

(Plane disk, 7/8 in. diam; 11.06 rpm; load 40 lb per sq in.; castor oil, average temperature, 71.8 F; $\mu = 117(10)^{-6}$ lb sec per sq in.)

The torque-versus-speed curves requested by Mr. Hersey are shown in Fig. 14 of this discussion. The data were taken with castor oil and a load of 100 lb per sq in. After a continuous run of 8 hr at 11.06 rpm, rotation was stopped and the film was allowed to remain undisturbed for 15¾ hr. Variations of torque with speed were then observed and plotted in curve 1. Rigidity at zero speed is shown by the intercept at about 1.05 lb-in. Continuous rotation was then resumed and when the constant torque of the previous day had been reached, the speed was again varied with the results shown by curve 2. As in all cases when rigidity is not present, the torque is proportional to the speed and the curve is a straight line passing through the origin. From Fig. 12 of the paper, the film thickness with castor oil at 100 lb per sq in. is $38(10)^{-6}$ in. and, for the ordinary bulk viscosity of the oil, the theoretical torque is shown by the broken-line curve 3. Comparison of the slopes of curves 2 and 3 shows that, in this film, surface influence has increased the effective viscosity to nearly 5 times its normal value.

That the data may be readily explained on the assumption of a layer of foreign particles between the parallel plates, as suggested by Drs. Mooney, Muskat, and Morgan, is not quite clear to the author. It is true that no elaborate precautions were taken definitely to exclude dust from the atmosphere during the short time required to apply the oil and start the test, but to visualize a particle that could account for the observed phenomena is very difficult indeed.

Dr. Terzaghi's suggestion that the point of departure from Stefan's Equation [6] may be more clearly seen by replotting the data, has been carried out in Fig. 15 of this discussion. Data therein presented are from a test with castor oil and a load of 40 lb per sq in., with continuous rotation at 11.06 rpm. The horizontal broken line represents the constant value of $h\sqrt{t}$, which in this case is 0.000648 from Equation [6]. The point of departure A is at $\sqrt{t} = 32$. Therefore, during the first 17 min, the surfaces are approaching at the rate calculated for a purely viscous fluid. Torque becomes constant at B, 2 hr after starting, and approach of the surfaces ceases. From the slope of the curve beyond B, the minimum film thickness is $11.7(10)^{-6}$ in. This may also be found from the observed torque and Equation [11]. But from Fig. 12, however, we find the actual minimum film thickness is about $41(10)^{-6}$ in., nearly 4 times the theoretical value.

From Fig. 8 of the paper, it is seen that, with olive oil at 100 lb per sq in., the torque increases from 0.125 to 1.54 lb-in. over the 2-hr period CD. Time, in Fig. 9, is plotted in hours instead of minutes; hence, it is not quite so clear that, at 40 lb per sq in., the torque increases from 0.08 to 0.8 lb-in. in a similar 2-hr period. The rate of torque increase, therefore, is greater at the greater pressure and the final values reached depend upon pressure and time.

With reference to film rigidity and the general behavior of these thin films, there seems little difference between the conclusions which were reached by Dr. Terzaghi and those expressed by the author.

It is evident that further study of the boundary-film problem is desirable and warranted by the promise of additional information. This discussion has been most valuable in that it points out several paths for future research.

High-Speed Lightweight Trains

By C. T. RIPLEY,[1] CHICAGO, ILL.

The purpose of this paper is to outline the changes which have occurred during the last five years in high-speed passenger-train cars and in motive power for hauling them and the economic factors which have brought about these changes. The new designs for passenger cars and the materials used in their construction are discussed. A detailed comparison of steam-locomotive and Diesel electric-locomotive characteristics as they affect the operation of these new high-speed trains is presented. Test data are included to indicate the importance of comparative stress in track produced by two types of power. Reference is made to the steady improvement which has been made in steam-locomotive design, but it is shown that there is a need for some rather extensive experimentation to make this type of power more suitable for this particular class of service. In conclusion, the author presents his views on the general results which have been secured from the operation of these new trains and the probable trend in their future development.

DURING the last twenty years the travel habits of the American people have expanded greatly. The development of the low-priced automobile, and the construction of hard-surfaced roads have been the major factors in this change. In the face of increased travel, railway passenger traffic steadily declined until in 1933 it produced only about one third the gross revenue which it did in 1920. The data in Table 1 show this decrease both in the number of passengers carried and in the rates and revenues.

TABLE 1 PASSENGER-TRAFFIC STATISTICS, CLASS 1 RAILROADS IN UNITED STATES

Year	Passenger revenue, dollars	Revenue per passenger mile, cents	Passengers carried
1921	1,153,792,000	3.09	1,035,496,000
1925	1,057,704,231	2.94	888,267,000
1930	729,470,279	2.72	703,598,000
1933	329,342,000	2.61	432,980,000
1934	346,325,993	1.92	449,775,000
1936	412,379,000	1.84	490,091,000
1937	442,809,000	1.79	497,288,000
1938	405,476,000	1.87	452,808,000

The large decrease in railway passenger traffic was undoubtedly due to the inroads of bus travel, private-automobile travel and, to a lesser degree, airplane travel. Prior to 1930, the railway managements, with properties still fairly prosperous because of good freight traffic, did little to remedy the situation except to reduce rates, as indicated in Table 1. They also eliminated some nonpaying trains and in the case of branch-line operation, where they were usually forced by governing bodies to continue passenger service regardless of losses involved, they substituted gasoline-electric motorcars for steam trains. These cars were definitely successful in reducing operating costs to such an extent that their first cost was paid for in a few years, but there was nothing about their service to attract new passenger business or even to hold what was left. Their usage did influence later developments in that they brought to the attention of railway managements the possibilities of utilization of the internal-combustion motor in railway service. Their success in mechanical performance led the manufacturers to develop the new type of lightweight two-stroke-cycle Diesel motor, which is now playing such an important part in the operation of high-speed streamlined trains.

About 1930 the railroads started air-conditioning passenger cars. This was an instant success with passengers and though the cost was high, about $8000 per car, it became necessary to air-condition practically all main-line cars, with the result that there are now about 11,000 such cars in operation. In some of these cars there were other improvements made for the comfort of the passengers such as more comfortable seats and better lighting. The success of this development, from a traffic viewpoint, convinced the passenger-traffic officers that it might be possible to recapture at least a part of the lost business.

In 1900 the 60-ft wooden passenger car, seating about 80 passengers, weighed about 40 tons or 1000 lb per passenger. In the interests of safety, designs were changed first to include steel underframes, and in about 1910 to all-steel construction. Various parts were also increased in size and weight in order to secure greater strength and durability, until in the 1920's the 80-ft passenger car seating about 70 passengers weighed approximately 80 tons or 2300 lb per passenger. About 1930 still further weight was added, due to the introduction of air-conditioning equipment, weighing about 5 tons. As a result of this continued increase in weight of passenger cars, as well as a gradual increase in the speed of operation, the size of steam motive-power units steadily increased. Track structures and bridges had to be made stronger to carry these heavier locomotives and cars, and thus there was, from all of these angles, an increase in the cost of operating passenger trains, while at the same time the total traffic was diminishing and there was a continual demand for lower rates to save the remaining traffic.

Development of Lightweight Cars

About this same time some new structural materials became available for use by the car builders, namely, aluminum alloys, stainless steel, and various so-called low-alloy high-tensile steels. Because of these developments the railway engineers and the car manufacturers started active work in the design and construction of new trains of a lighter type for main-line operation. The first of these were small trains consisting of three or four cars with 600-hp Diesel engines located in the head car. They were made as light as possible in order to hold down the power requirements and to enable them to compete with buses and private automobiles by giving cheap transportation. The cars were of non-standard height and some were narrower than the standard. They were streamlined to reduce power requirements and also to make an appeal to the public, already educated to such design by automobile developments. The reaction of the traveling public was so favorable that there was an immediate demand for more elaborate and larger trains for longer runs, with sleeping accommodations and other features for maximum comfort. Low first cost was soon lost sight of in this development. Interior decorators designed the most elaborate fittings and the trains were built with as many as 14 cars with power units totaling as

Prepared for presentation at the Railroad Session, at the canceled Fall Meeting of The American Society of Mechanical Engineers, which was to have been held jointly with The Institution of Mechanical Engineers of Great Britain in New York, N. Y., September 4-8, 1939. Presented at a meeting of the A.S.M.E. Metropolitan Section, November 21, 1939, New York, N. Y.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

much as 5400 hp and auxiliary power for the cars of 1200 hp. A few of these trains were powered with streamlined steam locomotives but there was little change in the design of these locomotives from the old type except that higher driving wheels (84 in.) were used together with higher steam pressures (300 psi) and larger tenders to reduce delay in taking fuel and water. They also had roller bearings and some other refinements in design.

Most of the early trains had articulated cars because it was thought that this design reduced weight and gave better riding conditions. It developed however that neither of these factors proved to be important. There was a definite disadvantage in articulation particularly on long runs, in that standard cars could not be mixed with such cars. In case of difficulty, such as a bearing or wheel failure, a car failure might become a train failure. In the last few years practically all the lightweight cars have been built as individual units with standard floor and coupler heights and standard outside dimensions, so that they can be associated with any standard car. The weights of these cars were reduced about 40 per cent from those of the conventional structural-steel cars and thus four-wheel trucks could be used.

Specification Requirements for Passenger Cars

The only standards for design strength available at the time most of these cars were built were the provisions of the United States Railway Post Office mail-car specifications (1).[2] These specifications were first prepared in 1912 by a group of representatives of the Post Office Department, the Master Car Builders Association, and the car manufacturers. It was required that all postal cars meet these specifications. While other cars were not required to meet them, practically all passenger-train cars were designed at least to these requirements. In July, 1938, they were revised to clarify certain features. These new specifications were written so as to cover practically all types of construction with all types of materials. The major provisions of both the 1912 and 1938 specifications were, first, a minimum strength of center-sill construction based on 400,000 lb buffing static load and a factor of safety of two, and second, a minimum strength of end construction to protect against telescoping action. This latter required minimum section moduli for vertical end members and minimum shear values for their top and bottom connections. There were also numerous other limitations of stress in frame members.

Cars built to meet these specifications have rendered excellent service with a remarkably good record in the protection of passengers under wreck conditions. As a consequence when lightweight construction was started in about 1931 these specifications were used as a minimum requirement, even though there were no rules of the American Railway Association or of the Government setting such limitation. However, a feeling developed that because of the operation of lightweight cars between heavy cars in trains, it was necessary for the Association of American Railroads to set up more detailed specifications to cover the construction of all passenger-train cars built in the future, giving particular attention to prevention of damage from telescoping. A committee of the Association of American Railroads has recently developed these new specifications and they will probably govern all new construction of passenger cars. While these new specifications are generally based on the Railway Post Office specifications, they include some major changes: They provide for a center-sill strength such that an 800,000-lb load applied on line of draft will not produce any permanent deformation. The Railway Post Office specifications contained only a stress limitation and permitted the load application to be divided between the coupler line and the buffer line. This change will probably result in the addition of more material than is now used in center sills of lightweight cars designed with high center sills and buffers, with little compensating benefit from added protection. The new specifications also include increased requirements for strength of couplers, carrier irons, and end construction, all of which mean some increase in weight, but which are apparently justified in view of the importance of maximum protection against telescoping of cars.

Generally speaking, the new lightweight cars are being designed and built just as strong and safe as the older heavy types. Better engineering, stronger materials, and improved methods of fabrication make this weight reduction possible. New welding technique largely eliminates the human element and when properly applied should be preferable to the old riveting practice.

Need for Light Weight

Light weight is almost a necessity for high-speed operation in order to hold down the size and cost of power units, as well as the cost of operation. This is particularly true with Diesel-electric locomotives with their high first cost. Experience indicates that 450 lb per hp (including weight of locomotive) is a proper design ratio for high-speed operation. Some of the new trains have a power ratio as high as 550 lb per hp but the maintenance costs appear to run higher on such trains. In order to secure satisfactory performance on high-speed schedules, it is necessary to have some reserve power in the locomotive because some delays are inevitable and extra power is needed to make up the lost time. While the schedules may indicate that maximum speeds of only about 90 mph are required, actual operation requires at times speeds of 100 mph or even higher. This fact must be taken into consideration when designing locomotives and trains for this type of service.

Car Construction Materials

Several of the early trains were built of aluminum alloys but in recent years the majority of them have been built of stainless steel or low-alloy high-tensile steel. The major claims for the stainless steel are lower weight due to higher physical properties, better welding by the automatic shot-weld process, and high resistance to corrosion. Stainless steel does not have to be given paint protection of any kind, which reduces both first cost and maintenance cost. Its polished surface gives an attractive modernistic appearance to the cars and is easily cleaned. In high-speed operation the sandblast effect of particles from the ballast or right of way damages paint finishes quite rapidly. The low-alloy high-tensile steel advocates claim that they secure equally low weights for lower costs. Tests indicate that these steels have from two to four times the corrosion resistance of ordinary carbon steel. They are made to various formulas and have different trade names. It is claimed that some of them have somewhat better welding qualities than others.

Inasmuch as no exactly similar cars have been built using the different types of steel or aluminum, it is not possible to make accurate weight comparisons. While it is true that the full use of the superior physical properties of stainless steel or the light weight of aluminum is limited to some degree by deflection requirements, it should be possible, by using these materials instead of low-alloy steel, to construct a lighter car of equal strength. A general comparison of the large number of cars of the various types which have been built indicates a weight advantage for stainless steel and aluminum of at least 5 per cent. It would be expected that the construction cost of cars built of these materials would be somewhat higher due to the high cost per pound of such materials, but competition between builders has resulted in about equal bid prices.

It is too early to evaluate fully the different types of lightweight-car construction. Maintenance costs over a longer period

[2] Numbers in parentheses refer to the Bibliography.

and performance in accidents will ultimately provide the answer. It appears, however, that a weight of about 100,000 lb for an 80-ft coach is entirely practicable with full safety to passengers. If too much space for extra luxuries is provided, part of the advantage of lightweight construction is lost, as the important factor is the weight per passenger carried. Table 3 shows the major parts of a typical lightweight car in which the weight saving has been made.

TABLE 3 COMPARATIVE WEIGHTS OF CONVENTIONAL AND TYPICAL LIGHTWEIGHT AIR-CONDITIONED PASSENGER COACHES

	All weights in pounds	
	Conventional steel coach	Lightweight stainless-steel coach
Length over end sills, ft	70	79
Seating capacity	58	63
Weight of trucks	52800	34000
Weight of car-body structure	66500	33000
Weight of inside furnishings	7000	5000
Weight of equipment	45400	25000
Total weight	171700	97000
Weight per passenger	2962	1540

Riding Characteristics of Lightweight Cars

Due to higher operating speeds, the design of passenger-car trucks is a most important factor. The former six-wheel trucks were not entirely satisfactory at these increased speeds, and doubt existed in the minds of some engineers as to the possibility of securing good riding qualities with four-wheel trucks. The weights of the new car bodies were so low that only four axles were necessary to carry the load, affording further opportunity for weight reduction by the use of four-wheel trucks. Extensive experiments were made by various railroads and manufacturers, which resulted in the development of many new features of truck design with a decided improvement in riding characteristics.

Among these new features were the use of softer springs with greater deflections, hydraulic shock absorbers to control both lateral motion and vertical spring reactions, multiple-spring systems in triple-bolster trucks, and roll stabilizers. The use of cylindrical tread contours on wheels to reduce the nosing of trucks, and the grinding of treads to secure true rotundity and concentricity, were both helpful in softening the ride. Balancing of the wheels was also practiced to some extent, although a complete check of this feature has not been made due to lack of balancing machines in this country. It is now being given careful check on one railroad, which has installed the necessary machine. In an effort to reduce noise in the cars, rubber or other semiresilient materials have been introduced in various parts of the trucks, such as pedestals, spring seats, and center plates. The mounting of the brake cylinders on the trucks instead of the body has also reduced the noise produced by the brakes. Improved insulation of car floors, as well as the sealing of windows, has also made a marked improvement, but there is still need for further noise elimination. The passengers can still hear the click of the wheels on the rail, the grinding of brake shoes on the wheels, and in some cases generator noise. Longer rails and better track maintenance would help to reduce rail and wheel noise and the use of disk-type brakes would reduce brake noise.

In some of the lightweight cars a certain amount of vertical body vibration was noticeable to passengers. This has been reduced by stiffening the car-body structure. The fore-and-aft vibration of cars which is so noticeable in many of the standard cars, particularly in operation with reciprocating steam locomotives, has been largely eliminated through the use of tight-lock couplers, which have little or no free slack and by softer acting draft gears.

The most unpleasant shocks in these cars are those of lateral acceleration, resulting either from nosing of trucks on tangent track, or the entering or leaving of curves. A novel attack on this problem is being made by one manufacturer, who has developed a pendulum type of car. This method of mounting the car on the truck differs completely from standard practice, in that the car body is virtually suspended from the truck, floating on soft vertical helical springs located well above the center of gravity of the car body. These springs permit through horizontal deflection the necessary truck motion relative to the body, and this motion is positioned and controlled by a pair of horizontal links, which are restrained by rubber disks and shock absorbers acting between the car body and vertical extension of the truck frame at a point above the center of gravity of the body. In going around curves this type of car tends to bank and thus avoids the unpleasant sensation resulting from car-body roll. Preliminary tests of this type of car indicate an improvement in riding characteristics particularly on curves.

In general it appears that there is still need for research in truck design, in order to secure even greater comfort for passengers and to make possible higher operating speeds on sharp curves which, particularly on western roads with much track curvature, are a definitely limiting factor to fast over-all operating schedules.

Improvements in track structure and maintenance are also necessary if still higher speeds are to be attained. Whatever de-

sign of truck is used, satisfactory riding characteristics cannot be secured in high-speed operation over bad track.

Braking

The introduction of high-speed lightweight trains brought many new problems in braking. The stopping of these trains within reasonable distance is a difficult problem. While the car weights are less, individual wheel loads are as high and in some cases (particularly with the articulated type) higher than with the old heavy cars. In order to reduce the stopping distance, there have been a number of changes from former practice, such as truck mounting of brake cylinders which increases rigging efficiency, much higher braking ratios (some as high as 250 per cent), decelakrons to reduce pressures as the train slows down and thus prevent sliding of wheels, automatic car sanders acting only in emergency application, and electropneumatic control. In some cases the very high brake ratios resulted in considerable wheel and brake-shoe trouble. With all of these improvements there is still a question whether emergency stopping distances are as short as they should be. To effect shorter stops without undue punishment to wheels and shoes, new types of disk brakes are being tested. One train so equipped is now in operation. This type of brake has the advantage of a more uniform coefficient of friction throughout the speed range, thus permitting brake pressures which more closely approach the coefficient of adhesion between the rail and the wheel. Unfortunately, this coefficient of adhesion varies widely under different rail conditions. Thus if higher braking pressures are used, there is danger of sliding under unfavorable conditions. To meet this problem, either car sanding equipment or governors to reduce pressures automatically, when sliding begins, may prove to be a necessary complication.

In both steam- and Diesel-powered lightweight trains, the locomotive weight is a large percentage of the train weight, but in most cases locomotives do not do their full share of the braking. The steam locomotive is particularly lacking for three reasons: First, there are often some unbraked wheels on engine trucks for operating safety; second, the large spread between light and loaded weight of tenders makes it necessary to design braking power on the basis of light weight, and third, enginemen have to relieve engine brake pressure frequently to guard against the loosening of driving tires due to heating. The Diesel is better in that all wheels are braked and the spread between light and loaded weight is relatively small, but the small-diameter wheels are so highly loaded that the braking ratio must be limited in order to protect the wheels from damage. It would be advantageous if Diesel-electric locomotives had a supplementary dynamic electric brake such as is used in some electric locomotives as well as in the new experimental turboelectric design.

Comparison of Diesel-Electric and Steam Locomotives

It may be noted from Table 7 that the Diesel-electric locomotive is more commonly used in these new high-speed streamlined trains than is the steam locomotive. It is claimed by some that this is chiefly due to the interest of the public in a new type of power, but the users apparently have good engineering arguments to support their choice. The advantages claimed for the Diesel are: First, high availability; second, rapid acceleration because of high tractive power at lower speeds; third, low maintenance costs; fourth, low fuel cost (usually less than half that of steam); fifth, lower rail stresses. The steam locomotive is less expensive, costing about $37 per hp. However, it is harder on track at high speeds due to the dynamic augment produced by overbalance in the driving wheels. It appears that a radical change in the design of the steam locomotive is necessary to make it capable of fully competing with the Diesel in this service. The important objects of such redesign should be the securing of a more constant torque and the reduction of track punishment. Three outstanding locomotives of new design are under construction or in service, namely, the 5000-hp turboelectric being manufactured by the General Electric Company for the Union Pacific Railroad, the Baltimore and Ohio Railroad's four-cylinder engine, and the Pennsylvania Lines' four-cylinder high-speed engine. All of these new types are experimental, but they indicate a trend toward a type of steam locomotive having more constant torque. A step still further in this direction is involved in a new Baltimore and Ohio design, which includes individual axle drive.

The comparison of typical modern high-speed steam locomotives and Diesel-electric locomotives on a horsepower basis, as shown in Table 4, is open to criticism because of the basic difference in the horsepower curves of the two types and also the difference in method of power transmission. The nominal horsepower of the Diesel-electric locomotive is available over practically the entire speed range, whereas the maximum indicated horsepower of the steam locomotive is available only during a limited speed range. With locomotives of equal horsepower, the Diesel has the advantage of greater power for accelerating at low speeds and greater sustained horsepower at very high speeds. Some difficulties with pistons, heads, and liners have been experienced in services where Diesel-electric locomotives were operated with such loads and schedules as to require almost continuous maximum output of power. Recent improvements in materials and designs of these parts have largely overcome this trouble. Nevertheless, the maintenance cost of any type of locomotive increases as the working-load factor increases. Proper design of a motive-power unit should provide some reserve power for emergency use, but not such an excess as to result in uneconomically high cost of construction.

TABLE 4 COMPARISON OF TYPICAL MODERN HIGH-SPEED STEAM AND DIESEL-ELECTRIC LOCOMOTIVES

	Diesel-electric	Steam 4-6-4	Steam 4-8-4
Nominal hp of Diesel motors	4000	....	....
Maximum indicated hp	....	4300	5750
Weight with fully loaded tender, lb	608000	809000	896000
Weight, lb per hp	152	188	156
Approximate cost per hp	$87.50	$35.00	$34.00

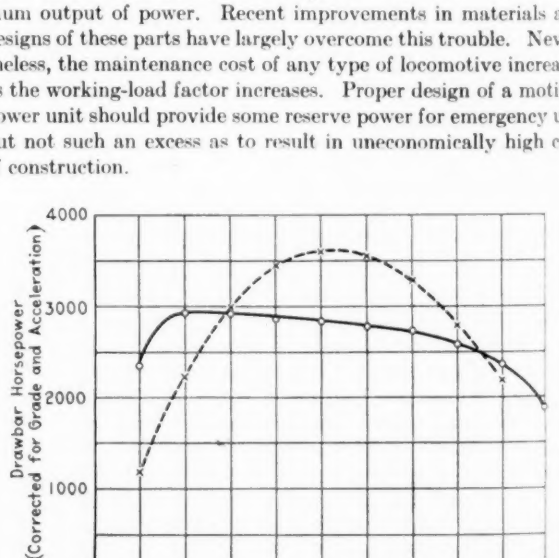

Fig. 1 Comparative Drawbar-Horsepower Curves for Steam and Diesel-Electric Locomotives

(Solid curve. Diesel-electric locomotive, 4000 nominal hp. Dotted curve. 4-6-4 steam locomotive, 4300 max ihp.)

Fig. 1 shows the relative drawbar horsepower of a 4000-hp Diesel-electric locomotive and a modern (1938) high-speed steam locomotive of the 4-6-4 type with 4300 max ihp. These curves are plotted from actual dynamometer-car readings with necessary corrections for grade and acceleration. They show the advantage

of the Diesel-electric locomotive at low speed and very high speed and also the advantage of the steam locomotive at intermediate speeds, such as would exist in ordinary grade working. This advantage in grade climbing is offset to a considerable extent by the 33 per cent greater weight of the steam locomotive.

The sharp dropping off of the horsepower curve for steam locomotives at high speed is due largely to low mean effective pressure in cylinders. To improve this condition, radical changes both in the design of valve and of valve gears appear to be necessary.

In the case of Diesel-electric locomotives, the curve does not drop off as sharply as does that for steam locomotives and further improvement has already been secured in the latest designs by change in the generator voltage control. This change has also increased the power output at low speeds.

In regular operation of the two types the performance of the Diesel-electric locomotive is usually that which is indicated by the drawbar-horsepower curve, but in the case of the steam locomotive there are a number of variables which may result in average performance somewhat below what is indicated by the horsepower curve derived from tests. The skill of the engineer varies and the condition of the locomotive is not always as nearly perfect as it is in the test.

Manufacturers of Diesel-electric locomotives have an advantage in that they produce a practically standardized product and thus can reduce cost through line production. On the other hand almost no two lots of steam locomotives are the same. Each order means a new design with resulting high costs for engineering and production. This also means higher cost for and larger stocks of repair parts. American railroads have made a marked advance in the standardization of freight cars but there has always been strong opposition to any plan for standardization of steam locomotives or passenger cars, due mainly to differences of opinion among different managements. The usual explanation is that operating conditions vary but this is hardly a valid excuse at least when certain railroads are compared.

The use of Diesel-electric locomotives is more extensive on western roads than on those in the East. This is probably due to the following factors: Most of the oil production is in this territory, which results in lower prices, and the traffic in oil and its by-products is a more important source of revenue than that from coal, whereas the reverse is true in the eastern territory. In the Southwest most of the steam locomotives use oil as fuel because of its lower first cost. The usual Diesel-locomotive fuel is about 28-gravity furnace oil costing about four cents per gallon at the refinery. Steam-locomotive fuel oil is a low-grade residuum costing about two cents per gallon at the refinery. The boiler-feedwater supply and treatment is also much more of an expense and problem in at least a large part of the West than it is in the East.

Diesel-electric locomotives provide better vision for the engineer because the cabs are located at the head end. The riding quality of Diesels is better than that of steam locomotives. They also provide smoother-riding trains as their high tractive effort at low speeds enable them to start and accelerate trains more quickly and smoothly.

Steam locomotives have an advantage in that more horsepower can be put in one unit. It may be noted in Table 4 that the increase in horsepower is secured with a lower percentage of increase in first cost and weight, that is, both the cost and weight per horsepower are lower for the 4-8-4 locomotives than for the 4-6-4 type. The maintenance cost per horsepower should also be somewhat lower for the 4-8-4 locomotives. It is true that any number of Diesel units can be coupled and controlled from one cab, but this increase in number of units means increased first cost and increased weight. A 2500-hp Diesel unit would appear to be a desirable size for heavy service, particularly in mountainous territory, but this does not appear practicable at present.

The performance records of Diesels show fewer failures than similar records for steam locomotives, even when the latter are operated in slower-speed service. The multiunit power plant is a helpful feature in the prevention of failures. If something goes wrong in one power plant the locomotive can still go on to its terminal and in many cases the defect can be repaired en route with little or no delay. A major breakage or defect on a steam locomotive means a failure.

If an entire territory were completely Dieselized, major savings could be secured in elimination of water and fuel facilities and also intermediate terminals. With partial Dieselization, it is necessary to provide certain special facilities for water and fuel, but these are not expensive. Diesel-electric locomotives are designed to operate about 700 miles without refueling or watering, whereas steam locomotives with large tenders operate only about one half of this distance for fuel and one third the distance for water. Fewer and shorter stops for fuel and water are essential in making high-speed schedules.

Diesel-electric locomotives have a higher availability than steam locomotives because they need less servicing. Furthermore, individual major parts can be changed in a short time, thus avoiding delay of the unit for repairs. In service they are regularly making $1^1/_2$ to 2 times as much mileage as steam locomotives, though it is only fair to say that part of this may be due to their use on preferred runs. Diesel-electric locomotives are cleaner in their operation, due to lack of smoke. This is particularly advantageous in cities and towns. It also adds to passenger comfort in that the view from the car windows is not obstructed by smoke.

Table 5 gives a breakdown of the weight of a typical 2000-hp Diesel-electric locomotive. The large percentage of the weight involved in the trucks may be noted. This is due to the heavy construction needed to support the traction motors and withstand the shocks of high-speed operation. The trucks are constructed of alloy steel and there appears to be little opportunity of making them lighter. The Diesel motors are almost as light as they can be made to withstand the service, but it may be possible in future development to take more power out of each cylinder, which would result in a reduction of weight per horsepower. The transmission accounts for a considerable percentage of the total weight. There is some possibility of reducing both the cost and weight of this part through the development of suitable hydraulic transmissions, but no large locomotives of this type have as yet been built in this country. The weight of the body structure cannot be reduced to any great extent as alloy steel and welded construction are already used throughout.

TABLE 5 WEIGHT OF STANDARD 2000-HP DIESEL-ELECTRIC LOCOMOTIVE

	Per cent
Two 1000-hp Diesel motors and auxiliary equipment	23
Two electric transmissions with auxiliary equipment	21
One steam boiler with auxiliary equipment	2
Two trucks (less traction motors)	28
One car body	26
Total	100

Total light weight	277000 lb
Weight of oil (1420 gal)	11000 lb
Weight of water (1360 gal)	10800 lb
Weight of sand (16 cu ft)	1600 lb
Total	300400 lb

The center of gravity of the Diesel-electric locomotive is considerably lower than that of steam locomotives and this fact, together with the shorter rigid wheel base makes it possible to operate the Diesel-electric locomotive at about 15 per cent higher speeds on sharp curves. This is an important factor in making high-speed schedules, particularly on runs where there is a great deal of curved track.

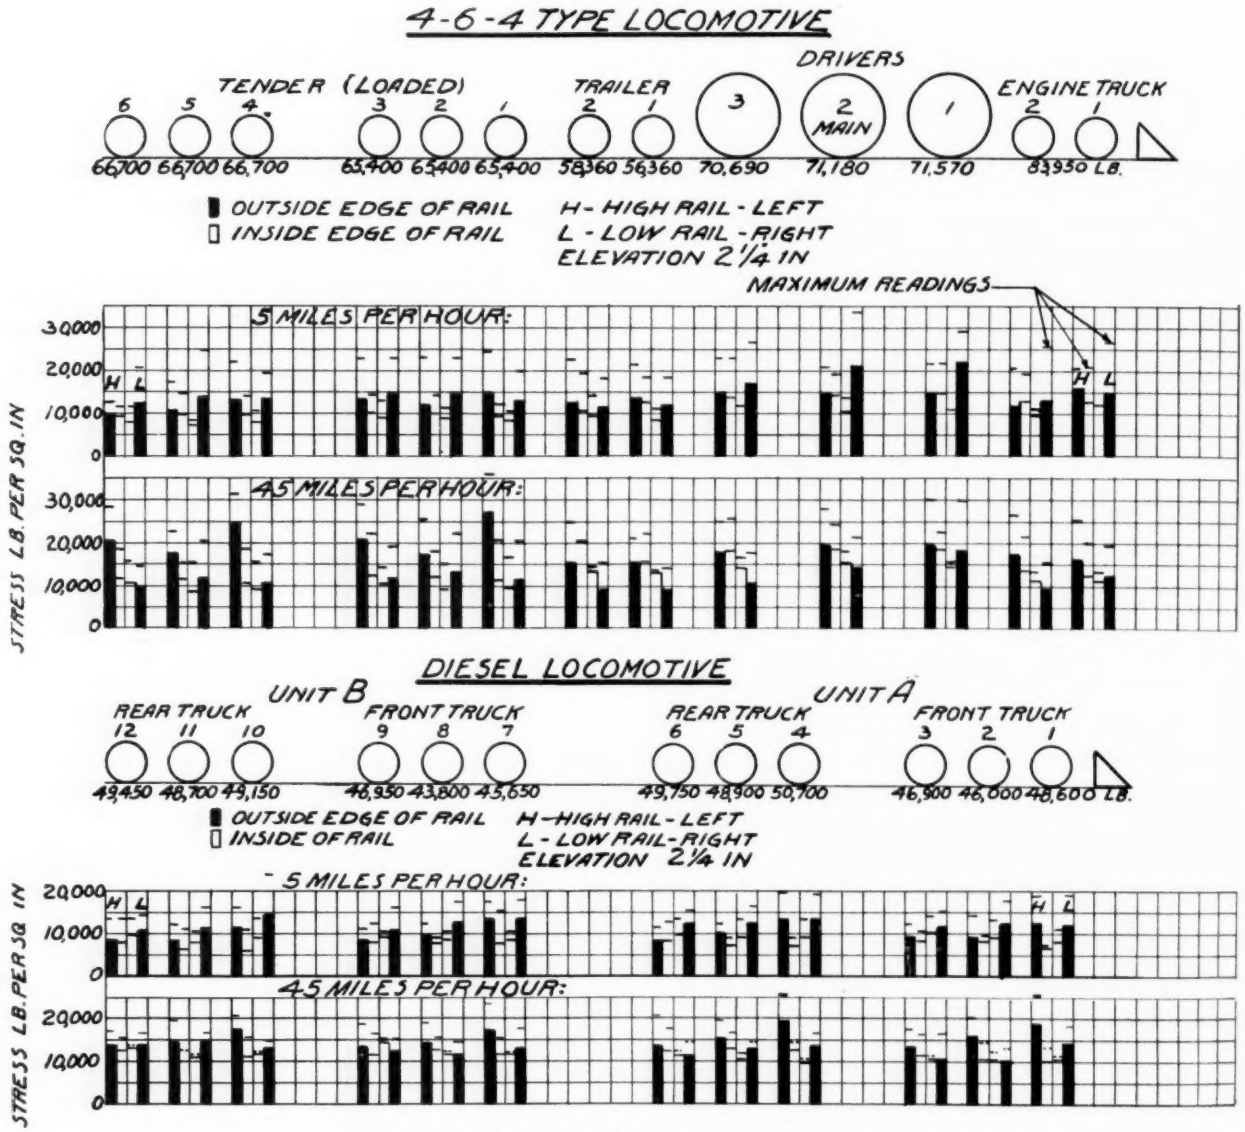

FIG. 2 MEAN STRESSES IN RAIL BASE UNDER EACH WHEEL
(Five-deg curve, 110-lb rail.)

RELATIVE COST OF MAINTENANCE OF DIESEL-ELECTRIC AND STEAM LOCOMOTIVES

There is a great deal of controversy as to the relative cost of maintenance of Diesel-electric locomotives and steam locomotives. It is difficult to secure reliable data from which to make comparisons. The comparison of costs on different railroads is open to question because of difference in operating conditions and accounting practices. The two types of power are not regularly used in the same type of service on the same railroad. Furthermore, the Diesel-electric locomotives are rather new and very few of them have received general repairs. It may be said that the two types are definitely different in regard to general repairs; the steam locomotive because of its boiler, flues, and firebox must be given general overhauling at relatively frequent periods. The Diesel-electric locomotive, on the other hand, is being constantly repaired by the regular replacement of the wearing parts. Some roads have put them in the back shop for general repairs after about 750,000 miles of service. It was originally thought that this might be the life of the major element of the Diesel motor, the crankshaft, but it has developed that the life of this part will normally be greatly in excess of this figure, and some roads are planning on one million or more miles between general shoppings.

The best available data appear to be the five-year-period maintenance-expense figures of a group of Pacific-type locomotives with approximately 3800 max ihp capacity, operating in normal passenger service, and similar figures for a group of 3600-hp Diesel-electric locomotives in high-speed service on the same railroad. These data show that the steam locomotives cost about 20 cents per mile for maintenance, whereas the Diesel-electric locomotives cost approximately 17 cents per mile for maintenance. These particular Diesels have never been given a general overhauling and, therefore, in order to be conservative, it might be fair to add as much as 3 cents per mile to this figure. These data indicate that it may be conservatively claimed that Diesel-electric locomotives can be maintained for at least the same cost as steam locomotives. If this same group of steam locomotives were operated at high speed, the repair costs would

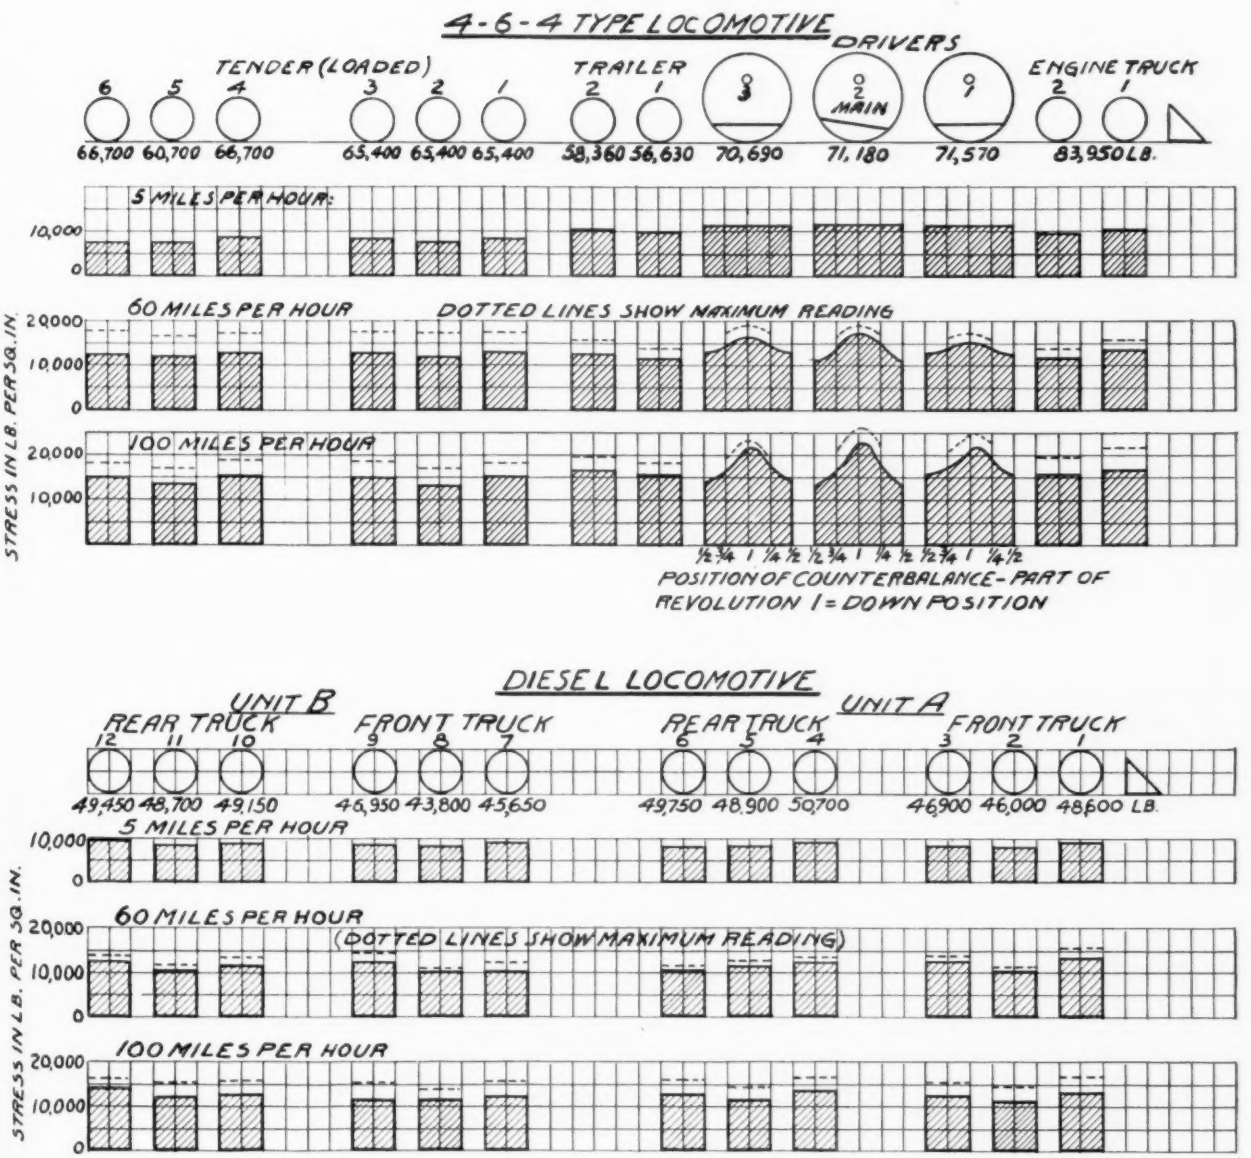

FIG. 3 VERTICAL STRESSES IN BASES OF BOTH RAILS
(Tangent track, 110-lb rail.)

undoubtedly be greater than the 20 cents shown. It is claimed by the builders of steam locomotives that the most modern type will have a lower cost of maintenance than older types, but it can also be claimed that the details of Diesel-electric locomotives are being steadily improved with a resultant reduction in maintenance cost. It must be recognized that costs on different railroads vary widely, particularly those applying to Diesels, since they are new and maintenance forces are not as familiar with them as they are with the steam locomotive. Furthermore, most railroads' repair facilities were designed for steam-locomotive work and are not suitable for efficient handling of Diesel repair work. New facilities are gradually being provided for taking care of Diesel work and their use should result in some reduction in maintenance cost.

TRACK STRESSES

Every steam locomotive must have a certain amount of overbalance in the driving wheels, in order to balance the reciprocating parts. This overbalance results in a dynamic augment which increases as the square of the speed and thus becomes an important factor in producing stresses in the rail and roadbed at high speed. In some cases this effect has been so serious that the main drivers actually lift from the rail at high speed and may produce kinked rail. Improvement in this condition has been made by reducing the weight of the reciprocating parts to a minimum and reducing the percentage of the reciprocating weight balanced to a minimum limited by the production of nosing and fore-and-aft motion of the engine. A still further effort along this line is embodied in the new experimental designs of locomotives having two complete sets of cylinders and motion work. This not only reduces the weight of reciprocating parts but gives another desirable characteristic, that of more constant torque. In order to illustrate the difference in rail stresses produced by a large Diesel-electric locomotive which has no reciprocating parts and a large modern high-speed reciprocating steam locomotive, Figs. 2 and 3 are included. These show the results of

rail-stress measurements on 110-lb rail with a modern 4-6-4 steam locomotive and a 3600-hp Diesel-electric locomotive. Fig. 2 shows stresses on a 5-deg curve at speeds of 5 and 45 mph and Fig. 3 stresses on level tangent track at speeds of 5, 60, and 100 mph. In Fig. 2 the stresses are shown separately for both edges of both rails, and the maximum stress at each location, as represented by the average of three highest readings at each location, is shown in short horizontal lines. In Fig. 3 the average vertical stress in the rail base is shown and the effect of the counterbalance by indicating its relative position. The maximum stress is also an average of three maximum values. The damaging effect of counterbalance is clearly shown in these data which are actual stress measurements and not calculations.

If a steam locomotive slips at high speed, the rotational speed of the driving wheels may be greatly in excess of that involved in these tests, therefore, the dynamic augment and resulting rail stress are greatly increased. The high rail stresses under steam-locomotive tenders due to too-high loads on small-diameter wheels may also be noted. Large tenders are necessary on high-speed locomotives in order to reduce to a minimum the delays for taking fuel and water, but it appears necessary to add two more pairs of wheels or increase the diameter of the wheels, in order to reduce wheel loads to a reasonable figure where damage to both track and wheels is not excessive.

No complete data are available for rail stresses under 4-8-4 type high-speed steam locomotives. However, the tests made indicate that rail stresses under the main drivers of such locomotives are about 25 per cent greater than those shown for the 4-6-4 type. This is due to the fact that the reciprocating parts in these larger and higher-powered engines are heavier and the driving-wheel diameter is usually made smaller to meet heavy-grade operating conditions.

All of these track-stress data point to the need of a radical change in steam-locomotive design for competition with the Diesel-electric locomotive in high-speed passenger-train operation. The four-cylinder design is a step in the right direction. The individual axle drive proposed by the Baltimore and Ohio Railroad is a further step and also the new turboelectric type. Up to the present time the gear-drive turbine locomotive has not been tried out in this country, but it too may have possibilities. The individual axle drive for a steam locomotive appears to have the most interesting possibilities since it involves not only relatively constant torque but also better track protection resulting from complete balance. A lower center of gravity can also be secured since driving wheels of smaller diameter can be used. A special committee appointed by the Association of American Railroads composed of leading railway mechanical engineers and representative engineers of the locomotive builders is making a thorough study of the entire question of design of steam locomotives for high-speed operation. Out of their work there will probably come some concrete and valuable recommendations on this important question.

Until some marked changes are made in steam-locomotive design it appears that the Diesel-electric locomotive will have a definite advantage in so far as effects on rail and roadbed are concerned.

Lightweight passenger cars also have an advantage over conventional cars in the matter of track-maintenance costs. Though their individual wheel loads are just as high, their lower total weight and trucks with shorter wheel base result in lower lateral rail pressures in high-speed operation.

Thermal Efficiencies

The theoretical maximum thermal efficiency of the Diesel-electric locomotive figured on the basis of energy developed at the rail is about 27 per cent, whereas the corresponding figure for a modern steam locomotive seldom exceeds 7 per cent, which would indicate a relative fuel consumption of about 1 to 4. This is somewhat altered for over-all performance by difference in weight of the two types of locomotive and difference in stand-by losses. It is difficult to find accurate comparative fuel-consumption data because the two types of power are not ordinarily used on similar runs. One comparison available is on a main-line fairly high-speed through train where steam power was superseded by Diesel-electric locomotives. The relative round-trip fuel-consumption figures based on a 12-month average on this run are as follows: Steam locomotives used 124 tons of coal; Diesel-electric locomotives used 3950 gal of Diesel oil. Based on the Btu content of the two types of fuel, these data indicate that the thermal efficiency of the Diesel-electric locomotives figured at the drawbar was 5.5 times that of the steam locomotives.

A careful check was made on another railroad to determine the relative amount of Diesel oil consumed by 3600 hp Diesel-electric locomotives and modern Pacific-type oil-burning steam locomotives, when pulling both light and heavy medium-speed main-line passenger trains on a 550-mile run. These data show the steam-locomotive oil consumption to be approximately four and one half times that of the Diesel-electric locomotives.

There appears to be little chance of improving the efficiency of the Diesel-electric locomotive except in the factor of transmission loss. There should be a possibility of marked improvement in steam-engine efficiency because of the many losses now involved. There has been a steady improvement in steam-locomotive thermal efficiency as indicated by the figures of the Association of American Railroads, which show that in 1920 it took 173 lb of coal to produce 1000 gross-ton-miles of freight transportation and 18.8 lb of coal per passenger-car-mile, whereas in 1938 these figures were only 113 lb for freight and 14.7 lb for passenger trains. A large part of this fine showing is undoubtedly due to improvements in steam-locomotive design and the reductions would be even greater if all the locomotives in service were of a modern type. Credit is due the designers for these improvements, which incidentally have been developed without the urge of competition from other types of power. Naturally under noncompetitive conditions the designers have been more or less bound by precedent. Conditions have now been changed. The young virile Diesel locomotive (whose designers were not swayed by precedent and who had at their disposal the vast amount of research data developed by the automotive industry) has reached a remarkable state of development in the short period of five years. This new competition should prove to be a spur and a benefit to the steam-locomotive designers, as is indicated by the numerous new designs which are mentioned elsewhere in this paper.

The Diesel designers had an advantage in connection with high-speed operation in that they started their development of road locomotives on the basis of high speed (top speed 118 mph). On the other hand, steam-locomotive designers focused their attention on the improvement of thermal efficiency and greater power development with top speeds of about 90 mph. Thus when the demand for high-speed operation developed so rapidly, their designs were not entirely adequate. This feature of high speed is the one which is now being given major consideration, and improvement should result.

Electric Locomotives

The modern electric locomotive is also a highly satisfactory type of motive power for high-speed operation, both from the viewpoint of capacity and effect on track structure. Early types had detrimental effects on track due to high lateral forces, but later designs have overcome this. The use of this type of power in this country has been limited, due to the fact that the

density of traffic on most railroads does not warrant the high cost of overhead construction. Where it is used for long-distance high-speed operation, as on the Pennsylvania Railroad, between New York and Washington and Harrisburg, it has shown excellent performance, but there appears to be little probability of electrification of less dense traffic lines, particularly those in the western part of the United States.

Operating Expenses

In 1938 Coverdale and Colpitts (2) issued a comprehensive report covering the results of their studies of operating costs and revenues of a majority of the streamlined trains in operation at that time. The cost data for the various railroads show such wide variations that it is difficult to arrive at a fair average figure for cost of operation of Diesel locomotives as compared with steam. Unfortunately, there are no roads on which comparable trains are operated with steam and Diesel-electric locomotives, so that there is no fair basis for comparison. However, a study of all the data in this report indicates that the cost of maintenance of a 3600-hp Diesel-electric locomotive is no greater and probably less than that of a modern steam locomotive of similar power, handling equal-weight trains on fairly comparable schedules. The fuel cost is approximately one half as much. The cost of crew wages is about the same, though it should be noted that on some roads a maintainer is included in the crew of Diesels for long-distance operation. This should not be necessary when firemen are fully trained in their work on this type of power. Lubrication costs (a lesser factor) are greater for Diesels than for steam locomotives. It is noticeable that the maintenance costs for Diesels are higher when the total load is much above 450 lb per hp.

The outstanding feature of this report is the large margin between gross revenue and net revenue (depreciation charges are not included). Most of the trains show net revenue over 50 per cent of gross revenue and in some cases this is as high as 75 per cent. These figures, are, of course, unduly favorable because of the omission of two important factors, namely, the overhead charges for depreciation and interest, and the item of track maintenance. The overhead in one particular case is shown in Table 6 of this paper. Even with the high mileage made by such trains, the overhead is a major item of expense because the first cost of these trains is high. As to track maintenance, it is well recognized that safe and comfortable high-speed operation necessitates a high standard of track maintenance. Furthermore high-speed operation, particularly with steam locomotives, increases the cost of maintenance, though no definite figures are available to determine such extra cost. It is a fact that large expenditures have been made, particularly on the western railroads to eliminate curvature and alter curves to make high-speed operation successful. As an example of this, it may be noted that one transcontinental railroad spent over four million dollars on such work during the last three years, and similar work is still under way. The total cost of these improvements should not be charged against the operation of the new trains for these changes also benefit the operation of other trains. Nevertheless, it must be admitted that there is a considerable part of this extra expense, which should properly be charged against the new trains to give a full picture of the financial results. If speeds are still further increased, this factor will become of even greater importance as more work of this kind will be necessary to make such schedules.

Coach-Type Streamliners on Long Runs

Table 6 shows a comparison of weights and operating costs between two streamlined trains operating in similar transcontinental service on one railroad. One of these trains is a first-class all-sleeping-car train and the other is an all-coach train. All of the data are prepared on the basis of full load of passengers which, of course, is not always the case. Estimated data are also shown for a train similar to the coach streamliner but with twice the capacity. All operating costs are taken from the Coverdale and Colpitts report (2).

TABLE 6 COMPARISON OF OPERATING COSTS FOR A FIRST-CLASS ALL-SLEEPING-CAR STREAMLINER AND AN ALL-COACH STREAMLINER

Item	First-class train	All-coach train	Estimated 10-car all-coach train
Number of cars	9	5	10
Number of Diesel power units	2	1	2
Horsepower of locomotive	3600	1800	3600
Total weight of cars, tons	482	248	496
Weight of power units, tons	287	147	287
Total weight of train, tons	769	395	783
Length of train, ft	890	473	970
Total salable seats or berths	121	156	312
Out-of-pocket cost per mile of operation[a]	$0.88	$0.68	$0.88
Train length per passenger (full load), ft	7.4	3.0	3.0
Car weight per passenger, tons	4.0	1.6	1.6
Train weight per passenger, tons	6.4	2.5	2.5
Out-of-pocket cost per passenger per mile of operation	$0.0073	$0.0043	$0.0028
Total yearly operation, miles	232,000	232,000	232,000
Total first cost of train	$1,110,000	$580,000	$1,160,000
Overhead cost per mile, based on 10 per cent of first cost	$0.48	$0.25	$0.50
Overhead cost per passenger per mile (full load)	$0.004	$0.0016	$0.0016
Overhead and operating cost per passenger-mile (full load)	$0.0113	$0.0059	$0.0047

[a] This cost does not include sleeping-car employees' wages or maintenance expense for sleeping cars.

It may be noted that the train weight per passenger for the first-class train is 6.4 tons, whereas for the coach train it is only 2.5 tons, which accounts largely for the higher out-of-pocket cost for the former. The overhead cost per passenger is more than twice as great. The total overhead and operating cost per passenger-mile is approximately twice as great for the first-class train as for the coach train. It is thus apparent that much lower rates can be charged on coach trains. This latter type of train has been remarkably successful in attracting passengers for this long run, although it involves their spending two nights on the road.

It is the coach type of train that primarily has the possibility of diverting traffic from private automobiles and buses to the railroads. Because of the low rates it also has the possibility of developing a large amount of new traffic among people in the low- and medium-income group, who are becoming more and more travel-minded and have more and more time available for such travel. There is almost no limit to the possibilities for development of this type of travel. People of this class want low-cost transportation with high speed and comfort. All of these are being provided in such trains.

The Coverdale and Colpitts report shows remarkably successful results from the operation of all of the high-speed streamlined trains. They have undoubtedly brought back to the railroads some of the lost traffic and give promise of developing new traffic.

It appears that these new high-speed trains, particularly those in the western territory are now operating at about the maximum speed, which is possible on the present track structure. The limitation to further increase in speed lies in the large number of rather sharp curves which are unsafe for too high speed and uncomfortable for passengers when taken too fast. The number of unprotected grade crossings is also a limitation, as well as speed restrictions through towns with grade crossings. It would be very expensive to correct all of these track conditions.

Outside of the passenger-traffic gain, these new trains have been warranted by the public interest which they have aroused.

TABLE 7 LIST OF HIGH-SPEED LIGHTWEIGHT STREAMLINED PASSENGER TRAINS

NOTE: Six more trains for various railroads are under construction at the time of preparation of this tabulation, and also a considerable number of lightweight cars for use in other trains.

Prior to their advent, there was a feeling that the railroads had not kept pace with developments as they should have, and consequently the public had less interest in their welfare. They are now much more favorably inclined and this may have an influence on future legislation.

Large numbers of new lightweight cars are now being added to main-line trains, and there is a gradual replacement of old types. The public demand for such cars is due largely to their many comforts and attractive appearance. There is every indication that there is a real revolution in American passenger trains. Table 7 shows a list of the high-speed streamlined trains now being operated on the railroads of the United States.

CONCLUSIONS

The streamlined high-speed passenger train has been definitely successful on American railroads in recovery of traffic, financial return, and mechanical performance. The number of such trains in service should continue to increase.

Both steam and Diesel-electric locomotives will pull these new trains, but the Diesels will predominate unless new designs of steam locomotives prove themselves better suited for the long high-speed runs than are the present types. There should be a continual improvement in the design details of Diesel-electric locomotives. Radically new designs of steam locomotives will probably be built to meet the high-speed operating conditions.

Schedules faster than those now being made are possible and probable as soon as roadway conditions are further improved by curvature reduction and grade-crossing elimination.

Discussion

T. R. Cook.[3] The writer agrees with the author's conclusions that the railroads have and can regain considerable of their lost passenger business by the adoption of better schedules and the provision of more comfortable passenger trains, and there is no question but that lighter construction is the principal fundamental factor involved.

As to whether these trains will be hauled by Diesel or steam power is a question which will be resolved by the economies of the situation. There are over 43,000 steam locomotives in existence in the United States, divided in the order of freight 65 per cent, passenger 17 per cent, and switchers 18 per cent.

It is quite evident that the major activity, that of hauling the freight will alone keep the steam locomotive on the rails for some years to come. A number of the railroads are coal carriers. It would, therefore, seem logical that the roads and the steam-locomotive builders, to say nothing of other investments in property and plants dependent upon steam, should constitute a sufficient urge to force the advancement of steam locomotives. There is no doubt but that there is room for improvement both in engineering and in operation of steam power.

As to the present situation of steam, the writer is doubtful of the superiority of the Diesel as indicated in the paper, particularly when the Diesel locomotive is considered as a prime mover. The author gives a thermal efficiency at the rail of 27 per cent for the Diesel and 7 per cent for the steam locomotive. The 27 per cent is correct for the Diesel, but 7 per cent in the writer's opinion is quite low for the modern steam locomotive.

A more interesting figure, however, would be a statement of the efficiency at the drawbar where the work is done, and not only at full load but at various load factors and at various speeds. We are dealing with types of power having entirely different characteristics. In order to make a comparative statement, the writer has worked out the thermal efficiencies of a modern 4-8-4 and a Diesel locomotive each of 5400 hp, through a range from 30 to 100 mph, and load factors varying from 100 per cent down to 40 per cent. The results indicate that the maximum efficiency of the Diesel is developed at 30 mph with 100 per cent load factor; this efficiency decreases as the speed increases and as the load factor decreases. The steam locomotive, on the other hand, generally increases in efficiency as the load drops and has higher efficiency at 80 per cent load at all speeds than at 100 per cent load; up to about 50 mph this increase in efficiency continues down to a 40 per cent load factor. It may fairly be assumed that, in high-speed passenger service, the load range is primarily between 60 and 80 per cent, at speeds varying from 50 to 70 mph. In the example taken in the ranges cited, the Diesel shows an efficiency of 22 per cent and the steam slightly over 8 per cent. This would indicate that the cost of the fuel in the normal range of unit prices would be about equal.

As to the cost of repairs, it is believed that the age of the equipment must be taken into consideration. The increased cost in repairs of steam locomotives with increasing age has been thoroughly demonstrated. The Diesel switcher has shown a greater rate of increase and, although there are no figures available, it is safe to assume that the Diesel road locomotive will show a similar increase.

The author in Fig. 1 shows comparative drawbar-horsepower curves of a steam versus a Diesel locomotive, stating that the curves are plotted from actual dynamometer-car readings. As a rule, dynamometer cars are placed in a given scheduled train and the readings taken show the resistance of the train under various conditions, but do not show the capacity of the prime mover at various speeds. The writer has found it of interest to compare the theoretical drawbar horsepower with that shown in the author's curves. His calculations indicated that the Diesel was operating below full load up to 80 mph and, thereafter, was working at an overload; while, in the case of steam, the locomotive was operating at full load up to 50 mph and was working considerably under capacity at higher speeds.

In Table 4 of the paper, in reference to steam power, what is

[3] Coverdale and Colpitts, Consulting Engineers, New York, N. Y. Mem. A.S.M.E.

the author's definition of "maximum indicated horsepower?" The indicated horsepower of a steam locomotive increases with speed up to a point where the steam-pipe valve and port resistance prevents the use of all the steam the boiler can evaporate.

Under the section on "Maintenance," it is stated that the cost of repairs of a steam locomotive is 20 cents per mile, and the comparative Diesel costs 17 cents per mile; the writer would like to know the age of both the steam and the Diesel units used in this comparison.

Under the section on "Thermal Efficiency," a comparison is made between Diesel and steam power. In one case, a ratio of 5.5 is shown and in another a ratio of 4.5. In the two instances was the work done the same, i.e., did the Diesel and steam locomotives haul the same-weight trains over the same tracks?

L. B. Jones.[4] The author quite properly calls attention to the attractive weight reduction made possible by the use of lightweight cars. Parallel with the development of lightweight

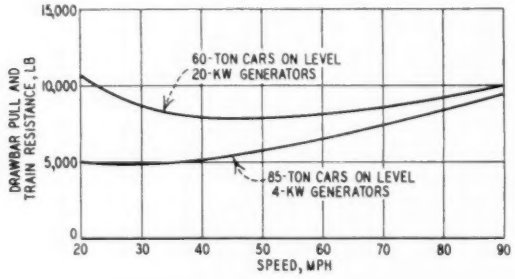

Fig. 4 Drawbar Pull Required for 12-Car Trains (85-ton cars, 1020 tons per train; 60-ton cars, 720 tons per train.)

cars, however, has come the development of mechanically driven air-cooling systems which offset any advantage the locomotive might realize from the substitution of lightweight cars in the train.

In Fig. 4, two 12-car trains have been assumed, one made up of 85-ton cars having 4-kw axle generators working to rated capacity, and another 12-car train of 60-ton cars, with 20-kw generators, generating at rated capacity. It will be noted that the drawbar pull required for the 60-ton cars is greater, up to speeds considerably in excess of 90 mph. The figures are for level track. On an upgrade, the lightweight cars would gain some advantage.

The development of heavy axle-generator loads has, therefore, robbed the locomotive of whatever advantages the lightweight cars offer in the way of drawbar pull. The development of air cooling has been very rapid, and sufficient consideration has not been given to a logical and comprehensive method of supplying the power necessary. As a starting point, it is suggested that a 440-v, 3-phase train line, powered from a small plant on the locomotive, would supply all necessary power for cooling and lighting at an over-all efficiency probably double that of individual axle-generator units. Storage batteries could also be reduced to about 1/4 of their present size, and kept charged through a small automatic rectifier. Stand-by service would be provided in large terminals, as is now done with steam heat.

Reference is made to the lower center of gravity of Diesel-electric locomotives, with higher possible speed on curves. This is no doubt true as regards speeds at which the locomotive will upset, but there have been cases where it was necessary to raise the center of gravity of electric locomotives in order to prevent serious lateral forces which pushed the track out of line or overturned a rail. In Figs. 5 and 6, curves have been plotted showing the maximum possible speed of stability of a locomotive on a 6-deg curve. Fig. 5 shows a curve with 5 in. superelevation and Fig. 6 a curve without superelevation.

While the speed required to upset the locomotive increases rapidly with reduced center of gravity, it will also be noted that the speed required to overturn the rail has the opposite trend, and the two curves cross at 98 mph in Fig. 5. These curves are plotted on the basis of centrifugal force only. When we consider the maximum forces resulting from nosing or lurching of the locomotive, it is evident that too low a center of gravity can create dangerous lateral pressure on the rail, and therefore the advantages of a low center of gravity must be circumscribed.

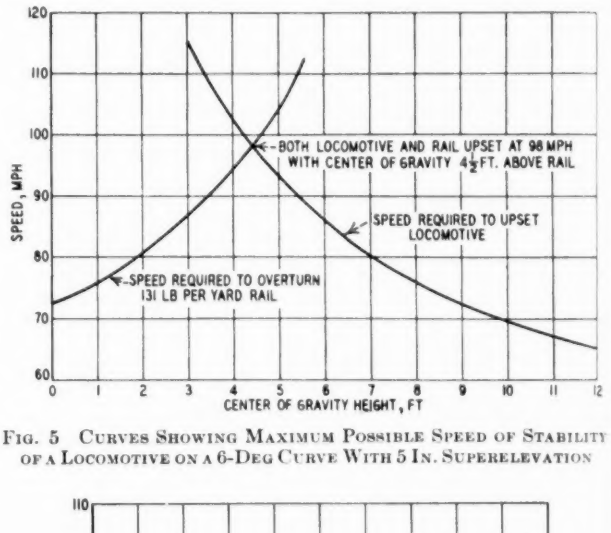

Fig. 5 Curves Showing Maximum Possible Speed of Stability of a Locomotive on a 6-Deg Curve With 5 In. Superelevation

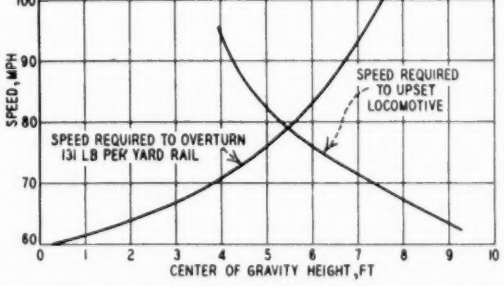

Fig. 6 Curves Showing Maximum Possible Speed of Stability of a Locomotive on a 6-Deg Curve Without Superelevation

Data are presented in the paper showing rail stresses under a steam locomotive in comparison with a Diesel. Omitting the steam-locomotive drivers for the moment, and considering only the engine and tender trucks, which are not subjected to dynamic forces, it will be noted that the rail stresses under the locomotive trucks increase much more rapidly from 5 to 100 mph than the stresses under the Diesel-locomotive trucks. It is not apparent why rail stresses should increase more rapidly with speed under a locomotive-tender truck, for example, than they do under a Diesel-locomotive truck.

Considering now the locomotive driving wheels, it will be noted that the minimum rail stress under the main wheel at 100 mph is only slightly less than the stress due to static loading at 5 mph (it is assumed that at 5 mph no dynamic stresses are noticeable). In most 2-cylinder steam locomotives which have been tested, there is a definite tendency for the main wheels to leave the rail

[4] Engineer of Tests, The Pennsylvania Railroad, Altoona, Pa. Mem. A.S.M.E.

at a speed of 100 mph and, although with well-balanced locomotives no lifting actually occurs, the rail stress at one point of the revolution should be very nearly zero. This raises the question whether the strain gages used were sufficiently sensitive to record the actual stress variations. If average figures were used in plotting the vertical stresses, this might explain the tendency to level off the variations throughout one revolution.

While there can be no challenging the author's statement that future development of the steam locomotive should look toward reduction of the dynamic augment, it seems only fair to observe that the comments on undesirable dynamic behavior have been based upon the performance of a few locomotives, whereas hundreds of other steam locomotives are handling fast schedules every day without any symptom of trouble. We recently conducted a series of tests in which several locomotives were slipped on greased track up to speeds very much in excess of their maximum operating speeds and, while the dynamic effect was definitely noticeable, there was no trace of rail damage in 100-lb rail on cinder ballast, and the rail stresses recorded were not excessive. The only precaution taken in connection with the locomotives tested was that the counterbalances were precisely checked in advance of the tests, as well as the quartering and tramming of the locomotive wheels.

A. I. Lipetz.[5] There is a common but unjustified notion that a Diesel-electric locomotive has the advantage of greater acceleration as compared with a steam locomotive. This is a remnant of the common theory that the electric locomotive provides quicker acceleration than the steam locomotive. In this consideration, the fact is overlooked that the electric locomotive usually draws power from an outside source to about double its nominal power at low speeds. However, this is not true for the Diesel-electric locomotive, in which the electric feature lies only in the transmission, not in the generation of power. The advantage of the Diesel-electric locomotive is in the magnitude of the tractive effort only at low speeds, since the power is always limited by the power of the Diesel engines and by the greater number of drivers which are carried on the locomotive chassis, just as the power of the steam locomotive is limited by that of the boiler on the locomotive frame and its number of drivers. Thus, the author's statement regarding the "rapid acceleration (of the Diesel-electric locomotive) because of the high tractive power at lower speeds" may be literally correct, but can be misleading if the speeds to which this applies are not given. This advantage of a Diesel locomotive is of comparatively short duration and is not of the same order, as in the straight electric locomotive with an outside source of power. In order to evaluate this advantage, a more accurate and detailed calculation is necessary. This has been done and is presented in Fig. 7.

Referring to Table 4 of the paper, the steam locomotive shown in the third column is the one discussed by the author. The maximum indicated horsepower is given as 4300, and the graph, which is shown in Fig. 1, gives the drawbar horsepower, both for a steam and some Diesel locomotives. The steam locomotive is referred to as a modern locomotive of the 4-6-4 type. Regarding the drop of the horsepower shown in the curve, it is explained that this can be improved if a change both in the design of the valve and the valve gear is made. Fig. 7 also refers to the 4-6-4-type steam locomotive of the New York Central of a lighter design but, nevertheless, of 4700 ihp, built for high speed with this very improvement in the valves; the steam curve is taken from actual tests.

The drooping characteristic of the horsepower curve of the

[5] Chief Consulting Engineer, American Locomotive Company, Schenectady, N. Y. Fellow A.S.M.E.

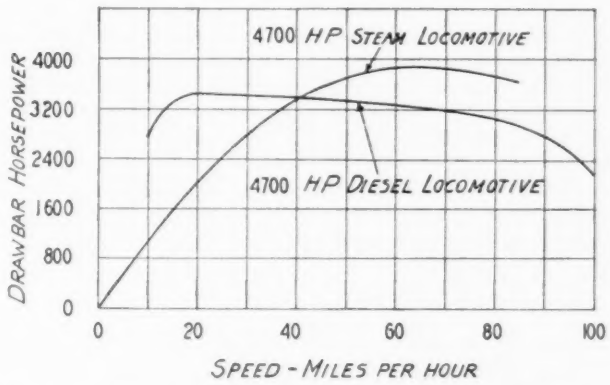

Fig. 7 Comparison of Drawbar Horsepower of Steam and Diesel Locomotives of Identical Indicated Horsepower

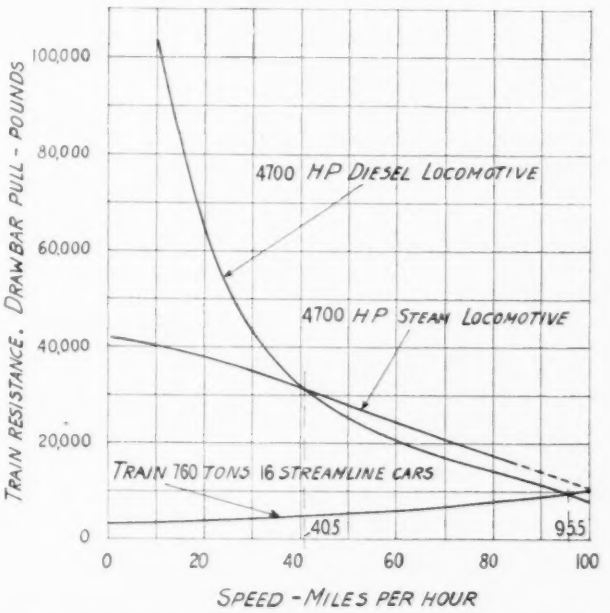

Fig. 8 Tractive Effort in Relation to Speed in Miles Per Hour of Steam and Diesel Locomotives of Identical Horsepower

steam locomotive of Fig. 1 has been corrected in Fig. 7; the part of the curve at high speeds has a flatter appearance. Furthermore, the weight of the locomotive with a fully loaded tender is given in Table 4 of the paper as 809,000 lb. For the 4700-hp steam locomotive it is only 674,300 lb and, therefore, the weight per horsepower, instead of being 188 lb as shown in Table 4 is only 144 lb. Moreover it should be noted that the steam locomotive is not running all the time with its tender fully loaded and, therefore, has the advantage of reducing its dead weight; this remains practically constant in a Diesel locomotive. However, this slight advantage of the steam locomotive will be disregarded and the resistance will be based upon the weight of the locomotive with fully loaded tender as given, namely, 674,300 lb. The maximum drawbar horsepower of the 4700-hp steam locomotive is 3880 hp, as established by very elaborate tests[6] of the New York Central.

[6] "New New York Central Locomotives Show High Power Concentration," *Railway Age*, vol. 104, 1938, p. 601. Also: "The New York Central Receives 50 Powerful 4-6-4 Locomotives," *Railway Mechanical Engineer*, vol. 112, 1938, p. 173.

As to the Diesel-electric locomotive shown in the second column of Table 4, the power of the Diesel engines is only 4000 hp and the maximum drawbar power is 2950 hp, against 3880 for the steam locomotive. In fairness to the Diesel-electric locomotive, which the writer will compare with the steam, the drawbar power given by the author in Fig. 1, from actual dynamometer tests of the 4000-hp Diesel locomotive, should be increased in proportion to the maximum indicated horsepowers of the steam and Diesel locomotives; in other words, for the Diesel-electric locomotive, the maximum drawbar power should be

$$2950 \times \frac{4700}{4000} = 3465 \text{ hp}$$

It is only fair to the Diesel-electric locomotive to assume that the Diesel power is equal to the indicated power of the steam locomotive, since both must be multiplied by the efficiency of power transmission and mechanical efficiency of the chassis, in order to arrive at the drawbar powers. Thus, we are impartially comparing a steam and a Diesel locomotive of identical maximum indicated horsepower, which is 4700 in either case, by studying their corresponding drawbar-horsepower curves.

Fig. 8 shows the tractive efforts in pounds in relation to speed in miles per hour for these two locomotives of identical maximum horsepower. The advantage of the tractive effort of the Diesel locomotive at low speeds is evident from this illustration. It is true that, due to the electric transmission there is an advantage in developing greater tractive effort than with the steam locomotive for all speeds below 40.5 mph, but the difference between these two curves drops very rapidly and is negative at speeds above 40.5 mph.

Also in Fig. 8 is shown the resistance of a 16-car lightweight streamlined train weighing 760 tons, or 47.5 tons per car. This is what the Diesel-electric locomotive would be able to pull on level track at high speed. The balancing speed of the Diesel-electric locomotive is about 95.5 mph on the level. For the steam locomotive it is slightly higher, about 101 mph, because of greater sustained power at high speed.

The acceleration curves of these two trains are shown in Fig. 9. From the comparison, it may be observed that the intersection point of 40.5 mph is reached by steam in 2 min 10 sec within a distance of 0.75 mile, whereas the Diesel will do it in 1 min 16 sec in a distance of 0.51 mile. The Diesel will thus gain 54 sec and 0.24 mile. But, we are concerned here with performances at higher speeds than 40.5 mph and, if we continue beyond 40.5 mph, we shall be gaining time with steam; in fact, the steam locomotive will reach 95.5 mph in 10 min 17 sec from the start, while the Diesel will take 15 min 20 sec to attain this speed. In other words, the Diesel will lose the 54 sec which it gained at the start before reaching the intersection point of 40.5 mph, but will lose an additional 4 min 9 sec, showing a total loss from the start of 5 min 3 sec, just contrary to what might be expected. Every time the train is slowed down (due to speed restriction) to a speed about 40.5 mph and accelerated again, the total gain in time, in the case of the steam train, will be increasing cumulatively.

It is interesting to note that L. Dumas, assistant director of the French National Railway, who has had considerable experience with Dieselized streamlined trains, made a special report,[7] in which he gave a summary of three different reports before the International Railway Congress Association. In this report he also made a statement concerning the advantage of quick acceleration of trains due to Dieselization with electric transmission, as compared with steam locomotives, but confined his remarks to trains with electric-motor coaches, essentially rail cars, and high-speed trains of the German and French types, in which the ratio of Diesel power to the weight of the cars is very high. The acceleration is, therefore, due not to the electric transmission, but to the high power-to-weight ratio, which is lacking in the American high-speed trains with sleeping accommodations.

In connection with the author's remark that the performance of the steam locomotive, especially of modern type, depends largely on the engineer and is subject to increased efficiency and capacity, an interesting incident demonstrating this fact occurred on the Chicago, Milwaukee, St. Paul & Pacific on November 18, 1939. On one of the new class F-7 locomotives of the 4-6-4 type, which is now operating fast heavy trains out of Chicago, something went wrong and the locomotive was cut out at Milwaukee.

A 4-4-2 *Hiawatha* locomotive, which is lighter and less powerful than the 4-6-4 regular locomotive, was put on in its stead and pulled the 10-car train, weighing approximately 1,000,000 lb from Milwaukee to Minneapolis, bringing it in on time and making up almost the entire delay of 22 min; the train arrived at St. Paul only 2 min late. It is interesting to note that originally the *Hiawatha* was designed to pull only 6 cars weighing 700,000 lb, but lately has pulled 8 cars of corresponding weight. A Diesel locomotive would meet its requirements only, and no more; it does not have the flexibility of the steam locomotive.

Referring to the matter of counterbalancing, discussed in the section on "Track Stresses," there can be no doubt but that the steam locomotive is at a disadvantage as compared with any other locomotive without dynamic augment, such as Diesel-elec-

[7] "Methods Used to Speed Up Passenger Trains, and Resulting Expenditure," Special Report by L. Dumas, Bulletin of the International Railway Congress Association (English edition), July, 1939, pp. 661–663.

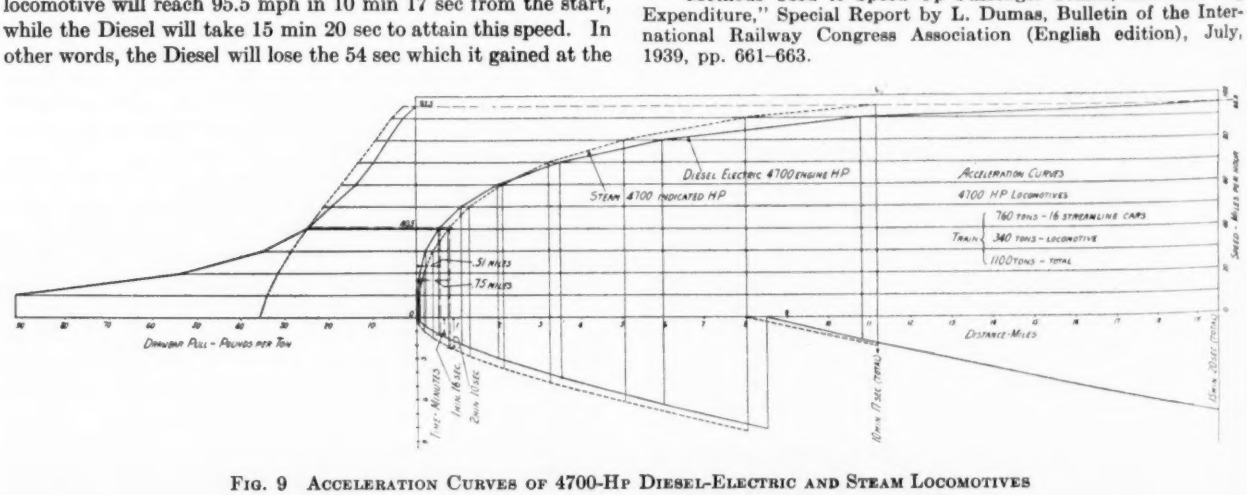

FIG. 9 ACCELERATION CURVES OF 4700-HP DIESEL-ELECTRIC AND STEAM LOCOMOTIVES
(Train composed of 16 streamlined cars, 760 tons; locomotive 340 tons; total 1100 tons.)

tric, turbine, or straight-electric. However, the examples given in the paper are not fully convincing; first, because the steam locomotive in question was heavy, 71,570 lb on the first driving axle, as compared with 50,700 lb on the fourth driving axle of the Diesel-electric. Furthermore, the locomotive, as may be judged from Fig. 3, was dynamically counterbalanced, or as we call it, cross-balanced, only on the main wheel, which was the second driving wheel. The front and back wheels were statically balanced. The percentage of balancing is not given and it is natural that the dynamic stresses in the rail should be greater for the steam locomotive. It is remarkable that, with all the handicaps of this steam locomotive, the difference is so small; the maximum rail stress is 19,000 lb for the steam locomotive at a speed of 100 mph as compared with 17,000 lb for the Diesel-electric at the same speed, or an increase of 12 per cent for the steam; much less than the increase in static weights, which is 41 per cent. For the Diesel-electric locomotive, the maximum at 100 mph is about the same as for the tender of the steam locomotive, although the weight on the tender axle is still about 30 per cent greater. This proves that the dynamic augment of the steam locomotive is not so grave as it is usually represented; it is the static weight which matters most, probably due to the element of time.

The old-time track and bridge engineers were mainly concerned about the static weight per axle. It is only recently, when the balancing of locomotives became better known and understood, that the dynamic stresses in rails began to bother them, especially when improperly evaluated.

The questions of track stresses and of counterbalancing of locomotives had a very peculiar history. Without going into details, it is enough to say that only lately proper attention is being paid to the question of counterbalancing of steam locomotives.

With the old-time counterbalancing, speeds up to 80 mph could be easily obtained. Hammer blows as high as 15,000 lb per wheel and more, which would kink and break rails, were evidently tolerated on a great many railroads. The track was simply built very stiff so the locomotives could run at these speeds. As one engineer expressed it, the "anvil" was strong enough to stand the "hammer blow." However, when the electric and the Diesel-electric locomotives came into being and proved their superiority for track conditions and their maintenance, the steam-locomotive engineer became cognizant of the unfitness of the old-time steam locomotive to modern high-speed conditions. Cross-balancing and lighter reciprocating weights, to which 15 years ago no one would listen, became very popular.

To a great extent the question of adaptability of steam locomotives to high speeds depends upon designing the locomotive so that it may have good tracking conditions at high speeds. American locomotives, especially of the type with front and rear trucks, have been very well suited to good negotiation of curves at high speeds. This partly eliminated the necessity of paying much attention to proper counterbalancing of locomotives. The recent development of lateral-motion and cushioning devices in locomotives was also a great help in this direction.

It is now possible to build locomotives with very small overbalances on wheels and, consequently, small hammer blows. Although it may not yet be possible to bring it down to zero, as was done on the Madras & Southern Mahratta Railway of British India, an improvement in track stresses, nevertheless, would result from the small overbalances, if the percentage of balancing is reduced to a figure close to zero and compatible with the shaking forces of light reciprocating weights in modern steam locomotives.

Wide discussion is taking place concerning the low center of gravity of some trains and Diesel-electric locomotives, as compared with the high center of gravity of steam locomotives, although nothing is pointed out as to what kind of disadvantages may result from the high center of gravity of the steam locomotive. This question was investigated years ago by many locomotive designers. In the 1870's, it was even proved experimentally that the high center of gravity is an advantage because it stabilizes the locomotive at high speeds. Of course, on curves, the centrifugal force may overturn a locomotive, if proper care is not taken in the design, but if the correct track elevation is made and the centrifugal forces are thus neutralized, nothing will happen on a properly designed and maintained track. However, the locomotive will run more smoothly.

It should be remembered that any train, even on first-class track, is subjected to violent vibrations due to the unevenness of the permanent way, its discontinuity due to rail joints, the resiliency of rails, ties, and ballast, and that a certain limit of speed must be set for any train with any locomotive—steam, turbine, Diesel, or electric, on a flexible track.

In a recent paper,[8] F. G. Gurley, vice-president of the Atchison, Topeka & Santa Fe Railway, predicted speeds of 140 to 150 mph and indicated the motive-power equipment which would satisfy this condition. He even saw some possibilities for the steam locomotive, but, of course, had no doubts about the Diesel-electric locomotive at those speeds. As far as the writer is concerned, the figure of 150 mph cannot be accepted for any locomotive on any track until by actual experience the possibility of these high speeds is proved. It is not known that they are wanted for rail transportation.

It is interesting to note that electric locomotives on the Pennsylvania Railroad, which has first-class track, the heaviest in the world, are limited to 90 mph and are permitted to run at this speed only because their weight per axle is comparatively low.

Modern steam locomotives, properly cross-balanced on all axles, with cushioning devices on properly selected axles, can easily run at 100 mph, and have already proved their riding qualities at 115 mph. In fact, abroad, a steam locomotive developed 125 mph in the presence of the London Institution of Locomotive Engineers. References to this trip have been widely published.[9]

Speeds at 100 mph with steam locomotives are now not unusual in this country. There is no doubt in the writer's mind but that the steam locomotive can meet any higher speed, limited only by the speed of cars, obtained by any other type of locomotive.

In discussing the economics of the problem, the author in Table 6 gave us a comparison of operating costs between two streamlined trains in transcontinental service on one railroad. He also referred us to the well-known report prepared by Coverdale and Colpitts (2). He mentioned, however, that interest and depreciation charges have not been taken into account by these analysts.

This comparison has been completed by the writer by adding several more trains to Table 6, and by trying to figure out from various sources the cost of streamlined trains, using for this purpose a paper[10] by E. E. Chapman on the subject. The results of this comparison are given in Table 8. Several representative streamliners, like the *City of San Francisco*, *Denver Zephyr*, and *Hiawatha*, have been added and the table is complemented by the cost of locomotives and cars, fixed charges per year on the basis of 10 per cent of interest and depreciation, the income per train-

Period of amortization in years	2.58	2.17	3.85	2.83	1.69	1.86	1.98	3.72	2.56

mile (net revenue less fixed charges), and amortization of the investment.

A study of Table 8 is illuminating. The number of cars is greatest only in the case of two trains, namely, in that of the *Daylight* on the Southern Pacific (14 cars) and the *City of San Francisco* on the Union Pacific (also 14 cars). The gross revenue of these two long trains amounts to more than $4 per train-mile, irrespective of whether Diesel or steam, thus indicating the obvious fact that the gross revenue depends upon the number of passengers, which naturally is greater on the longer trains. To the same class of large-revenue trains belongs the Milwaukee *Hiawatha* steam train, which has only 9 cars. This is due to its great popularity. All the Diesel trains, except the *City of San Francisco*, earn less gross income per mile.

The percentage of net revenue to gross is about the same in all streamliners (60 to 70 per cent), but the greatest is the *Hiawatha* (74.1 per cent), except the *Denver Zephyr* (included in the Burlington *Zephyrs*) for which it is 75.1 per cent. This is because the mileage of this train is very high, being more than double that of the *Hiawatha*. The return on investment, however, is lower.

The costs of the trains are, of course, different, the greatest being that of the long steam and Diesel-electric trains, especially the Diesel. This, of course, reduces the net revenues by the amount of fixed charges, making the income per train-mile lower for the Diesel trains. Only the steam *Daylight* and the steam *Hiawatha* show high incomes, above $2.50 per mile. The steam *Ann Rutledge* makes only about $1 per train-mile, probably due to traffic conditions. The total income per train-mile is figured, and the total per year is then referred to the investment. It will be seen that again the highest figure is for the *Hiawatha*, the cost of which is paid up in the shortest time, a little over $1^1/_2$ years.

The return on the investment of all these trains, both steam and Diesel-electrics, is not only the result of their utilization, especially the latter, but also a result of the comparatively low costs of the steam locomotives. In some cases the Diesel-electrics show remarkable mileage, as, for instance, the *Denver Zephyr*, which makes 1036 miles daily. However, but few trains, even in this country, have such a long run and can show such a remarkable utilization, which, after all, depends also upon the convenience of schedules, location of cities, meeting points, turnover of locomotives, and other factors. Therefore, the writer does not think the author's conclusion that Diesel trains will predominate is at all obvious, because to a great extent the success of Diesel trains is the result of novelty, streamlining, comfort, air conditioning, special service, etc., all of which are obtainable with steam trains and are matters of competition. In the long run the preference is given on economic grounds, as pointed out by Mr. Gurley,[8] if the engineering of the product is right. There is nothing inherently wrong in the design of the steam locomotive, and this type of prime mover may be further perfected for high speed.

The writer agrees with the second part of the author's conclusion in which he states that radically new designs of steam locomotives will probably be built to meet high-speed operating conditions. He enumerates the possibilities. It should be added that the combustion-gas-turbine locomotive of Brown, Boveri & Company looms now on the horizon, and although it is not strictly a steam locomotive, it can be built with direct drive, which has been spelling the success of the steam locomotive for over a hundred years. Furthermore, it has no dynamic augment. So far, the steam locomotive has been able to meet new conditions in similar circumstances.

Of course, we cannot foresee the future. But there are no indications which would point away from the locomotive with direct drive.

K. F. Nystrom.[11] In the cost of operation of lightweight trains, it is necessary to include the initial cost of the power plant and cars. In the writer's opinion the costs of steam locomotives and passenger-train cars, at the present time, are entirely too high, as the railroads, and particularly the builders, have failed to standardize on designs. It is appreciated that different operating conditions exist. However, both steam locomotives and passenger-train cars might be standardized to a point where the cost would be substantially reduced. If we are to continue making inroads on the private automobile and recapture passenger business for the American railroads, considerably greater economies will have to be made so that railroad fares can be placed at a popular-price level.

Much has been done in regard to reduction in weight of passenger-train cars, however, much remains to be done. Trucks under passenger cars delivered to railroads this year weigh 34,000 to 36,000 lb per carset. This weight, considering the total weight of the car, is too high. At the present time, one railroad is experimenting with a truck which will not weigh more than 25,000 lb per carset and appears to offer some decided advantages.

The author of the paper commented on the change in the Railway Post Office Department specification as follows: "This change will probably result in the addition of more material than is now used in center sills of lightweight cars designed with high center stills and buffers, with little compensating benefit from

[11] Chief Operating Officer, Chicago, Milwaukee, St. Paul & Pacific Railroad Company, Milwaukee, Wis. Mem. A.S.M.E.

added protection." The author, in his modesty, failed to mention that under his supervision a design[12] of passenger-train car was developed by the Federal Co-Ordinator of Transportation. This design was developed after exhaustive studies had been made and met all the requirements of the Railway Post Office Department's specification then existing. The estimated weight of this design was 96,900 lb and in the writer's opinion would have been entirely satisfactory.

Unfortunately, the Association of American Railroads prematurely adopted the so-called "tight-lock coupler" before a satisfactory application was developed, with the result that the car builders abandoned the conventional practice which had been in vogue for more than 20 years and lowered the center sills, taking all the stresses on the coupler instead of on the buffer and coupler. This change created an undesirable condition when new cars were coupled with older-type cars. To correct this condition, the specification for passenger cars was hastily changed and it is the writer's strong conviction that this specification is causing an undue penalty when employing material other than low-carbon or so-called high-tensile steel.

Three passenger cars were recently built for one railroad by three different carbuilders, one employing high-tensile steel, the second, stainless steel, and the third, aluminum. All three cars weighed substantially the same. The writer is satisfied that the reason for practically the same weight was not that one concern applied greater engineering skill than the other, but was solely due to arbitrary deflection requirements in the new specification. The foregoing is, in the writer's belief, substantial proof of the inconsistency in the existing specification and it is hoped that the Association of American Railroads will not stand in the way of progress, but correct this inconsistency.

J. W. Ragsdale.[13] The author cites the case of a 79-ft coach which weighs 97,000 lb. To the uncalculating reader this weight may appear to be at variance with the weights more recently published (6). These figures approximate 104,000 lb. One is apt to overlook the additional statement that they also refer to coaches having a length of 84 ft 8 in. The difference in weight and the difference in length are almost exactly proportional.

The author also refers to the Association of American Railroads specification which emphasizes the strength of the center sill in car construction. He does not mention the novel requirement that deflection may govern instead of ultimate strength. While the writer is absolutely in sympathy with the spirit which inspired the new A.A.R. specification and with all of its other requirements, he has differed on this matter of deflection. It penalizes the use of high-tensile steels such as stainless steel and it penalizes the Budd type of construction. On the basis of strength alone, a stainless center sill of 8 sq in. would be sufficient. We are now using as much as 18 sq in. If we "floated" the center sill instead of making it an integral part of the structure, we could meet the strength requirement with 8 sq in. and have absolutely no deflection of the car body at all. But, this member should be made to serve a general structural purpose rather than to be a mere part of the draft gear. This belief costs us 2200 lb. This weight might be used to better advantage elsewhere.

After all, it is the resiliency of a structure which counts, not its deflection. An 800,000-lb end loading presumes a crash. A resilient structure might better withstand this crash than an absolutely rigid one. The A.A.R. limits the deflection under this loading to 1 in. or less. A truly resilient car structure might hump up in the middle as much as 4 in. and yet suffer no damage other than to the trim. When we have a wreck, trim is of small consideration compared to passenger safety. The writer, therefore, is opposed to the deflection clause of the A.A.R. specification.

Another phase discussed by the author, and again in the interest of safety, relates to braking. He indicates that any increased braking must automatically involve some means of sanding. While this is quite true, the writer wishes to point out that wheel locking results largely from the peaks of the braking-torque curve and that these peaks are far more pronounced with a metal shoe-to-wheel braking than they are with the disk type of braking, such as has been developed by the company with which he is connected. The eventual development may well be not only disk-type braking but automatic sanding and a torque control.

E. W. Test.[14] The writer wishes to discuss several points, particularly the references involving stainless steel in comparison with the low-alloy high-tensile steels in car construction. The author states: "While it is true that the full use of the superior physical properties of stainless steel or the lightweight of aluminum is limited to some degree by deflection requirements, it should be possible, by using these materials instead of low-alloy steel, to construct a lighter car of equal strength."

The writer is prompted to discuss this statement, principally in view of the publicity which has been given stainless steel, in which the virtues of the metal have been widely heralded to the complete exclusion of its eccentricities. It is felt that, in an engineering discussion of this kind, utmost care should be exercised not to foster any questionable ideas which may have been implanted in the minds of readers by an overzealous publicity effort. Most readers do not have the opportunity carefully to study this enormous flow of publicity, hence, the value of such engineering papers as the present one.

The author's statement might be accepted without question by many, if consideration were given only to those physical properties of stainless steel which are superior. Tensile strength is the property which has been generally overemphasized, not only in the case of stainless steel, but of other metals as well.

A study of the tensile properties alone either of stainless steel, high-tensile low-alloy steel, or mild steel, as the basis for the selection of a material for passenger-car construction, is not the proper approach to such an important problem. A material with 4 times the tensile strength is not 4 times as strong. The word "strong" must embrace all the properties of a metal and the quality of each must be such that the metal will not fail under any of the conditions in which it is to serve.

A very important requirement of a metal, if it is to be used in a structure, is that it have high compressive-stability properties. Dr. C. S. Aitchison and Dr. L. B. Tuckerman of the National Bureau of Standards, in the introduction of their report No. 649 to the National Advisory Committee for Aeronautics, clearly expressed this idea as follows:

"During recent years, a remarkable expansion has taken place in the use of thin sheet and thin-wall material in lightweight structures, such as airplane wings and airplane fuselages. The strength of these structures is generally limited by the strength of certain members carrying compressive loads. These members have frequently been designed on the basis of the tensile properties of the material. This is convenient as the tensile test is relatively simple and is widely used. However, it may lead to an unsafe structure, on the one hand, or an uneconomical structure,

[12] "Design of Typical Lightweight Coach," Report of Mechanical Advisory Committee to the Federal Co-Ordinator of Transportation, Washington, D. C., 1935, pp. 597–678.

[13] Chief Engineer, Stainless Steel Division, The Edward G. Budd Manufacturing Company, Philadelphia, Pa.

[14] Assistant to President, Pullman-Standard Car Manufacturing Company, Chicago, Ill. Mem. A.S.M.E.

on the other hand, if the compressive properties of the material differ from the tensile properties. There is an urgent need for a method which makes possible a direct determination of compressive stress-strain graphs for thin-wall material."

Any material offered for lightweight car structures comes in this category and it is essential that the compressive stress-strain ratio of these materials be satisfactory so that sufficient stability may be assured. In case of a wreck, which must always be considered in the design of railway passenger cars, substantially every structural member may be called upon to resist high compressive stresses.

It is a well-known fact, at least for the last several years, that compressive tests on 110,000-lb per sq in. yield strength 18-8 stainless steel show a drop in the modulus of elasticity to 22,000,000 at stresses as low as 44,000 lb per sq in. At 57,000 lb per sq in. stress, the modulus of elasticity has dropped to 19,000,000. In other words, a very important factor with reference to the ability of the metal to stand up as a column has been reduced in the ratio of 29 to 19, as the unit compressive stress was increased from zero to 57,000 lb per sq in. Compressive tests further reveal that, long before the stress has reached the alleged yield point of 110,000 lb per sq in., the modulus of elasticity has dropped to 12,000,000. Incidentally, under increase of tensile stress, test samples also show a reduction of the modulus of elasticity. At a tensile stress of 88,000 lb per sq in. the modulus of elasticity has decreased to 22,000,000. This is the disappointing quality of stainless steel which is revealed by stress-strain graphs. It is a major deficiency and it must be a limiting factor in the design of a structure using this material.

We are not unmindful of the many good qualities of stainless steel but these, including its superior tensile strength, cannot be used to offset the deficiencies when the material is called upon to resist buckling, in which case the low and variable modulus of elasticity becomes the weak link in the otherwise strong chain.

A theoretical conclusion as to the weights of structures, based upon a comparison of the known properties of the metals involved, is at the best a precarious adventure, particularly so in the case of a passenger-car structure. It has been difficult, as the author stated, to make accurate weight comparisons of the different types of structures used in passenger cars because of the dissimilarity in specifications.

We have, however, one comparison available, which probably has been published since the paper was prepared. The following statement is quoted from the article[15] in question:

"Early in January the Pennsylvania ordered 15 dining cars, 5 from the Pullman-Standard Car Manufacturing Company, 5 from the Edward G. Budd Manufacturing Company, and 5 from the American Car & Foundry Company. All of the cars are built to the same general specifications and are believed to represent the first instance in which three dissimilar sets of materials and techniques of construction have been so employed."

In this instance, the stainless-steel car was approximately 5000 lb heavier than a similar car with a structure of low-alloy steel:

Stainless steel: 118,170 lb; designed and built by Edward G. Budd Manufacturing Company. Low-alloy steel: 113,240 lb; designed and built by American Car & Foundry Company.

It is felt that the author has dismissed too lightly the economic aspects of the stainless-steel car. If there have been instances where bids on cars with stainless-steel structures, including the variety of equipment, accessories, and trucks, have by some method been reduced to the total price of other cars having low-alloy-steel structures, it would appear that this total car price is of little significance in an engineering analysis of the relative costs of the two body structures. The cold facts are that stainless steel costs 30 to 40 cents more per lb than the low-alloy steels. If no decrease in weight can be obtained by the use of the high-priced metal, the body structure alone will be penalized for material only, as much as $8000 to $10,000 per car. Recent competitive bids have fully reflected this differential in cost of materials.

It has not been the writer's purpose to advance the opinion that stainless steel is not a suitable material for passenger-car structures. By the recognition of its deficiencies it can be successfully used. We doubt the possibility of producing a car of stainless-steel structure which will weigh less than a car of low-alloy high-tensile-steel structure and which will be of equal strength. Even though high-tensile stainless is nowhere used structurally in any important way in vehicles engaged in major transportation, except in the case of railway passenger cars, it is believed that no one disputes the propriety of such use. The one question in relation to its use is that of economics, namely, as to what it may prove to be able to do toward cheap maintenance in order to justify the substantially higher investment.

J. R. Thompson.[16] The writer has been with the Bureau of Valuation of the Interstate Commerce Commission since the valuation work started in 1914, and has also been assigned to cooperate with the Depreciation Section of the Bureau of Accounts since the depreciation order affecting equipment was put into effect in 1934. In this connection, they have been interested in the service life of all railway equipment in the United States and, in recent years, particularly in the new designs of locomotives and passenger-train cars. Therefore, it will be helpful if the author in his closure will comment further upon the life expectancy which modern Diesel locomotives and lightweight passenger-train cars may attain.

Victor R. Willoughby.[17] The A.A.R. passenger-car specification, wherein additional strength in the end portion of the center sills and the end sills is required, is in the writer's opinion a very necessary requirement, especially where the new lightweight equipment is operated in the same trains with the old heavier equipment having high center sills. It is true that this adds considerable weight to the underframe of the car but this additional weight is in the proper place and is of material value at the time of an accident. The author states that no cars exactly similar in type but of different materials and construction had been built.

Recently there has been built a lot of 15 dining cars;[15] 5 using aluminum, 5 using stainless steel and 5 using low-alloy high-tensile steel. These cars were all constructed to the same strength specifications, practically the same floor plans, and very similar equipment.

The interior design of the stainless-steel car added about 700 lb to its weight, as compared with the low-alloy high-tensile-steel car. The differences in specialties amounted to a saving on the stainless-steel car of about 200 lb, making a net weight credit for the stainless-steel car of 500 lb. The trucks were supposed to be identical. The dry weight of the stainless-steel car was nearly 5000 lb more than the low-alloy high-tensile-steel car, meaning that after adjustment, because of interior equipment and finish, the stainless-steel car weighed about 4500 lb more than the low-alloy high-tensile-steel car.

It is the writer's opinion that the modern passenger car, with

[15] "Pennsylvania Receives Diners From Three Builders," *Railway Age*, vol. 107, 1939, p. 469.

[17] Vice-President in charge of Engineering, American Car & Foundry Company, New York, N. Y. Mem. A.S.M.E.

an over-all length of about 85 ft, meeting all the strength requirements of the A.A.R. specification, when equipped with 4-wheel trucks, will weigh in the neighborhood of 108,000 lb.

The most important problems, which yet require solution, are better riding trucks and improved braking.

W. E. Woodard.[18] The author mentions the fact that steam-locomotive designers are studying the question of improving their designs, particularly for high-speed work, and out of this will probably come some valuable recommendations. He speaks of this as in the future. The writer will mention some results already accomplished in this direction.

Fortunately, the writer's experience relates to a locomotive which has a little less than 4000 ihp, so the data are comparable with the 4000-hp Diesel mentioned in the paper.

The method of comparing modern locomotive types, as used by the author, is open to question. For the steam locomotives the weights are given with a full load of coal and water. This is an unfair basis of comparison, so far as the steam locomotive is concerned, and makes the figures look extremely favorable for the Diesel. If we use two-thirds coal and water in the tender, the comparison can be made much more nearly on the basis of actual conditions of continuous operation. Moreover, this is the figure used in all tests[19] and comparisons of the Association of American Railroads.

Using this basis, the steam locomotive, to which reference has been made, compares as follows:

	Diesel locomotive	Steam locomotive 4-6-2 type
Nominal hp	4000	.....
Maximum hp	.....	4000
Weight with two-thirds fuel and water, lb	609600[a]	506000
Weight of locomotive only, lb	.....	330800

[a] Latest published weights of 4000-hp Diesel.

Actual drawbar pulls have been secured from this 4000-hp steam locomotive and the curve looks very much different from that given in Fig. 1 of the paper. The steam-locomotive drawbar-pull curve crosses and goes above the Diesel at about 40 mph, touches almost 3000-drawbar hp at about 65 mph, and remains above the Diesel curve all the way to 100 mph. Such a drawbar-horsepower curve gives operating characteristics far better than the steam-locomotive curve in Fig. 1.

The author mentions the accelerating abilities of the Diesel locomotive as compared with steam locomotives. On all runs in passenger service, except strictly local, the ability to reaccelerate from 40 mph up to about 70 or 75 mph is far more important than the rapidity with which the train reaches 40 mph. Almost any division, say of 200 miles in length, has at least five or six slowdowns; it is the ability to reaccelerate at these points which counts. In other words, normally there are five or six slowdowns to one start from zero speed. This is the reason why the increased drawbar-horsepower curve of the 4000 ihp steam locomotive at 40 mph and above is of such vital importance, particularly in high-speed work.

As an example of what a 4000-hp steam locomotive is doing in regular service, some interesting runs recently made with a 13-car train, weighing approximately 900 tons, are mentioned as follows:

Distance traveled 98.3 miles at a speed of 83.07 mph
Distance traveled 78.8 miles at a speed of 84.4 mph
Distance traveled 25.1 miles at a speed of 100.4 mph

These figures are from the official train sheet. The maximum-speed stretch of 25.1 miles was over rolling profile (not all downgrade).

In the case of a 12-car train, consisting of standard Pullmans and diners, weighing about 1100 tons, a maximum speed of 96 mph was attained on the run from Fort Wayne, Ind., to Crestline, O., which was accomplished in 2 hr flat, 5 min less than the "Broadway Limited's" schedule. One stretch of 116.4 miles was negotiated at a speed of 74.3 mph.

These are not mentioned as outstanding, simply because they were high-speed runs. Many such runs have been and are being made. The writer wishes to emphasize the fact that they were accomplished with a 4000-hp steam locomotive, the locomotive itself weighing 330,800 lb. This locomotive did not have any special crew or preparation. The runs were made in regular "pool service."

Author's Closure

Mr. Cook presents theoretical calculations indicating that the cost of fuel for Diesel and steam locomotives should be equal. The figures given in the paper are actual performance data for similar operations and the author feels that such data are more reliable than any estimates which might be made.

There is no basis for the theory that the maintenance expense for Diesel engines increases with the increasing age of the equipment. Thirty years' history with rail motorcars refutes this theory. Furthermore, the comparisons made by the author involve comparatively new steam locomotives as well as new Diesel locomotives. The steam locomotives referred to in the study of maintenance costs were built in 1928 and the figures were taken from records for the years 1930 to 1935. The figures used for the Diesel locomotives were taken from records for their first 4 years of service.

There is a misunderstanding of the methods mentioned as being used in making dynamometer-car tests. In testing a new type of locomotive, various train consists are used on numerous runs, so that the maximum performance can be checked. The steam locomotive referred to was not working below capacity at high speeds, but was being worked to maximum capacity. By maximum indicated horsepower the author refers to the maximum computed from the many hundreds of indicator cards taken during the various tests.

A question is raised regarding the comparison shown for thermal efficiency. The author made the comparison on exactly the same basis, that is, the same trains were handled on the same schedule.

Mr. Jones raises an interesting point as to the extra power required by the use of large axle generators, in connection with air-conditioning equipment. The author feels that the best answer to this problem is in the use of the steam-ejector system of air conditioning, wherein the power is secured from the locomotive boiler. The suggestion for the use of a head-end electric power plant to provide electricity for the cars may be suitable for certain conditions but its disadvantage lies in the fact that nonwired interchange cars could not be used in such trains.

It is undoubtedly true that locomotives with too low a center of gravity may produce serious lateral forces. It is noted from Mr. Jones's curves that the ideal height for the center of gravity is approximately 4 ft 6 in. This is the approximate height for Diesel locomotives, whereas the center of gravity for steam locomotives is considerably higher. The stress curves shown in Fig. 2 of the paper indicate that the Diesel locomotive does not produce any undue rail stress on curves. The question is asked why rail stress increases more rapidly with speed under locomotive tenders than is the case under Diesel locomotives. This is probably due to the fact that there is a greater shifting of wheel load in high-speed operation with steam locomotives than with

[18] Vice-President, Lima Locomotive Works, New York, N. Y. Mem. A.S.M.E.

[19] "A.A.R. Passenger Locomotive Tests," Report of Association of American Railroads, Chicago, Ill., October, 1938.

Diesel locomotives. Most track stress tests with steam locomotives have indicated this shifting of load.

The author does not agree with the inference that stresses developed under driving wheels are not serious unless rails are kinked. Higher stress must result in greater punishment to the rail and more chance of failure. It also results in increased roadbed-maintenance expense.

The curve presented by Mr. Lipetz for drawbar horsepower of a steam locomotive does not go beyond 85 mph and no figures are given to indicate how it droops beyond that point. His calculation of theoretical time for acceleration is interesting but in the dynamometer-car tests referred to in the paper different results were obtained. In mountainous territory, where there is sharp curvature, speeds are often brought below 40 mph. Furthermore, in service the steam locomotives do not appear to produce their theoretical power at all times. Most of the tests are made under the best operating conditions. The human element, the element of weather conditions, and the condition of locomotives all play an important part in steam-locomotive operation, whereas the performance of Diesel locomotives is much more uniform. There is no skill required to apply the power; rail conditions have very little effect because of nonslipping characteristics; and very cold weather is in no way detrimental to the Diesel. Another factor which appears to be a distinct advantage in the Diesel or electric locomotive is the continuity of the torque.

The author does not feel that the lack of cross-balance on other than the main wheels of a steam locomotive has any appreciable effect on track stress. It is not understood how Mr. Lipetz arrives at the figures quoted for maximum rail stress. It appears that there has been a misunderstanding of the diagrams Fig. 3, of the paper. The actual maximum stress at 100 mph is 27,000 lb for a steam locomotive and 17,000 lb for a Diesel locomotive at the same speed. Thus the increase for the steam locomotive is about 60 per cent instead of the 12 per cent referred to. It is undoubtedly true, as Mr. Lipetz states, that some locomotives have been built which may show a better performance than the one referred to in the paper. It is also true that a great many locomotives show poorer performance. It may be noted that the particular steam locomotive therein recorded was a strictly modern high-speed locomotive built in 1938, and therefore, should be fairly representative of present-day power.

As regards permissible speeds of operation on curves, the best indication of the facts is the definitely higher speeds permitted for Diesel locomotives than for steam locomotives on individual railroads. These rules have been based on actual experience.

As regards comparative costs of operation, the author does not believe it possible to compare operation on different railroads, because of the fact that operating conditions, traffic conditions, and equipment-maintenance conditions are different. It is for these reasons the author confined his comparisons to trains operating on one railroad.

The author does not agree that the success of the Diesel has been due to its novelty, steamlining, etc. In various parts of the paper the economic reasons for the success of the Diesel engine have been brought out. Economy of operation is the governing factor in the selection of any type of power.

The comments of Mr. Nystrom, Mr. Ragsdale, Mr. Willoughby, and Mr. Test indicate the wide difference of opinion which exists regarding materials and design best suited for lightweight passenger-car construction. The major parts of a passenger car must be designed to have strength characteristics far in excess of what is needed for ordinary operating conditions, in order to stand up in case of wreck. The best criterion is a study of wrecks which have actually occurred with equipment of various designs built with different types of lightweight materials and also the old-style heavy equipment. The author's observation of these results leads him to believe that the importance of deflection requirements has been exaggerated. What is desired in a passenger car is protection to lives of passengers in case of wreck rather than to minimize the damage to equipment. This feature should be the primary object in designing passenger cars. The author does not have the data upon which to base a comparison of the weights of the diners referred to in the discussion, but it is his understanding that there were certain requirements in the specifications which did not permit of the manufacturers designing the cars to make maximum usage of all the strength properties of the particular materials which they used.

Mr. Thompson requests further comments on service life of Diesel locomotives and lightweight passenger cars. There is no reason why this equipment should not have just as long physical life as the older types. However, there is a question as to how rapid will be the rate of obsolescence. Because of the Diesel power as well as the lightweight car construction being new developments, it is possible that there may be many improvements developed during the next 10 years, which would affect the rate of obsolescence to a greater extent than has been the case in the past with the older-type equipment, when there was much less new development work going on.

Steam-Boiler Performance and a Method of Comparison

By E. G. BAILEY,[1] NEW YORK, N. Y.

This paper presents data from two methods of determining rates of heat absorption in different sections of steam-boiler units. One by direct measurement of evaporation, first published in France in 1874, describing French locomotive-boiler tests, is compared with recent data on modern furnaces using the gas-temperature-weight method. A method of comparing data from all types, kinds, and sizes of boiler units at diverse rates of output is presented. It consists briefly of plotting "heat absorbed" in per cent of total heat available against "equivalent surface area," which results in all points, having the same Btu available per sq ft per hr, being on the same ordinate. Representative data from modern stationary and marine boilers are compared, together with the data from the French locomotive-boiler tests of 65 years' standing. Data on volumes of furnaces and entire boiler units are given together with draft losses and efficiencies.

THE three branches of steam engineering—locomotive, marine, and stationary—have developed their individual terms with respect to rates of boiler output and performance. Some of these terms are becoming less significant due to varieties of fuel, the addition of superheaters, economizers, air heaters, etc. However, there are common bases for comparison which can and should be used in ways that will be universally applicable to all forms of fuel-burning and heat-absorbing equipment. One of the principal purposes of this paper is to present a method which is believed to be of value, not only in comparing boilers of different types, but also in comparing more accurately the relative results from similar boilers.

As a basis for comparison with the modern locomotive boiler, which is being covered in another paper from the A.S.M.E. Railroad Division,[2] data are given in this paper on the performance of present-day stationary boilers. Because of the great diversity of boiler types, a really comprehensive treatment of the subject has not been possible within the space limitations. However, it is believed that the most value can be obtained by giving performance data from a few representative types of modern stationary boilers, and presenting them in a form which may be readily compared with similar data from locomotive or other boilers.

Coal-burning locomotives are fired by hand or stoker and none greatly exceeds an output of 100,000 lb of steam per hr. Many locomotives in the South and West are oil-fired. In order to make the results more directly comparable, the stationary-boiler data presented herewith are taken from boilers of a smaller size than is normally used in central-station practice and with working pressures approaching those now used in locomotives.

In addition to hand, stoker, and oil firing, one unit burning pulverized coal is included, since many stationary boilers are now designed for burning pulverized coal, oil, or gas without any change in the equipment. Some marine-boiler performance data are also given to show wherein conditions aboard ship have influenced the design and performance requirements.

While boiler efficiency is the final basis of comparison, with a complete heat balance to show the distribution of heat losses in unburned fuel, stack gases, excess air, etc., it is of further importance to know the distribution of heat absorbed by the boiler, superheater, economizer, and air heater and, from the surfaces of each, to know the average rates of heat absorption of these component parts. The absorption of radiant heat in the furnace, the effect of slag, cleanliness of heating surfaces, and the absorption of heat in different parts of the boiler sections are also factors of importance in connection with the design of furnaces and boilers, as well as in the operation of the fuel-burning and steam-generating equipment. The latter information is not obtainable from present standard tests.

Methods of Measuring Heat Absorption
